Key Words: *Discrete Multiphysics, Dissolution Problem, Mass Transfer, core-shell microparticles*

Summary: We present the dissolution of composite particles utilising the Discrete Multiphysics [1] (DMP), a numerical model that combines particle-based techniques. We have focused on core-shell particles that have numerous applications in food-processing and healthcare industries. Figure 1 represents the time evolution of the dissolution of a single core-shell particle in fluid flow. It will be shown that DMP is a suitable tool for modelling the dissolution process due to its Lagrangian particle-based nature and can be utilised for modelling more complex structures.

The numerical results will be validated against available analytical and numerical data in literature through different mass transfer processes. We will conduct a systematic study on the dissolution of core-shell solute particles by considering the effect of fluid inertia and the ratio between the diffusion coefficient of core and shell materials. Thus, we will investigate the variations of Reynolds number and the Schmidt number ratio, respectively. We will conclude the discussion by providing design guidelines for specific applications of core-shell microparticles.

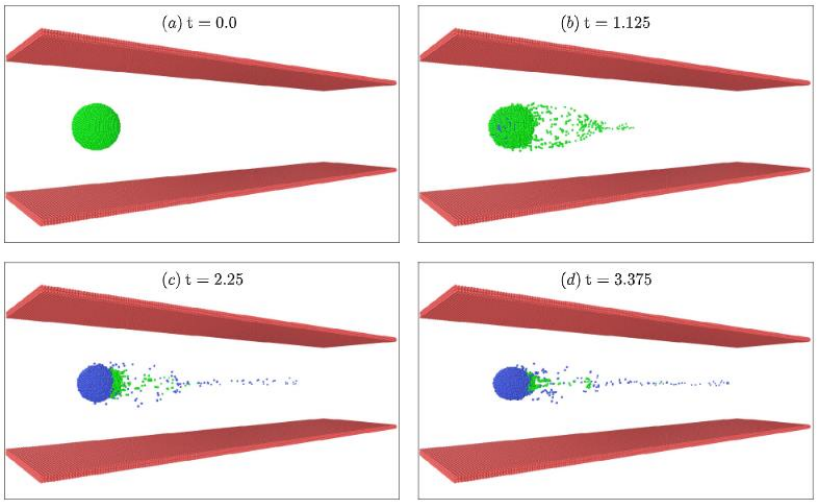

Figure 1: Dissolution of a core-shell particle at different simulation times; shell and core phases are shown by green and blue particles, respectively, while fluid particles are removed for better illustration.

A low-cost resolvent analysis of flow around a bluff body

Aoi Sato[1*], Yusuke Nabae[1] and Koji Fukagata[1]

[1] Keio University, Yokohama 223-8522, Japan

Key Words: Resolvent analysis, Cylinder wake, Randomized method

In order to solve various environmental problems discussed around the world, it is of great importance to develop practical flow control methods for suppression of the vortex shedding in flow around a bluff body. However, assessment using the high fidelity numerical simulation such as direct numerical simulation requires an enormous computational cost to capture the turbulent phenomena accurately. To overcome this problem, McKeon and Sharma (2010) proposed the resolvent analysis, which is one of the modal analysis methods. So far, application of the resolvent analysis has mostly limited to one-dimensional flow, e.g., fully developed channel and pipe flows. Therefore, in the present study, we extend the resolvent analysis to a two-dimensional flow, i.e., flow around a circular cylinder. However, in two-dimensional flows, we need to solve the governing equations in the two-dimensional domain, so that the size of the matrix in the resolvent operator is drastically increased and the computational resource required becomes large. To reduce the computational cost, we develop a resolvent analysis based on the energy-conservative finite difference method on a staggered grid system. In addition, to reduce the matrix size, the randomized method proposed by Riberio et al. (2020) is applied. It is found that the present staggered grid-based randomized resolvent analysis is able to accurately compute the forcing and response modes as well as their singular values as far as a sufficient size of randomized sketch is used. Moreover, using this low-cost method, we analyze the forcing and response modes in the flow around a cylinder in detail. In the presentation, we will also propose effective flow control methods to suppress vortex shedding.

We thank Mr. Hikaru Murakami (Keio Univ.) for providing the DNS data and Ms. Riko Uekusa (Keio Univ.) for fruitful discussion. We also thank Dr. Kunihiko Taira and Dr. Jean Helder Marques Riberio (UCLA) for the instruction on the randomized resolvent analysis. Key Words: *Free-surface flows, Particle finite element method, Finite element method, Fluid dynamics, Shallow water*

This work presents a partitioned method for landslide-generated wave events. The proposed strategy combines a Lagrangian Navier Stokes multi-fluid solver with an Eulerian method based on Boussinesq shallow-water equations.

The Lagrangian solver uses the Particle Finite Element Method [1, 2] to model the landslide runout, its impact against the water body and the consequent wave generation. The results of this fully-resolved analysis are stored at selected interfaces and then used as the input of the shallow water solver [3,4] to model the far-field wave propagation.

This one-way coupling scheme reduces drastically the computational cost of the analyses while maintaining high accuracy in reproducing the key phenomena of the cascading natural hazard.

Several numerical examples are presented to show the accuracy and robustness of the proposed coupling strategy and its applicability to large-scale landslide-generated wave events. The validation of the proposed method is performed versus available results of other numerical methods, analytical solutions and experimental measures.

Deep Learning-based Unsteady Flow Estimation: Nonlinear Convolution of Wakes behind an Oscillating Cylinder

Hikaru Chida[1]*, Taichi Nakamura[1], Kai Zhang[2] and Koji Fukagata[1]

[1] Keio University, Yokohama 223-8522, Japan
[2] Rutgers University, Piscataway, NJ 08854, USA

Key Words: Convolutional neural network, Machine Learning, State estimation, Unsteady flow

In our daily lives, there are many vibrating objects with fluid flows, e.g., flapping wings of birds [1], heat exchanger [2], and tidal power generator [3]. The detailed information about such flows can be utilized for flow control or anomaly detection via fluid flows; however, few available sensors in the practical situation make it difficult to obtain the flow information over the entire region. To tackle this issue, we here utilize machine learning. Machine learning has been regarded as an effective tool for fluid flow analysis thanks to its ability to consider nonlinearity. We estimate the flow field with an oscillating cylinder at the Reynolds number $Re = 150$ utilizing convolutional neural network (CNN) [4]. The CNN estimates the wake behind the cylinder from the flow field around it. The training data is prepared by direct numerical simulation (DNS). We prepare various types of datasets whose direction and frequency of vibration differ from each other. The present CNN model successfully estimates the flow fields, which are in qualitatively agreement with the reference DNS under any vibration condition. The L_2 error norm also suggests reasonable estimation performance, although it has a high dependency on the frequency. To clarify the cause of this, the cosine similarity is introduced as a measure of correlation between the snapshots. The evaluation using the cosine similarity reveals that the L_2 error norm tends to be smaller when the flow field has periodicity. This result indicates that we can achieve efficient training by reducing the number of snapshots according to the periodicity.

Direct Numerical Simulation of Turbulent Flow Controlled by Wall Oscillation in Concentric Annular Pipe

Ayaka Higashimoto[1*], Junichi Morita[1], Hiroya Mamori[1], and Takeshi Miyazaki[1]

[1] The University of Electro-Communications, 1-5-1, Chofugaoka, Chofu, Tokyo 182-8585, Japan, h2132080@edu.cc.uec.ac.jp

Key Words: *Turbulent flow, Annular pipe Flow, Wall Oscillation Control, Direct Numerical Simulation*

Drag induced by flow usually consists of contributions from pressure and skin friction, referred to as pressure drag, and friction drag, respectively. The friction drag accounts for about 50% of the total drag for an aircraft and about 100% of the drag for a pipeline [1]. Therefore, control techniques to reduce the skin-friction drag are essential in engineering from the viewpoint to improve energy efficiency in several decades. The wall oscillation technique is well known to reduce the skin-friction drag in the turbulent channel flow, e.g. [2]. In the present study, we employ the wall oscillation control technique and aim to investigate the skin-friction reduction effect of the turbulent flow in the concentric annular pipe using direct numerical simulations. The concentric annular pipe is widely used in fluid engineering. We expected to reduce the skin-friction drag efficiently by using the different radius of the inner and outer cylinders.

We apply the wall oscillation control for the inner and outer cylinder, and the control parameters are the amplitude A and the frequency f. We refer to the same control for the turbulent channel flow [3] to determine the range of the parameters. As a result, if the oscillations on both cylinders are synchronized, the maximum skin-friction drag reduction rate was 47% and 52 % at the inner and outer cylinder surfaces, respectively. On the other hand, if the oscillation is applied on the inner cylinder and the outer cylinder is immobile, the maximum drag reduction rate is 39% at the inner cylinder surface and decreases as the frequency increases.

In the presentation, we will discuss in detail, e.g., the drag reduction mechanism, the influence of the ratio between the inner and outer radius onto the control effect.

DNS-CNN Simulation of Viscoelastic Turbulent Flow using U-Net

Masaya Tashiro[1*] and Takahiro Tsukahara[2]

[1] Tokyo University of Science, Yamazaki 2641, Noda-shi, Chiba 278-8510, 7521532@ed.tus.ac.jp
[2] Tokyo University of Science, Yamazaki 2641, Noda-shi, Chiba 278-8510, tsuka@rs.tus.ac.jp

Key Words: *Viscoelastic fluid, Turbulence, Deep learning, Surrogate model*

Viscoelastic fluid is a non-Newtonian fluid obtained by adding a polymer or surfactant to water. The characteristic feature of this fluid is the drag reduction due to the suppression of vortices by the intensification of polymer extension in turbulent flow conditions. This drag-reducing effect saves pumping energy in fluid transports. From the viewpoint of engineering applications, many experiments and numerical simulations have been carried out, but the flow mechanisms of viscoelastic fluids are still not fully understood. Numerical instability is one of the factors that hinder numerical studies. In numerical simulations of viscoelastic fluids, a constitutive equation is required as a governing equation, which should include viscoelastic stresses. However, due to the absent of a diffusion term in the constitutive equation, e.g., the Giesekus model, the numerical instability often becomes a problem at high Weissenberg numbers [1].

Deep learning has been widely used in the field of fluid mechanics with the aid of the recent development in computational hardware and the emergence of many network models. In fact, attempts have been made to address many issues in fluid mechanics, such as low-dimensional modeling, experimental-data processing, shape optimization, turbulence closure modelling, and flow controls [2]. Since the deep learning builds models from data, it is possible to discover essential features. Applying the model built by deep learning to the constitutive equation has a potential to extract features of viscoelastic-fluid turbulence and to solve the problem of numerical instability at high Weissenberg numbers.

In this study, we applied deep learning to construct a surrogate model of the constitutive equation to simulate the viscoelastic turbulent channel flow. We adopted U-Net, a convolutional neural network (CNN), to predict the conformation stress field from the velocity field obtained from direct numerical simulations (DNS). Using the trained U-Net, we demonstrated an integrated calculation of DNS and CNN in which the constitutive equations were replaced by the U-Net. The mean profile of c_{xx} (the streamwise normal component of the conformation tensor) and the flow field were reproduced with high accuracy by using U-Net. However, the prediction accuracy of c_{yy} (the wall-normal component) in the buffer layer, where polymer rotation is induced by vortices, is rather low. The predicted instantaneous field exhibit somewhat noisy distribution caused by the convolution operation in the U-Net. In the surrogate model of U-Net, we compared the result of the DNS-CNN simulation to the pure DNS. The obtained statistics showed a good agreement between both simulations.

Key Words: *Direct Numerical Simulation, Drag Reduction, Riblet, Stress Field*

A riblet is an object with a fine groove structure that can reduce the frictional drag of wall-bounded turbulent flows. For example, Sasamori *et al.* (2014) confirmed 12% drag reduction by a sinusoidal riblet in a turbulent channel flow [1]. Because of such a micro-groove structure, riblets poses a durability problem for practical use. Therefore, we focused on the force acting on riblets. Direct numerical simulation (DNS) of a turbulent channel flow was conducted with riblets generated by an immersed boundary method. Each riblet has rectangular cross sections with variable height and spanwise position changing by random Fourier series in the streamwise direction.

It is found through a flow visualization that when vortices are close to a riblet, the surface stress of the riblet is far from the mean wall shear stress without the riblets. This indicates that the approach of vortices to riblets makes a significant contribution to surface stress of riblets.

Next, we investigate the relation between the riblet shape and the torque around the root of riblet, T^+. The superscript $()^+$ denotes the normalization with the frictional velocity and the kinematic viscosity. The correlation coefficients between T^+ and a streamwise variation of the relative spanwise displacement, h_z^+, and its streamwise derivative, dh_z^+/dx^+, are 0.16 and 0.88, respectively. This suggests that the riblet is subjected to the high surface stress where it deforms in a spanwise direction. Similarly, the correlation coefficients between T^+ and the height, h_y^+, and dh_y^+/dx^+ are respectively –0.57 and 0.57. Further study will reveal the statistical tendency of the torque and geometrical features of riblets with other shapes

yagi.tomomi.7a@kyoto-u.ac.jp

Key Words: *Dry Gauze Method, Computational Fluid Dynamics, Porous Media Model*

Since airborne salt causes corrosion in steel materials, it must be evaluated for the management of steel structures. The dry gauze method, which uses a gauze embedded in a wooden frame, is often used to evaluate the amount of airborne salt. This method evaluates the amount of salt captured by the gauze while salty air passes through it. Although observation results using this method are abundant, the collection efficiency for salt particles has not been clarified owing to complex airflows around the device. Obata and Murakami [1] reported that the collection efficiency differed in each observation period and did not sufficiently explain the cause of this difference.

Therefore, to clarify the collection efficiency, the authors simulated the flow field around the device using computational fluid dynamics (CFD) with a large eddy simulation to estimate the collection efficiency with particle tracking. To represent a fine structure of the gauze fiber, a very fine computational grid is required, which is computationally expensive. Therefore, in this study, the gauze was modeled as a porous medium [2] to reduce computational costs. Wind tunnel tests were performed to obtain the pressure loss coefficients of the gauze, which are necessary for the porous media method.

In the research process, first, the flow field around the collection device was evaluated using visualization tests in a wind tunnel. Then, the flow field around the device was calculated using CFD and compared with the results of the flow visualization tests. The flow visualization tests showed that airflows were perpendicular to the gauze on the leeward side of the gauze, regardless of the wind direction. This is because the airflow is rectified when the airflow passes through the gauze with a small porosity. The flow fields around the device were reproduced well in all the wind directions investigated using the porous media model in this study, which considered the tangential resistance as well as the normal resistance of the gauze. This result suggests that the tangential resistance must be considered in the porous media model when the porosity of an object is small, even if the thickness is small. Then, particle tracking was performed to quantitatively evaluate the dependence of the collection efficiency on the wind speed and direction. The results indicated that the collection efficiency was affected by the complicated flow around the collection device.

Flow Separation Control by Using Wave-like Body Force in Backward-facing Step Turbulent Flow

Junichi Morita[1*], Hiroya Mamori[1] and Takeshi Miyazaki[1]

[1] The University of Electro-Communications, 1-5-1, Chofugaoka, Chofu, Tokyo 182-8585, Japan, j.morita.uec@icloud.com

Key Words: Backward-facing Step Flow, Reattachment Length, Traveling Wave Control, Body Force, Direct Numerical Simulation

Flow separation is a canonical phenomenon in fluid dynamics and fluid machinery. The phenomenon enhances heat transfer and fluid mixing while causing an increase in drag and noise pollution due to abrupt changes in pressure and flow rate. Therefore, controlling it is strongly required in engineering applications. In this study, we perform direct numerical simulations of backward-facing step turbulent flow with the traveling wave-like body force control. We chose the traveling wave to control the flow separation due to twofold reasons; Schäfer *et al.*[1] pointed out that the reattachment length is greatly oscillated by the separation bubble; Mamori *et al.*[2] reported that the traveling wave control enhances the mixing of the vortex. Therefore, we expected that the traveling wave enhances the separation bubble mixing and affects the reattachment length. Accordingly, the purpose of this study is to investigate the effect of control parameters on the reattachment length and to clarify the mechanism.

In the stationary wave (i.e., the wavespeed is zero), the separation bubbles became smaller and the reattachment length decreased as compared with those in the uncontrolled case. This was because the negative wall-normal velocity was induced by the body force in the downstream half of the step. Additionally, since the velocity fluctuation and the vorticity in the recirculation region decreased, the mixing of the separation bubble was suppressed. In the downstream traveling wave, the reattachment length decreased compared to that in the uncontrolled case and the stationary wave case. The velocity fluctuation and the vorticity in the recirculation region increased, which decreased the size of the separation bubble. Moreover, the separation bubble was oscillated and was released periodically. The phase analysis showed that this period was consistent with that of the traveling wave, which means that the traveling wave dominates the oscillation period of the separation bubble. The periodic component of the velocity showed that the traveling wave produced alternately slow and fast mainstream velocities on the step.

Key Words: *Aeroacoustics, Mode Decomposition, Flow Visualization*

In a subsonic free jet, a vortex sound is generated at the end of the potential core. However, the mechanism leading to the generation of vortex sound is still under discussion. A recent study proposed that pressure waves propagating upstream along the jet axis interact with Kelvin-Helmholtz (K-H) instability possibly forming a feedback loop that intensifies (Bogey, 2021) [1]. In this study, TlsDMD (Total least-square Dynamic Mode Decomposition) [2], a kind of Dynamic Mode Decomposition (DMD) [3], is applied to the time series of numerical results of an axisymmetric subsonic free jet [4], and a detailed analysis of this hypothesis is performed. In the study, the DMD mode at the K-H instability frequency, which is the dominant frequency peak near the nozzle exit, was extracted. From this result, we found that this DMD mode describes not only the K-H instability wave but also pressure waves propagating upstream along the center axis. Based on this result, we applied the Spatio-temporal Fourier analysis to detect the waves propagating upstream direction. As a result, we confirmed that they originate from the end of the potential core. In other words, there is a *feedback mechanism* at the frequency of the K-H instability. Then, our results support the presence of a feedback mechanism in a subsonic free jet. For the flow characteristics, there is a possibility that there exists an unstable global solution that takes the form of a feedback loop. This content is currently under investigation, and we believe that the mechanism can be elucidated by the time of the presentation.

Key Words: *Air Quality, CFD, RANS, Sensitivity Analysis, Sense-City, Full Scale Experiment*

As majority of people spend 90% of their time in indoor environment, air quality has become an important scientific field in the last few decades. Indoor air quality is affected by many factors. One of the significant factors is outdoor air pollutions [1]. They enter the indoors through ventilation systems or natural ventilation and may stay indoors for a long time due to the airtightness of buildings. The present study especially focuses on nitrogen dioxide (NO2) concentration in a natural ventilating room that comes from outdoor pollutant source such as vehicle emissions.

In the present study, we have performed numerical simulations of a controlled environment in Sense-City urban area [2]. Sense-City is a unique full-scale equipment that can reproduce controlled conditions of temperature, humidity, airflow and pollution using an atypical climatic chamber. Reynolds Averaged Navier-Stokes (RANS) simulations have been carried out to calculate outdoor and indoor NO2 concentrations. RANS simulations are performed in two steps: district scale and building scale. Pressure values and pollutant concentrations are extracted from the district scale simulation and applied to the building scale simulation as boundary conditions. As expected, a sensitivity analysis study shows that the NO2 concentration in the building depends mainly on the pollutant concentration at the windows. Once opening windows, indoor pollutant concentration reached the almost same level of that of outdoor within a few minutes. Therefore, the interaction between outdoor and indoor air quality cannot be negligible for indoor air quality.

This study can be useful for engineers and for local authorities to understand the importance of considering the interaction of the indoors and outdoors, the potential and limitation of RANS simulation in a natural ventilating. Considering the limitation of the number of sensors for air pollution in real applications, CFD simulation is promising to obtain air pollutant distribution cartography. It can also be used as a decision-support tool for relevant urban planning such as the optimal placement of sensors and depolluting systems in urban areas.

Key Words: *Multiphase Flow, Multi-phase-field Model, Conserved Allen-Cahn Equation, Numerical Simulation*

Multiphase flow is a universally important phenomenon in science and engineering. Thus, there is a requirement to explore in detail the characteristics of multiphase flow. However, as the direct experimental observation of multiphase flow is difficult, numerical studies are indispensable to create a deeper understanding of multiphase flow.

The phase-field (PF) method is a powerful interface tracking model within the multiphase flow simulation, as it does not require explicit tracking of the interface position. The Cahn-Hilliard (CH) equation [1], which can conserve the liquid volume accurately, has been used extensively in the multiphase flow simulation. However, it requires small time increments as it reduces to the fourth order differential equation which is a significant drawback. To overcome this challenge, the conserved Allen-Cahn (CAC) equation [2] has been proposed, where a larger time increment can be utilized. Recently, the CAC model was applied by the authors to a multiphase flow with three or more phases by employing the multi-phase-field (MPF) method [3]. In the CAC-MPF model, the Lagrange multiplier method was introduced to model the interaction among the multiple PF variables. Although the CAC-MPF model successfully simulated the multiphase flow with an arbitrary number of phases, the degree of freedom in the selection of the Lagrange multiplier remains to be determined.

In this study, a new CAC-MPF model without the Lagrange multiplier was developed for multiphase flow problem. To this end, the MPF model developed by Steinbach [4] was modified, that is, the Lagrange multiplier was removed by introducing the concept of interface field. Further, the accuracy of the model was evaluated through numerical simulations.

[1] Department of Mechanical Engineering, Tokyo Institute of Technology, 2-12-1 Ookayama, Meguro-ku, Tokyo 152–8550, Japan, tomisawa.y.aa@m.titech.ac.jp

Key Words: *Lifted Flame, Hydrogen Combustion, Steam dilution, Multi-Cluster Burner*

Hydrogen is expected as an alternative fuel due to its carbon free combustion features. The hydrogen combustion power plants which produce the stable output have an important role to realize hydrogen society. The thermal efficiency of a semi-closed gas turbine cycle designed for use in a cycle for hydrogen combustion power plants is expected to have higher than that of the combined cycle used in conventional thermal power plants [1]. A burner of the thermal cycle may burn pure hydrogen and oxygen diluted with steam. A diffusion flame configuration with multiple jets (referred to as a "multi-cluster burner") is considered to enhance mixing and avoid flame flashback since hydrogen combustion yields a high laminar burning speed. Also to further promote mixing, it is suggested that the jet ports are arranged in the combustor so that the jet flows impinge on each other.

DNS and experimental studies are investigated the combustion characteristics of a lifted flame formed in a multi-cluster burner, which consists of multiple jets where the fuel and oxidizer jet cores collide one another, which feed hydrogen and oxygen diluted with steam as fuel and oxidizer [2-5]. DNS study performed in the multi-cluster burner where two tilted oxidizer jets and one fuel jet are paired [2]. The present DNS study performed in the multi-cluster burner, which narrows the distance between the pairs and further enhances the interaction between them. The present study focuses on the investigation of the mixing and combustion characteristics of lifted flames formed cross jets in such a multi-cluster burner, and three-dimensional DNS of lifted flames formed in the multi-cluster burner has been performed and analyzed.

Key Words: *Unsteady Flow, Machine Learning, CNN, LSTM, Low-Dimensional Representation*

Deep learning is expected to be one of powerful tools for understanding, predicting, and controlling nonlinear flow phenomena. For example, Guo et al. constructed an approximation model for real-time prediction of non-uniform steady laminar flow based on convolutional neural network (CNN) [1]. Hasegawa *et al.* proposed a method to construct a machine-learned reduced order model for unsteady flows by combining a CNN autoencoder and a long short-term memory (LSTM) [2].

In this study, we build deep learning models with CNN and LSTM architectures to develop low-dimensional models to represent unsteady flows. As an example of unsteady flows, direct numerical simulation of a flow around a cylinder at Reynolds number $Re_D = U_\infty D/\nu$=100 is carried out to obtain a time-series data of the flow field for training and validation. Three types of the models have been constructed: Conv3D Model, Conv2D+LSTM Model and CNN Autoencoder (AE) Model. For Conv3D Model and Conv2D+LSTM Model, previous time series data of the flow field are given as input, and the flow field at the next time step are predicted as output. Conv2D+LSTM Model apply Convolutional 2D Layer for spatial dimensional reduction and LSTM Layer for time advancement in a sequential manner. Conv3D Model utilizes Convolutional 3D Layer to perform dimensional reduction in both space and time and output the flow field at the next time step in a batch processing. To obtain a time series of the flow field, time advancement is achieved sequentially in both Conv3D Model and Conv2D+LSTM Model. For CNN AE Model, a time series of the flow field for almost one cycle of the vortex shedding are given as input. The model applies Convolutional 3D Layer for dimensional reduction and extension in both space and time. The model then reconstructs the input as output approximately. CNN AE Model output a time series of the flow field in a batch process.

The flow fields predicted by all three models agree qualitatively and quantitatively with the ground truth obtained by numerical simulation of the flow (CFD), in terms of instantaneous distribution of the flow field, correlation coefficients and mean square of error between the prediction and the ground truth, and power spectrum of velocity. Compared with Conv3D Model and Conv2D+LSTM Model, CNN AE Model with only 1 mode, 2 or 3 modes in the latent space gives better agreements with the ground truth. Conv2D+LSTM Model showed the largest errors due to a phase shift. These differences of the model prediction can be explained by characteristics of the model architectures. The sequential processes for time advancement tend to accumulate larger phase shift errors, compared with batch processes with convolution operations. It is indicated that a reduced order model with only a batch process by the convolution operation could provide robustness against errors due to a phase shift. CNN AE Model with 2 modes in the latent space predicts the flow field better than the model with 1 mode or 3 modes. The two-dimensional unsteady flow around a cylinder can be represented with high accuracy by only 2 modes in the latent space.

For developing and evaluating microfluidic devices in various fields of science and engineering, we construct computational fluid dynamics (CFD) methods based on a phase-field model [1] and its extended version of a multi-phase-field model [2] to simulations of incompressible multiphase flows. For calculations of diffuse-interface advection and autonomous formation in the flow, both the CFD methods adopt a conservative Allen-Cahn (CAC) [3] equation instead of Cahn-Hilliard (CH) equation [4]. The AC form is advantageous over the CH form in terms of computational efficiency, interfacial tension effect and volume conservation because the former is free from curvature-induced diffuse-interface drift motion and it has a second-order differential diffusion term instead of the fourth-order term in the latter. A semi-Lagrangian formed lattice Boltzmann method (LBM) [1,5] is employed as a 2^{nd}-order numerical scheme for solving the Navier-Stokes equations with the AC equations. The LBM is useful for high-performance computing because of simple and conservative pseudo-particle kinematic operations on an isotropic spatial grid [5]. From numerical results of droplet motions it is confirmed that the methods would be applicable to complex multiphase systems with partially wetted and 3D micro/nano structured surfaces [6,7].

Modeling of PM2.5 Deposition Behavior on the Wall Surface

Yoko Fujima[1*], Rino Arai[1], Yusuke Nabae[1] and Koji Fukagata[1]

[1] Department of Mechanical Engineering, Keio University, Yokohama, 223-8522, Japan,
yokofujima@keio.jp

Key Words: PM2.5, Deposition behavior, Image force, Lagrangian particle tracking

In order to reduce various health risks due to aerosol particles, it is of great importance to analyze the behavior of aerosol particles. Especially, the health risk of PM2.5 are greater than those of larger particles sizes[1, 2]. Therefore, in the present study, we investigate the deposition behavior of PM2.5 by means of a direct numerical simulation. In the present simulation, we consider two different flow: a turbulent channel flow and a square duct flow. In turbulent channel flow, the amplitude of the applied voltage for particles deposition increases as the particles sizes increases. On the other hand, influence of the mirror image force is so small. In a square duct flow, which is similar flow geometry in the experimental study[3], we investigate the influence of the inlet flow and the particle size for the particle deposition. Similar to their experiments, the amount of the particle deposition increases as the particle size decreases and the inlet flow decreases. In the cases of smaller particle sizes, particles cannot follow the flow due to the Brownian motion. In the case of large inlet flow rate, the inlet flow make the particles separated from the flow, and they collide with the wall surfaces in the outlet plane. Therefore, many particles are deposited on the wall in the outlet plane. In the final presentation, we will show the results by the further investigation, i.e., the deposition behavior in junction flows.

We thank Drs. Tomoaki Okuda and Ayumi Iwata (Keio Univ.) for fruitful discussion. This work was supported from the Japan Society for the Promotion of Science (20H00636).

Neural-network-based estimator for turbulent flows from limited heat information

Reno Miura[1]*, Mitsuaki Matsuo[1], Taichi Nakamura[1], and Koji Fukagata[1]

[1] Keio University, Yokohama, 223-8522, Japan, renomiura0202@keio.jp

Key Words: Neural Networks, State estimation, Turbulent flow

Understanding of internal combustion phenomena is important for achieving high-efficiency engines; however, it is difficult to measure the detailed thermo-fluid phenomena directly. To tackle this issue, we aim to estimate physical quantities in internal combustion engines from wall sensor measurements. We here utilize neural networks for the estimation. Neural networks have become an indispensable tool and covered a wide range of fluid problems, such as flow control and enhancing simulation [1]. State estimation is not an exception. Many researchers have estimated the flow field from limited sensors with neural networks. In many of the previous attempts, the wall shear stress and the pressure are commonly used for the input attribute of neural networks [2, 3]. However, considering the practical measurement for engine combustion, it is favorable to use the wall heat flux for the input. Hence, we here estimate near-wall physical quantities from the wall heat flux using a convolutional neural network (CNN). As an example, we consider a turbulent channel flow at the friction Reynolds number $\mathrm{Re}_\tau = 180$ and the Prandtl number $\mathrm{Pr} = 0.71$. The CNN estimates three-dimensional velocity and temperature fields from sensors on the entire wall. In the region near the wall, the estimated streamwise velocity and temperature are in reasonable agreement with the reference direct numerical simulation data. Furthermore, towards the practical application, we aim to estimate from a smaller number of sensors. We investigate the dependence on the streamwise and spanwise spacings of sparse sensors on the wall. At last, we consider the utilization of time-series wall measurements as input data to improve the estimation accuracy. In the talk, we will show the statistical assessments on these estimation attempts.

This work was supported by the research association of Automotive Internal Combustion Engines (AICE) of Japan and partly by the Japan Society for the Promotion of Science (21H05007).

Key Words: *Solidification, Droplet Impingement, Supercooled Water Droplet, Aircraft Icing*

Icing on an aircraft degrades flight safety; it is important to develop the prediction method of the icing. Although many icing simulation methods have been proposed [1-3], it has still been difficult to predict the supercooled large droplet (SLD) icing because the SLD icing involves complex phenomena composing of splash and bounce of the droplet and runback of the water film. We proposed a coupling method [4] of a grid-based method for airflow and a particle-based method for droplet behavior to predict the SLD icing. However, it is still difficult to apply the SLD icing because the freezing process of the supercooled water droplet is complicated due to the nucleation of the ice. This study performs the numerical simulation of SLD impinging and solidifying on the cold substrate and compares the solidification model of the release of supercooling to apply the coupling method.

The numerical simulation of SLD icing is performed by explicit moving particle simulation (E-MPS) [4,5]. The governing equations are composed of incompressible continuity, Navier-Stokes and energy equations. These equations are discretized by using the weight function, and the pressure is estimated explicitly. The substrate temperature is set as a constant temperature which is the same as the temperature of initial supercooled droplet.

For the impinging droplet icing, we compare two cases. One is the model that the solidification occurs at the surface of the wall, then the mixture (mixed-phase between water and ice) appears within a certain thickness. The other model is that all particles composed of the droplet change into the mixture phase just after the impingement, i.e., the release of supercooling for all components inside the droplet instantly occurs after the impingement. For both cases, the substrate temperature is assumed to be constant, and we neglect the heat transfer from the droplet to the surrounding air. As a result, we confirmed that the solidification occurs from the near wall to the location apart from the wall for both cases. Then, the total solidification times are comparable for both cases, indicating the availability of the model. At the conference, we will show the results of aircraft SLD icing using these models.

Numerical Simulation of Droplet Impingement on Wall with Thin Liquid Film by E-MPS Method

Masataka Kaneshi[1*], Koji Fukudome[1] and Makoto Yamamoto[1]

[1] Tokyo University of Science, Niijuku 6-3-1, Katsushika-ku, Tokyo 125-8585 Japan, 4518021@ed.tus.ac.jp

Key Words: *Droplet impingement, Moving Particle Simulation, Liquid film*

Ice accretion is a phenomenon in which supercooled droplets or ice particles in the atmosphere impinge on a solid surface, and an ice layer is formed there. The ice accretion on an aircraft threatens the navigation safety because it causes deformation of the wing shapes and reduces aerodynamics performance. Hence, it is very important to predict icing at the design phase of an aircraft. In the glaze ice conditions, where the temperature is relatively high, impinged droplets do not freeze instantly and they runback along the airfoil as a liquid film. As a result, they form characteristic icing shapes, such as a horn. In addition, when supercooled large droplets (SLD), which has more than 40 μm diameter, impinge on an aircraft and they acconpanied by splash and rebound. Therefore, the physics is so complex and the prediction is very difficult. The purpose of this study is modeling the droplet impact behaviour on a thin liquid film in terms of SLD icing by using the three-dimensional E-MPS method.

Moving Particle Semi-implicit (MPS) method[1] is a Lagrangian approach based on the governing equations at the motion of each particle. It is a meshless method and suitable for analyzing phenomena with large deformations of interface between multi-phase fluids. In addition, MPS method strictly satisfies the conservation of mass. Furthermore, explicit moving particle simulation (E-MPS) method[2] is faster than ordinally MPS method because of the explicit pressure solver. In this study, we used E-MPS method with the incompressible Navier-Stokes equations and the mass conservation equation (i.e. continuity equation) as the governing equations.

In the present study, a water droplet of 1.95 mm diameter impinges on a wall at velocity magnitude of 3.75 m/s. On the wall a water film with 0.434 mm thickness exists. As the impact angle was changed is changed from 90 to 15 degrees. When the droplet impinge vertically, the crown is formed by the impingement, and no secondary droplet is generated by the finger jets. As the impact angle reduces, the crown width in the direction of droplet movement increases significantly, and secondary droplets from the finger jets are generated. However, the crown width perpendicular to the direction of droplet movement and the crown height slightly change. When the impact angle reduces more, the crown height decreases and finally the crown cannot form and the droplet coalesces into the water film.

Numerical simulation of interaction between two Savonius turbines aimed at practical application of ocean current power generation

Akiko Minakawa[1*] and Tetuya Kawamura[2]

[1]Ochanomizu University, 2-1-1 Otsuka, Bunkyo-ku, Tokyo 112-8610,Japan,

kawamura@is.ocha.ac.jp

Key Words: *Savonius type turbine, numerical simulation, rotating object, domain decomposition, incompressible flow, ocean current power generation*

Renewable energy is important as a way to solve global warming and energy problems. In this study, we investigate the flows around two Savonius turbines that rotate independently by numerical simulation considering the application of ocean current power generation since the stability of the entire device can be improved by rotating two devices side by side in the opposite direction. This drag type device is chosen considering that the speed of the ocean current is small.

In general, when analysing the flow around a rotating object, a rotational coordinate system is often used. However, it is difficult to calculate with such coordinate system when two objects rotate in the reverse direction independently.

Therefore, in this study, the entire area was divided into a plurality of rectangular areas including one rotating device. At this time, data is exchanged between each area through the sides of each rectangle. One rectangle is divided into an inner circular area and an outer circular hollowed out rectangular area. In the circular area, the rotating coordinates matched to the rotation of the rotating device were used, and in the external area, the stationary coordinate system was used. Since the data in the two areas are passed on the circumference, not only the calculation time required for interpolation is significantly shortened, but also the accuracy of interpolation is improved. The internal region is further divided into several regions in order to generate a grid along the blade of the Savonius type rotating device.

In this method, since an independent rotating coordinate system is used in each region, the rotation speed of the rotating device can be freely changed for each rotating device. Further, this method can be applied regardless of the number of rotating devices. This time, using this method, the flow was calculated for the case where two rotating devices rotate in opposite directions and in the same direction.

The basic equations are the incompressible Navier-Stokes equations expressed by the both rotational and stational coordinate systems. The nonlinear terms of the basic equations are approximated by the third order upwind difference in order to perform stable calculations even at high Reynolds number. The fractional step method is employed to solve the basic equations.

The calculation was performed by changing the angle of attack, the rotation speed of the rotating device, the distance between the devices, etc., and the influence on the torque and power was investigated together with the analysis of the flow field.

It was found that the total value of the torques of the two units may be maximized when the flow hits the line connecting the center of the rotating devices at an angle of 45 degrees. The calculations were performed not only by fixing the rotation speed of the rotating device, but also by changing the rotation speed according to the torque acting on the rotating device where the Newton's equation of motion for the device was solved.

Validation of a New 2-scalar Flamelet Approach of LES for Turbulent Combustion

Tongtong Cui[1*], Hiroshi Terashima[1] and Nobuyuki Oshima[1]

[1] Hokkaido University, Kita 8, Nishi 5, Kita-ku, Sapporo, Hokkaido,060-0808 Japan

Key Words: *Turbulent Combustion, Large Eddy Simulation, Flamelet Approach*

Large Eddy Simulation (LES) is a promising tool for predicting the combustion field when fluid dynamics and flame instability are encountered. Among the turbulent combustion models for LES, Kim[1] has proposed a new 2-scalar flamelet approach. It is based on a generalized theory of fluid interface which combines a conservation law of thermodynamics and the solution of a viscid level-set equation. To deal with the combustion problem, a conservation scalar, mixture fraction, is used to represent the global outer flame condition by referring to a distinct 0-dimensional detailed chemical reaction solution based flamelet database in which the equilibrium state characterizes the corresponding mixture composition, and a level-set of non-dimensional sensible enthalpies as a chemical progress indicator determines the inner flame structure by evaluating the conventional level-set variable G with a local burning velocity model[2] which explicit the diffusion term in a finite flame thickness. This study extended Kim's approach to the turbulent LES. Due to the non-empirical flamelet database, one just needs to alter the laminar burning velocity used in the burning velocity model to a turbulent one which is calculated by an experimental correlation[3]. To quantitively evaluate this new approach's prediction accuracy, a typical turbulent partially premixed combustion field, Sandia Flame D, is chosen as the validation target. This simulation is performed by the FrontFlow/red, and the computational grid comprises 21,388,608 hexahedral unstructured elements which are parallelly processed by 288 cores. The annular pilot jet inlets are constructed by simplified geometries. By furtherly introducing a premixed flame after these inlets, an experimental turbulent intensity at the burner exit is generated. Different from other simulations using this fluctuation as the inlet velocity condition, these robust turbulence motions improved the prediction accuracy of the velocity field at the regions after the burner exit. At all measuring sections of the combustion field, Kim's approach indicates good agreement with the experiment. At the fuel-lean and rich regions where the burning velocity is low, an extra diffusion term of the level-set equation uniforms the distribution of sensible energy, which led to an experimental tendency at those two regions. However, at the stoichiometric region, the simulation results overestimate the experiment slightly. The reason is that the flamelet database for LES requires an accurate turbulence diffusion resolved by grid scales at the inner flame region though it has already included a sub-grid scales diffusion model. Nevertheless, by comparing with the results of a recently released paper [4] in which the gird resolution is 15 times this one, the results of this study have a considerable degree of accuracy.

Key Words: Chemo-mechanics, Multiphysics Couplings, Large deformations, Finite elements

Biodegradable polymers are a class of polymers that break down after fulfilling their intended function. This unique property makes them very promising in healthcare applications such as sutures, stents, and scaffolds, as the need for retrieval surgery is completely eliminated. In this context, modelling of hydrolysis degradation in polymers is critically needed in view of accelerating device development. However, understanding the factors that affect the device performance and service life under complex environment remains limited. Great challenges remain in modelling the response of these materials due to the presence of highly coupled phenomena [1]. Early models either mainly focused solely on developing kinetics of hydrolytic degradation or examining the degradation of mechanical parameters using semi-empirical approaches and experimental tests. Only few very recent studies modelled the mechanical behaviours. However, these studies are incomplete in considering the diffusion of water or reaction products.

This study try to fill this gap by developing a general thermodynamically consistent constitutive framework for degraded polymers that couples water and short soluble chains diffusion, hydrolysis reaction, and large deformation. In the constitutive framework, the state-of-the-art kinetics of the hydrolysis reaction considering the effects of auto-catalysis and stress-enhanced reactivity have been incorporated in the continuum model in a consistent manner [1]. The constitutive equations for the stress, chemical potential, and dissipative driving force are derived by means of the reduced entropy inequality [2, 3]. The model is implemented in the finite element framework for solving representative problems with simple geometries. A general implementation is also proposed through an ABAQUS user-defined subroutine. The numerical results suggest that the developed model can predict the coupled phenomena and reveal the effects of design factors on the degradation process. We hope our constitutive framework and presented results would enable the rational design of biodegradable polymer materials and devices under possible service environments.

Key Words: *Surface Instability, Creasing, Wrinkling, Nucleation, Propagation, Elastomers*

We investigate crease nucleation and propagation from a V-shaped notch in an elastomer. Plane strain finite element analysis is performed considering the isotropic thermal expansion of an incompressible neo-Hookean solid (e.g., swelling can be mimicked by thermal expansion). The nucleation of the first crease occurs at a global compressive strain ε_{G1}, which decreases from $\varepsilon_{wrinkle}$ to zero as the notch depth increases (i.e., ε_{G1} causes mesh dependence). Here, $\varepsilon_{wrinkle}$ is the critical compressive strain for wrinkling while ε_{crease} is defined as the critical compressive strain for creasing [1–3]. The propagation mechanisms of sequential creases are analysed by self-organization and nonlinear perturbation approaches, leading to finding a threshold compressive strain $\varepsilon_{threshold}$. These three critical compressive strains are in the relation of $\varepsilon_{crease}<\varepsilon_{threshold}<\varepsilon_{wrinkle}$. The case of $\varepsilon_{G1}<\varepsilon_{threshold}$ predicts the crease propagation regularized at $\varepsilon_{threshold}$ whereas the case of $\varepsilon_{G1}>\varepsilon_{threshold}$ is supercritical. The former case (i.e., $\varepsilon_{G1}<\varepsilon_{threshold}$) allows a nonlinear perturbation to nucleate a sequential crease at an arbitrary place by overcoming an energy barrier [4]. The self-organization approach predicts narrow crease distances, which are different with the crease distance that minimizes the elastic energy. The critical crease distance is broader and increases sensitively approaching to $\varepsilon_{threshold}$ but the energy difference is slight.

Key Words: *Polyacrylamide hydrogels, Transient equilibrium swelling, Viscoelasticity*

The present study experimentally examines the linear viscoelastic property of polyacrylamide (PAAm) hydrogels during transient equilibrium swelling. To this end, we conduct dynamic mechanical analysis on various specimens with different monomer and cross-linker concentrations. The transient equilibrium swelling is replicated using specimens with different water contents at the equilibrium state. The swelling-dependent linear viscoelasticity based on the scaling theory[1] is originally formulated to support the theoretical discussion of measured results.

The elastic moduli of PAAm hydrogels follow the scaling theory during the swelling from the as-prepared state, yet they change more complex during the de-swelling process. To be more specific, although the elastic moduli of PAAm hydrogels with a high monomer concentration also follow the scaling theory[2], those with a low monomer concentration irregularly change for the volume swelling ratio. Further, they eventually converge to a characteristic value independent of the monomer and cross-linker concentrations at the sufficiently de-swelling state named the extreme state.

The relaxation times of PAAm hydrogels at the extreme state have a characteristic value, and thus their viscoelastic property is uniquely determined regardless of their constituents. The viscosity during transient equilibrium swelling does not follow Newton's law of viscosity; in particular, by the swelling, a PAAm hydrogel with a high cross-linker concentration behaves more elastically, yet the viscosity increases.

Key Words: *porous-fibrous material, multiscale modelling, out-of-plane bending, curl*

Paper, a hydrophilic material, is susceptible to deformations due to variations in moisture content which develop over time [1]. Understanding the moisture transport through the thickness of a paper sheet and the resulting time-dependent mechanical response allows us to predict the curling behaviour of paper [2,3].

In this work, the time-dependent factors involved in the deformation of a paper strip that is fully or partially wetted from one side and subjected to different boundary conditions is studied with a one-dimensional numerical model. The different time scales involved, in the process of imbibition in the inter-fibre pores and absorption (or water uptake) by the fibres, are analysed. The resulting hygro-expansion due to swelling of the wet fibres is then solved to predict the bending response of the paper strip due to the non-homogeneous through-thickness moisture distribution. We provide a phenomenological model here to describe the dynamic water flow through the thickness of the paper strip, via the pores, using the unsaturated flow theory. The pore-fibre water exchange is modelled as a diffusion process dependent on the wetted pore surface area. The resulting moisture-induced displacements are characterised through a hygro-elastic material model.

The numerical analysis shows a fair agreement with experimental observations. An independent immersion test provides us with an estimate of the time scales involved in the liquid transport, which is then used to characterise the curling response of the paper strip.

Key Words: *Composite Actuators, Electroactive Polymer, Chemo-electro-mechanical Coupling, Transport Modelling*

Electroactive polymers are well known for their large strain response under electrical stimulus, which can be utilized for actuation applications. However, for extensive mechanical use in electro-mechanical systems, they lack the necessary strength and stiffness. It has been proposed to utilize metal reinforcements to increase this stiffness, while ideally maintaining large actuation strains.

Here, we consider an interpenetrating metal-polymer composite actuator consisting of a ionically activated polymer and a nanoporous metal skeleton. The nanoporous metal exhibits a unique bicontinuous microstructure [4] that facilitates mechanical support as well as almost unhindered ion flow in the solvent-saturated polymer phase. The composite shows increased actuation strains while still retaining the metal's superior mechanical properties [2].

In order to exploit the full potential of these nanocomposite actuators, a detailed understanding of the underlying structure-property relationships and means to predict the actuator's response are necessary. Using continuum mechanical modelling and finite element simulations, the mechanical properties of this nanocomposite as well as it's functional behaviour are investigated [1,3,5]. It can be shown that by modification of the nanocomposite's structure, transport paths, mechanical properties and reaction times can be altered significantly, thus, providing the means to tailor the actuator behaviour to different applications.

Key Words: *Surface Instability, Wrinkles, Hydrogels, Swelling, Polyacrylamide*

We study the morphological evolution of surface patterns in polyacrylamide (PAAm) hydrogel bilayers comprising a thin stiff film on a thick soft substrate. A pre-gel solution of acrylamide in water is poured onto the hydrogel substrate and left in air for a prescribed period of time to allow the solution to become a hydrogel film bonded to the substrate. During the gelation process, hexagonally packed dimples form on the surface, which then evolve into randomly oriented wrinkles. We presume that the mechanism of the formation and evolution of the patterns is twofold. First, the film constrained by the substrate swells owing to uptake of water molecules from both the substrate and an uncured liquid layer present on the top surface in contact with air, thereby experiencing an in-plane equi-biaxial compressive stress. Once the stress exceeds a critical value, the surface instability occurs, resulting in the formation of hexagonal dimples. Second, as the swelling proceeds, the magnitude of applied stress in relation to the critical stress, or overstress, in the film increases, causing the dimples to transition into wrinkles [1]. We find that the wavelength decreases during the pattern evolution and remains nearly constant once the wrinkles form. Furthermore, the wrinkle wavelength can be controlled in the millimeter-scale range by adjusting the film thickness. The formation and evolution of the patterns described above are due to coupling between solvent transport and deformations. Our findings offer a route to fabricating large-scale wrinkles in PAAm hydrogels.

A Gaussian process based Bayesian optimization calibration approach and its application in terradynamics

Wei Hu[1], **Dan Negrut**[1]

[1] Department of Mechanical Engineering, University of Wisconsin-Madison, Madison, WI 53706, USA
whu59@wisc.edu, negrut@wisc.edu

Key Words: Gaussian process, Bayesian optimization, Terradynamics, Smoothed particle hydrodynamics, Semi-empirical soil contact model

We seek to accelerate terradynamics simulations with interaction to solid bodies by using an semi-empirical soil contact model (SCM) [1] with a few simulation parameters that can be calibrated from experiment data or high-fidelity simulation data. To this end, the Gaussian process (GP) based Bayesian optimization (BO) approach [2] is employed in this work. First of all, to get the high-fidelity simulation data as the "ground truth" in the calibration step, a more accurate continuum model based on the Smoothed Particle Hydrodynamics (SPH) method is employed [3]. The deformable terrain is modeled as an elasto-plastic continuum and discretized with SPH particles that dynamically interacts with the solid bodies in a co-simulation setup. The interaction between the solid body and the deformable terrain is handled through so-called boundary conditions enforcing particles. Several simulations are performed using the SPH model to obtain the "ground truth" data. Second, an initial guess of the SCM parameters (7 parameters in this work) is chosen according to experience, and used to run the SCM simulation. The SCM simulation result is then compared with the "ground truth" and use the GP-based BO approach to find the distribution of the next possible set of parameters that can be used to run the following SCM simulation. Finally, the above operation steps will iterate for several times until a set of SCM parameters is found, with which we can get a simulation result that matches the "ground truth" best. Both the SCM and SPH simulations will be performed in an open-source software called Chrono. The GP-based BO will be performed in an separate package by using Python scripts to interactively communicate with the developed terradynamics solver.

Key Words: *Dense Granular Flows, Silo Discharge, Non-local Effect, $\mu(I)$ Rheology*

In this work, we implement the non-local rheology [Bouzid *et al.*, Phys. Rev. Lett. **111**, 238301 (2013)] into a well-developed continuum flow solver [Lin and Yang, J. Comput. Phys. **420**, 109708 (2020)] to simulate the two-dimensional granular silo discharge flow. The discharge dynamics of non-local simulation show qualitative agreement with the particle-based simulation data and the continuum simulation using local $\mu(I)$ rheology [Staron *et al.*, Eur. Phys. J. E **37**, 5 (2014)], while the non-local effect enhances the volume discharge rate compared to the local model prediction when the silo orifice is narrower. Thus, we examine the difference between the local and non-local flow rate versus the silo orifice size, a monotonically growth of flow rate difference with decreasing orifice size is revealed, independent of silo aspect ratio and model parameters. Finally, we evaluate the time evolution of high-shear zone during discharge process and find the non-local momentum transport facilitating the flow over a wider domain to increase the flow rate for the narrower orifice.

Key Words: *Horizontal Stirred Bed Reactors (HSBRs), Mixing, Discrete particle model*

Horizontal stirred bed reactor (HSBR) is a type of reactor for axial powder mixing whose use in gas-phase polymerization of, e.g., polypropylene, has grown significantly in recent years [1]. The reactor usually has a bed of particles that is gently agitated by a series of paddles that are connected to a central shaft of the reactor.

In this work, we simulated the mixing of particles in an existing model of industrial HSBR based on a discrete particle model using the open-source software MercuryDPM [2]. The goal was to analyze the mixing process in terms of axial dispersion and mixing quality and determine the number of rotations required for efficient mixing. This process was analyzed by investigating different properties, including cycle time, Lacey index, and axial dispersion coefficient. First, the cycle time distribution was obtained by tracking the particles, and the result was validated using coarse-graining [3]. We obtained the Lacey mixing index using particle tracking and found the minimum number of rotations needed for efficient mixing. Finally, we measured axial dispersion, where we observed sub-diffusive behavior in the mixing process.

Key Words: *Discrete Element Method, Unresolved CFD-DEM, Resolved CFD-DEM, Multiphase Flow, Finite Element Method, High-Order Methods.*

Resolved and unresolved CFD-DEM couple CFD for the fluid phase with the Discrete Element Method (DEM) for the solids. Unresolved CFD-DEM solves the volume-averaged Navier-Stokes equations for the fluid at a scaler greater than the particle dimension and uses DEM to simulate the solid phase. Several particles occupy the same mesh cell. The two phases are coupled using expressions for the hydrodynamics forces (e.g., drag). Resolved CFD-DEM is more accurate than unresolved CFD-DEM because it fully accounts for the flow around each particle without additional models to couple the particle and fluid phases. Both approaches are complementary. Resolved CFD-DEM enables a deeper understanding of particle-fluid interaction whereas unresolved CFD-DEM can be used to accurately simulate processes at the pilot scale.

In this work, we introduce Lethe [1], a monolithic, open-source high-order unresolved and resolved CFD-DEM solver. Lethe solves the incompressible Navier-Stokes and volume-averaged Navier-Stokes equations by applying a stabilized continuous Galerkin Finite Element discretisation. It is built upon the well-established deal.II library. Through its deal.II heritage, Lethe is able to handle large meshes (>1B cells), supports dynamic mesh adaptation and is based on a solid C++ architecture. Lethe possess a full DEM module[3], which, coupled with it's CFD capabilities, enable the simulation of solid-fluid flows using both resolved and unresolved CFD-DEM strategies.

First, we present the implicit CFD solver of Lethe. We discuss how the solver is extended to resolved CFD-DEM using a high-order implicit sharp-edge immersed boundary approach. We demonstrate the accuracy of the solver using the method of manufactured solutions and demonstrate its capabilities by simulating the dynamic of sedimentation spheres. We present the unresolved CFD-DEM capabilities of Lethe. We present our implementation of a stabilized high-order formulation for the VANS equation. Using the flows in liquid and gas fluidized beds, we validate the capabilities of Lethe to predict complex solid-fluid flow dynamics under a wide range of regime. This presentation aims at giving an overview of our efforts to produce a state of the art, fully open-source high-order CFD-DEM code which will enable the simulation of complex solid-fluid both at the particle scale and at the process scale.

MercuryDPM: Fast, flexible, particle simulations

Thomas Weinhart[1*], Anthony R Thornton[1] et al

[1] Thermal and Fluid Engineering (ET), University of Twente, Drienerlolaan 5, 7500 AE Enschede, The Netherlands, t.weinhart@utwente.nl and a.r.thornton@utwente.nl

Key Words: *Granular materials, DEM, DPM, MercuryDPM, Open-source*

We introduce the open-source package MercuryDPM, a code for discrete particle simulations, that we are developing. It simulates the motion of particles, by applying forces and torques that stem either from external body forces, (e.g. gravity, magnetic fields, etc...) or from particle interaction laws. For granular particles, these are typically contact forces (elastic, plastic, viscous, frictional).

MercuryDPM is an object-oriented C++ algorithm with an easy-to-use user interface and a flexible core, allowing developers to quickly add new features. It is parallelised using both MPI and OpenMP and released open-source under the BSD 3-clause licence. Its developers' community has developed many features, including moving (wearable) curved walls (polygons, cone sections, helices, screw threads, level-sets, nurbs, triangulated, etc); state-of-the-art granular contact models (wet, charged, sintered, melting, cohesive, etc); specialised classes for common geometries (inclined planes/chutes, hoppers, etc); non-spherical particles (multisphere, superquadric, bonded particles, deformable clusters); general interfaces (particles/walls/boundaries can all be changed with the same set of commands); liquid droplet/spray models; STL readers for industrial geometries; restarting; visualisation (xBalls and Paraview); a large self-test suite; extensive Doxygen documentation; and numerous tutorials and demos.

For efficiency, it uses an advanced contact detection method, the hierarchical grid. This algorithm has a lower complexity than the traditional linked list algorithm for polydispersed flows, which allows large simulations with wide size distributions.

It also contains a coarse-graining tool: MercuryCG, which is both integrated and usable as a stand-alone tool. Coarse-graining is a novel way to extract continuum fields from discrete particle systems. It ensures by definition that the resulting continuum fields conserve mass, momentum and energy, a crucial requirement for accurate coupling with continuum models. The approach is flexible and the latest version can be applied to both bulk and mixtures; boundaries and interfaces; time-dependent, steady and static situations; and, even experimental data. It is available in MercuryDPM either as a post-processing tool, or it can be run in real-time, e.g. to define pressure-controlled walls.

2 MercuryLab, Mekkelholtsweg 10, 7523 DE Enschede, The Netherlands.

Granular materials are the most common type of raw material in industry, after water. A multitude of industries, such as mining, agriculture, food, pharma, manufacturing and construction, depend on processes involving granular materials. They are also common in many natural phenomena, from dune formation, soil erosion and water management to natural hazards, such as avalanches or volcanic deposition.

To develop trustworthy models for granular materials, one has to understand their behaviour on multiple scales: On the micro-scale, one has to understand the properties of single particles (their size, shape, density) and the contact behaviour of particle pairs (interparticle friction, cohesion, and elasto-plasticity). These properties in turn influence the granular behaviour on the macro-scale.

We have developed a multiscale model for granular materials, combining the Discrete Particle Model (DPM, aka DEM) with an application-specific continuum model (CM). Starting from simplified particle and contact models, DPM captures the collective behaviour of a granular material by simulating the movement of the individual grains. Bulk properties are then extracted from the DPM simulations and coupled to the continuum model.

To calibrate a DPM model, developers often use analytic relations between the micro- and macro-parameters that are either phenomenological or derived from contact mechanics. Alternatively, they use numerical studies, where hundreds of simulations are run for different parameters to develop a mapping between the micro and macro parameters. However, both approaches are not feasible for complex industrial materials, where wide particle size distributions, agglomeration, inclusion of liquids, sintering, drying, and other phenomena require complicated contact models with many micro-parameters.

To deal with these issues, we have developed an automated calibration technique: First, we measure the basic material parameters (e.g., particle size distribution, material density) and apply them directly to the discrete particle simulation. Next, we select standard bulk experiments (heap test, rotating drum, ring shear cell) appropriate for the process we want to model. We simulate the same processes in MercuryDPM [1] and measure the response of the simulated material. Then we apply a numerical optimisation algorithm to find the micro-scale parameters for which the response of the experiments and simulations match. This optimization is done using a probabilistic optimization technique as implemented in the open-source code GrainLearning [2].

We have preliminary data suggesting that this technique and methodology works, in fact it has already been used in several projects, yielding good results. The technique can find local optima in only two to three iterations, even for complex contact models with many microscopic parameters. We present several case studies, discuss the strengths and weaknesses of the technique, when and why it fails and when it does succeed.

[3] University of Wisconsin-Madison, Madison, WI 53706, USA, negrut@wisc.edu

Key Words: DEM, GPU, Complex Geometry, Open-source, Chrono

In this contribution we report the numerical features and development status of our open-source multi-GPU Discrete Element Method (DEM) simulation package, the next-generation upgrade of the existing simulator Chrono::GPU [1]. This package provides complex grain geometry support through clumped spheres. While the largest DEM simulation to date ran on **tens of thousands** CPUs with two billion particles, our simulator scales to hundreds of millions particles on **two** GPUs. To achieve this high efficiency without compromising the paramount accuracy requirement that defines challenging simulations, we employ the following salient numerical techniques:

- Using compressed integer-based data structures and just-in-time compiling to reduce memory footprint;
- Leveraging CUB (an efficient CUDA utility package) functions;
- De-coupling kinematic (such as contact detection) and dynamics computations (such as computing contact forces and numerical integrations) to split the workload onto multiple GPUs.

This package provides APIs to interface the multi-physics simulation engine Chrono [2], allowing co-simulations with complex mechanical systems, such as rovers operating on granular terrains.

Key Words: *Finite volumes, Flow Problems, CFD, Incompressible Limit*

Finite volume (FV) methods are ubiquitous in CFD simulations of industrial problems because of their robustness and efficient implementations. A drawback of existing cell-centered (CCFV) and vertex-centered (VCFV) strategies is their need for high-quality meshes, whose generation is extremely expensive in terms of man-hours of specialized technicians. Indeed, the accuracy of both CCFV and VCFV is compromised in the presence of distorted and stretched cells [1]. On the contrary, the face-centered (FCFV) rationale proposed in [2-6] provides a framework less sensitive to mesh quality, preserving the accuracy of the approximation even in the presence of complex unstructured meshes with highly distorted and highly stretched cells. The FCFV method defines unknowns at the face barycenter and uses hybridization to eliminate the degrees of freedom inside each cell. In addition, Riemann solvers are defined implicitly within the expressions of the numerical fluxes [6]. The resulting methodology provides first-order accurate approximations of the viscous stress tensor and of the heat flux, without the need of any gradient reconstruction procedure. In addition, FCFV is capable of constructing non-oscillatory approximations of sharp discontinuities, without resorting to shock capturing or limiting techniques. For flows at low Mach number, the method is robust and is capable of computing accurate solutions in the incompressible limit, without the need of introducing specific pressure correction strategies. Moreover, this strategy has been tested for a large variety of elements including prims and pyramids. Note that hexahedra with non-planar faces, where standard FV require a special treatment, can also be used. Numerical simulations of 2D and 3D benchmarks of external flows will be presented to validate the methodology in different flow regimes, encompassing compressible and incompressible flows, from inviscid to viscous laminar flows, from subsonic to supersonic flows.

An Arbitrary Lagrangian-Eulerian Algorithm for Multiphase non-Newtonian Fluid Flows

Cagatay Guventurk[1*,2] **and Mehmet Sahin**[1]

[1] Istanbul Technical University, Maslak, Istanbul, 34469, TURKEY, {guventurkc, msahin}@itu.edu.tr
[2] Turkish National Defense University, Yesilyurt, Istanbul, 34149, TURKEY,
cguventur@hho.msu.edu.tr

Key Words: non-Newtonian, Multiphase Flow, Arbitrary Lagrangian-Eulerian, Rising Bubble, Mass Conservation

Multiphase non-Newtonian flows are encountered in nature (e.g., particle-laden biological flows) and industrial applications (e.g., ink jet plotter). Numerical simulation of multiphase non-Newtonian flows is quite challenging because of the discontinuous material properties across the surface, a priori unknown deforming interface location, large extra stress values and large difference between polymer relaxation time and advective time scale (i.e., high Weissenberg number problem). In this study, the Arbitrary Lagrangian Eulerian (ALE) approach [1, 2] is extended to isothermal non-Newtonian fluids by implementing constitution equations. To the best of our knowledge, the ALE algorithm based on the side-centered unstructured finite volume method has been applied to the simulation of non-Newtonian multiphase fluid flows for the first time. The pressure field is treated to be discontinuous across the interface with the discontinuous treatment of density and viscosity. The discontinuous treatment of pressure field helps us to avoid errors due to the incompressibility condition in the vicinity of the interface. The surface tension term at the interface is treated as a tangent force. The jump conditions are exactly satisfied across the interface. The parasitic currents are found to be very sensitive to the computation of normal vectors [2]. Therefore, the mean weighted by sine and edge length reciprocals (MWSELR) is implemented for the computation of unit normal vector. The resulting algebraic equations are solved in a fully coupled (monolithic) manner and an approximate matrix factorization similar to that of the projection method is employed. The parallel algebraic multigrid solver BoomerAMG provided by the HYPRE library, which is accessed through the PETSc library, has been utilized for the scaled discrete Laplacian of pressure and the diagonal blocks of mesh deformation equations. The classical benchmark problem of a single rising Newtonian bubble in a non-Newtonian fluid due to buoyancy is presented in two- and three-dimensions.

Computational Analysis of Shear-thinning Coating flows

Key Words: *Shear-rate-dependent viscosity, Industrial applications, Mircrovortices, Pulsatile flows*

Complex fluids with shear-rate-dependent viscosity are widely used in the flows of several industrial applications. To have better control of the flows of such fluids, it is crucial to understand the underlying principles that govern the fluid flow. In this study, through two illustrative case studies, we present the use of flow modeling and simulation for a better understanding of the effects of shear-rate-dependent viscosities on the fluid flow.

In the first case, we explore the effect of the shear-rate-viscosity on the operating conditions that lead to the formation of microvortices in the slot coating flows, which are known to have a detrimental effect on the stable process operation and production of defect-free film products [1]. We simplify the microvortices found in the downstream region of slot coating flow as flow reversal and present the effect of the shear-rate-dependent viscosity on the critical operating conditions at the onset of the flow reversal [2].

Two methods for computing the critical condition in slot coating flows of generalized Newtonian fluids (GNFs) are presented. The two methods were applied to the flows of two illustrative GNFs, the Carreau-Yasuda, and Bingham-Carreau-Yasuda fluids. They were both found to be successful in computing the critical flow reversal conditions. It was also revealed that the critical conditions depended significantly on the local power-law index n, which quantifies the dependency of the viscosity on the magnitude of the shear rate.

In the second case, we explore the flow properties of pulsatile shear-thinning flows in a two-dimensional rectangular channel [3]. Since various external disturbances such as oscillations from flow pumps are commonly encountered in industrial processes and such disturbances may result in unexpected changes of the rheological properties of the complex fluids.

The characteristic viscosity chosen based on the steady-state analysis was defined for the pulsatile shear-thinning flow. It was used to form a non-Newtonian Womersley number, which acts as a critical model parameter of the system of interest. Numerical analyses of Carreau fluids revealed the existence of master curves for the amplitudes and phase lags of the flows. We advanced further to demonstrate that the flow dynamics can be predicted using the pre-computed master curves with high accuracy without explicit transient computations.

Key Words: *Mold filling, yield stress, viscoelastic, Saramito model, finite element, moving mesh*

Materials that behave as both fluids and solids can be seen in a wide variety of applications from pouring concrete to lava flows and food processing. Yield stress is a useful concept for developing models that demonstrate both fluid and solid behavior depending on the local state of the fluid. In this talk, we will discuss an ongoing project to use elastoviscoplastic models to understand the complex flow profiles of a model yield stress fluid, Carbopol, as it evolves in time in a free surface flow. We use a Saramito model to describe the rheology of the fluid [1]. This model describes the material as a Maxwell fluid above yield and an elastic solid below yield, with a yield criterion based on the von Mises stress. Conservation equations for momentum and mass and the Saramito constitutive equations for stress are solved using the finite element method coupled to a free-surface moving mesh algorithm. We verify our implementation by comparing our results to benchmarks in the literature such as flow past a sphere and a ball falling in a tube full of yield stress fluid. Furthermore, we compare results from mold filling simulations to validation flow visualization experiments in a quasi-two-dimensional flow where fluid fills a thin gap between transparent plates. The experiments show regions of low strain where the fluid displaces as a solid body and high strain regions where the Carbopol is fluidized. The computational model matches qualitatively for the yield stress fluid. Comparisons between the quasi-two-dimensional model and the fully three-dimensional will also be discussed.

[3] Department of Mechanical Engineering, The University of Texas at Austin, Austin, Texas 78712, USA

Key Words: plasma kinetics, glow discharge, Chebyshev collocation method, time periodic shooting

This talk aims to highlight the development of an efficient solver for the capacitively coupled glow discharge device within the scope of sensitivity analysis. The physical model is comprised of species continuity equations, electron and heavy species energy equations, and Gauss' law, closed by the drift-diffusion model and a chemical reaction mechanism, driven by an oscillating voltage applied on one side of the domain [1]. The high-aspect-ratio parallel-plate glow discharge device lends itself to a 1D analysis, meaning the model consists of a set of 1D, unsteady PDEs, where the solution of interest is periodic in time. The large number of simulations required for sensitivity analysis and UQ implies the need for a solver that rapidly converges to the periodic steady-state solution. However, the very slow ambipolar diffusion processes in a capacitive glow discharge, especially for pressures in the Torr regime and higher, means it can take thousands of periods of forward simulation to approach this periodic solution. To speed up this convergence, we have implemented a time-periodic shooting (TPS) algorithm [2], in which the periodicity of the solution is imposed as an additional constraint, and the resulting nonlinear system is solved using a standard Newton method. This approach is observed to be 100 times faster than time marching alone, which has enabled an initial global sensitivity analysis. Specifically, we have conducted an initial study using the libraries Chaospy [3] and Uncertainpy [4], in combination with the TPS-based glow discharge solver, to determine which input parameters (i.e., reaction rate coefficients and transport parameters) most influence the quantities of interest, e.g., electron density.

Novel Space-Time Finite Elements for Fluid-Based Processes

Marek Behr[1]*

[1] Chair for Computational Analysis of Technical Systems,
RWTH Aachen University, 52056 Aachen, Germany,
behr@cats.rwth-aachen.de, https://www.cats.rwth-aachen.de

Key Words: Deforming Domains, Space-Time Finite Elements

Moving-boundary flow simulations are an important design and analysis tool in many areas, including civil and biomedical engineering, as well as production engineering. Interface-capturing offers flexibility for complex free-surface motion, while interface-tracking is very attractive due to its mass conservation properties at low resolution. We focus on these alternatives in the context of flow simulations based on stabilized finite element discretizations of Navier-Stokes equations, including space-time formulations that allow extra flexibility concerning grid design at the interface.

Space-time approaches offer some not-yet-fully-exploited advantages; among them, the potential to allow some degree of unstructured space-time meshing. A method for generating simplex space-time meshes has been developed, allowing arbitrary temporal refinement in selected portions of space-time slabs. The method increases the flexibility of space-time discretizations, even in the absence of dedicated space-time mesh generation tools. The resulting tetrahedral and pentatope meshes are being used in the context of cavity filling flow simulations, such as those necessary to design injection molding processes.

In cases where a general space-time mesh is still out of reach, a variety of special approaches involving slipping and deactivation of elements can be used. Several examples will be given.

This is a joint work with Violeta Karyofylli, Max von Danwitz, Norbert Hosters, Michel Make, and Linda Gesenhues.

Numerical simulation of polymeric mixing process with non-conforming methods in OpenFOAM

Nicola Parolini[1*], Giorgio Negrini[1], Marco Verani[1] and Daniele Cerroni[2]

[1] Politecnico di Milano, Milan, Italy
[2] Pirelli Tyre S.p.A., Milan, Italy

Key Words: Non-conforming methods, Non-Newtonian fluids, Polymeric mixing

Mixing of polymeric materials is performed with the aid of machines characterized by complex geometries in which body-fitted simulations can hardly be applied. The adoption of non-conforming approach (such as diffuse interface, ficticious domain, immersed boundary or volume penalty methods) represent valid alternatives to simulate such processes with complex kinematics (single and twin screw extruders, banbury mixers etc.).

In this talk we present the results of a research activity finalized to the development of a simulation tool based on the open-source CFD library OpenFOAM for the analysis and optimization of the mixing process of polymeric materials. Different non-conforming discretization strategies, namely a diffuse interface penalisation method [2] and a discrete-forcing direct-imposition immersed boundary method [1], and different solution strategies for the solution of non-Newtonian fluid flows with temperature dependent viscosity are compared in terms of accuracy, robustness and computational cost.

Numerical results for simple similar industrial geometries and flow conditions will be presented and discussed.

RANS Model Assessment for Curved Turbulent Shear Layers and Retro-propulsive Flows

Kristen V. Matsuno[1*] **and Sanjiva K. Lele**[2]

[1] Stanford University, Stanford, CA 94305, kmatsuno@stanford.edu
[2] Stanford University, Stanford, CA 94305, lele@stanford.edu

Key Words: RANS modelling, compressibility effects, curvature effects, retropropulsion

Solving the Reynolds-Averaged Navier-Stokes (RANS) equations is one of the most affordable methods in CFD and remains vital in vehicle design and analysis. However, RANS solvers' deficiencies in capturing complex flow fields, such as those in supersonic retro-propulsive (SRP) flows, are well acknowledged [2, 5]. This work addresses the challenge of characterizing turbulence in retro-propulsive jet plumes by direct comparison of high-resolution large eddy simulations (LES) and RANS, to assess and improve turbulence modeling in canonical elements of SRP flows. The first component of this study is the production and analysis of LES of curved turbulent shear layers with varying compressibility, density variation, and curvature intensity using NASA's OVERFLOW code [3]. The second component of this study will focus on three of the most popular RANS models – the Spalart-Allmaras model, the $k-\omega$ model, and Menter's shear stress transport model. These high-fidelity studies enable an understanding of turbulent mixing characteristics when influenced by multiple competing physical mechanisms. RANS model comparisons with the LES database will demonstrate the state of the art in RANS models for these complex flows and highlight areas for improvement. In addition to the standard models, the performance of several turbulence model corrections will also be considered. Among others, Suzen & Hoffman's compressibility correction [4], which was formulated to assist the behavior of compressible free shear flows and targets the $k-\varepsilon$ part of Menter's models, and Catris & Aupoix's density gradient correction [1] are considered in this work. Preliminary comparisons of RANS and LES data suggests that the present RANS models with standard model coefficients show significant bias error relative to LES data in regards to mixing layer growth rates. This is a collaborative study with Dr. Robert Childs at NASA Ames Research Center.

Simulation of a droplet impact in a thin film using a phase-field model

Malú Grave[1] **and Alvaro L. G. A. Coutinho**[2]

[1] High Performance Computing Center, Federal University of Rio de Janeiro, P.O. Box 68506, RJ 21945-970, Rio de Janeiro, Brazil, malugrave@nacad.ufrj.br

[2] High Performance Computing Center, Federal University of Rio de Janeiro, P.O. Box 68506, RJ 21945-970, Rio de Janeiro, Brazil, alvaro@nacad.ufrj.br

Key Words: Two-phase flow, Phase-Field method, Drop impact

Droplet impact dynamics are an active research area due to the variety of their industrial applications. It appears in industrial processes employing spray coating and painting, spray cooling, inkjet printing, combustion engines, and anti-icing characteristics of critical industrial components such as aircraft surface, powder lines, and wind turbines [1]. The droplet impact is a special case of two-phase flow simulations, where the surface tension force plays an important role. One way to model the gas and fluid phases is with interface capturing methods. Three well-established interface capturing models are the Volume-of-Fluid (VOF), level-set, and phase-field models [2]. The main advantage of the VOF method is mass conservation, while the implementation of the surface tension may be challenging. The level-set is known for its ability to compute the surface tension accurately, and phase-field models are known for satisfying the second law of thermodynamics. This work uses a conservative Allen-Cahn equation based on [3] to model and simulates a liquid drop impact on a moving wall with a pre-existing thin film of the same liquid. We couple this interface-capturing method with the Navier-Stokes equations. The analysis takes into account viscous, inertial, and surface tension forces, neglecting gravity. We solve the equations with the residual-based variational multiscale finite element formulation. We implement the whole model in `libMesh`, an open finite element library that provides a framework for multiphysics, considering adaptive mesh refinement. The values of the Reynolds and Weber numbers determine different drop splash regimes. Numerical results are presented for 2D and 3D liquid drop impacts, and they are in good agreement with other simulations.

Key Words: *Computational Fluid Dynamic (CFD), Positron Emission Particle Tracking (PEPT), laminar flow stirred mixing, model validation*

Industrial fluid mixing is a unit operation intrinsic to the production of many Fast-Moving Consumer Goods (FMCG). Because there is a lack of analytical techniques capable of predicting the hydrodynamic flow of complex rheologies, the current challenge in these industries is how best to optimise the mixing of these fluids [1].

The research presented will focus on the development of Computational Fluid Dynamics (CFD) models capable of predicting mixing for rheologically complex systems in the laminar flow regime for a horizontal bladed mixer, reducing the need for costly experimental trials. The general method of model development is to build on simple Newtonian models by validating each iteration with experiment and to gradually add elements of complexity such as a non-Newtonian rheology. The main method of validation is Positron Emission Particle Tracking (PEPT), a powerful technique reliant on ergodicity which can generate a Lagrangian description of hydrodynamic flow *in-situ*. PEPT uses gamma-ray detectors to locate tracer particles in transit and is used uninvasively in opaque industrial equipment [2]. Validation using PEPT entails a 3D pointwise comparison of multiple parameters predicted by the CFD model containing multiple closure relations.

The current CFD model is developed in Siemens STAR-CCM+ and uses an Eulerian sliding mesh with a Volume of Fluid (VOF) physical model. With iterative validation, the next stage of the model is to predict the behaviour of the PEPT tracer particle by incorporating the Discrete Element Method (DEM) to ultimately create validated CFD-DEM models that can predict the coupled properties for a variety of rheologically complex laminar mixing systems.

Key Words: *OpenFOAM*, *Air Pollutants*, *Human Airways*, *Particle Deposition*, *Superellipsoids*

Humans are constantly exposed to pollutants in the air. These particles can originate from pollen, tyre wear, exhaust residue, microplastics, fabrics as well as asbestos fibres or, as highlighted in the recent pandemic, expiratory events leading to exhaled viruses encapsulated in saliva droplets. Understanding particle deposition in the human lung is of key interest to reduce the impact of harmful particles, or on the contrary, to improve the targeted delivery of drugs to reduce their side effects. A common simplification in the study of particle deposition in human airways is to assume perfectly spherical particles. This is an accepted approach for studies of aerosolized droplets, yet for inhalation of toxic fibres or arbitrarily shaped aerosol particles such as pollens, fibers or volcanic ash, the assumption of spherical shape no longer applies. In this context, shape factors are often used to account for non-sphericity effects, but these are often insufficient to accurately predict particle motion. Therefore, more sophisticated particle models need to be considered. However, there is a glaring lack of research in this area regarding the accurate prediction of inhalation of more complex shaped particles in realistic human airways. In this work, we investigate the effect of different particle geometries on the deposition behaviour in realistic lung models. The study includes spheres and prolate ellipsoids as well as more arbitrary shapes in the scope of superellipsoidal particles, fitted to naturally occurring pollutants, to cover a wide range of particles suspended in the air we breathe. In our study we focus on the deposition efficiency in the mouth-throat and tracheobronchial region as well as the level of bifurcuration of the chosen lung geometry. The computational study is based on Lagrangian particle tracking in RANS resolved turbulent flow in a realistic lung geometry performed using an in-house solver developed in the OpenFOAM framework. Finally, we present the identified key influences on deposition efficiency in the lung models used.

Numerical Analysis of Interaction between Multiphase Flow and Rain Chain

Minoru Shirazaki*, Takuya Nagatsuka and Keitaro Hanada

Yokohama National University,
79-2 Tokiwadai, Hodogaya-ku, Yokohama 240-8501 JAPAN, shirazak@ynu.ac.jp

Key Words: *Multiphase flow, Motion of connected bodies, Cartesian grids, Level-set method, Immersed boundary method*

A numerical analysis of the motion of a rain chain in multiphase flow was performed. The rain chain was modeled using connected cups. This study primarily discussed the relationship between the motion of the rain chain and the flow of running water from the top of the chain. The incompressible continuity and the Navier–Stokes equation were solved by means of the finite difference method on a staggered Cartesian grid. The velocity–pressure coupling was solved using the fractional step method. The interface between the two fluids was defined by means of the coupled level set and volume of fluid method [1]. In the Cartesian grid, the moving body was modeled using the body force-type immersed boundary method [2]. The surface tension was modeled by the continuum surface force model [3]. It was shown that the motion of the rain chain changes greatly depending on the conditions of the running water, the mass of the cups of the rain chain, and the number of the connected cups. In the case of a rain chain that comprised 10 cups, the displacement of the motion gradually increased and twisting motion was observed.

Key Words: *Bubbly flow, Bubble Dynamics, Inclined Pipe, Lateral Motion, Negative Buoyancy Effect.*

Three-dimensional direct numerical simulations are conducted for bubbly flows rising in a slightly inclined vertical pipe using the method developed by Ii et al. [1]. In the present method, multiple VOF function is introduced to avoid bubble coalescences and 78 rising bubbles are solved without coalescence which are often observed in the actual flows with contaminant effect. The simulation results are validated through the comparisons with the previous experimental data by Zenit et al. [2] for the inclined angle of 5 degree. The simulation results showed the good agreement with their experimental data. For other conditions, we have found interesting phenomena for lower inclined angle. The results show a negative buoyancy effect. That is, when the inclined angle is small enough (< 2 degrees), bubbles shown the lateral migration in the pipe against the buoyancy effect. This negative buoyancy effect disappears when the inclined angle becomes bigger than 2 degrees. To investigate the mechanism of negative buoyancy effect, we conducted the analysis of the force acting on a bubble. Due to the dynamical motion of a rising bubble, it is difficult to get the force by simply integrating the stress on bubble surface. Here, we introduce the macroscopic control volume analysis using the control volume containing an individual bubble inside. The analysis show that the negative lift force is caused by the unsteady component of the liquid phase.

We also conducted the simulations for non-Newtonian, Power-law fluid. The effect of power index and flow consistency index are investigated. The obtained results can be related to some practical applications such as deep ocean mining using an air-lift pump [3].

Key Words: *Multiphase flows, Bubbly flows, Electrochemistry, Industrial Applications, Multiphysics Problems*

Alkaline water electrolysers are commonly used for the industrial-scale production of hydrogen. Operating at high current densities leads to enhanced hydrogen production but reduced cell efficiency, partly due to ohmic losses from the gas-liquid flow. Gas blockage of the electrode surface and reduced effective electrolyte conductivity from increased void fraction are key contributors to these losses. We perform three-dimensional transient numerical simulations of an electrochemical cell under galvanostatic conditions, modelling the multiphase flow and the electrochemistry with the OpenFOAM libraries. We use a multifluid Eulerian model to simulate the bubbly flow, with oxygen and hydrogen as dispersed phases and the electrolyte solution as the continuous phase. The current distribution in the electrolyte is coupled to the Butler-Volmer equation at the electrode surfaces, and governs the local gas generation rate through Faraday's law. We investigate both free convection [1] and forced convection [2] configurations over a range of current densities, and compare void fractions, velocity profiles, turbulent intensity and cell potential with experimental results to validate our model. We then explore the impact of bubble size, distribution and inter-phase coupling terms on the flow in the cell, and observe the formation of waves along the electrode surface. We study the phenomena which give rise to these waves, and their impact on cell operation. Improved modelling and understanding of the flow within alkaline water electrolysers paves the way for optimisation of cell design and operation from a fluid mechanics perspective.

Key Words: *Porous Media, Multiphase Flow, Fluid Displacement*

The unstable fluid-fluid displacement patterns in porous media, featured with rough invasion fronts and trapping of the defending phase, are often observed in drainage processes, i.e., when the porous media are non-wetting to the invading phase. On the contrary, during imbibition, faceted and compact growth is expected in porous media with geometrically homogeneous pore structures. This is because the pore-scale non-local cooperative pore-filling event is favoured. In this work, we report the irregular growth of the invading fluid during imbibition processes in two-dimensional regular porous media composed of circular posts arranged on triangular and square lattices. The ramified invasion patterns associated with thin fingers and trapping of the defending fluids are reminiscent of capillary fingering, which are often observed only in drainage condition. Through examining the capillary pressure signals and type of pore-scale invasion mechanisms during multiphase flow, the differences between compact and faceted displacement and unstable growth are revealed. The critical events at pore-scale that determines the pore-filling process are analysed, leading to a phase diagram describing the dominance of event type across a wide range of porosity and wetting condition. Through conducting systematic quasi-static radial injection simulations, excellent agreement is observed on the transition boundary from faceted and compact displacement patterns towards irregular and dendritic invasion morphologies. This is reflected by the overlap of the transition boundaries from analytical prediction, type of pore-scale invasion events, and macroscopic morphology quantified by the fractal dimension. This work provides new insights on the role of geometrical features of solid structures during fluid displacement process with emphasis on the porosity and wettability of regular porous media. The findings would assist in guiding the design of microfluidic devices to deterministically control the multiphase flow, transport and reaction processes.

The influence of flow conditions on mass transfer in lyophilization in a vial

Matjaž Hriberšek[1*], Blaž Kamenik[1], Jure Ravnik[1] and Matej Zadravec[1]

[1] Faculty of Mechanical Engineering, University of Maribor, Smetanova 17, 2000 Maribor, Slovenia

Key Words: *Lyophilization, Heat and Mass Transfer, Computational Fluid Dynamics, Vial*

Modeling lyophilization in a vial is frequently done on a single vial level. When setting up the numerical model, the main focus is on the heat and mass transfer inside the lyophilizate, whereas the vapor dynamics in the upper part of the vial is taken into account simply through imposing the system pressure as a pressure boundary condition. The present research offers a deeper insight into the interaction of sublimated vapor flow and vial internal geometry by performing a detailed CFD analysis of the flow field inside and in the vicinity of a vial with installed stopper. The main attention is devoted to the analysis of the corresponding vapor pressure conditions inside the vial and their influence on sublimation kinetics, which governs the process inside the lyophilizate and which is modeled by a dedicated 0D lyophilization model. The derived computational model is based on a coupled numerical solution of the heat and mass transfer inside the lyophilizate by means of a 0D vial lyophilisation model and the 3D fluid flow through the vial. Due to low system pressures, the slip flow regime is considered, leading to the need of imposing the velocity slip conditions at the vial walls. The coupled model results in terms of temperature at the lyophilizate bottom and mass flow rate are validated with the results of dedicated experiments on the laboratory scale lyophilizer and Schott R6 vials, with 20mm internal and 13 mm throat diameters, respectively. The computational study shows that the vial geometry, especially the installed stopper, alters the pressure field conditions inside the vial, which results in a decrease of numerically computed mass flow rate and an increase of computed sublimation front temperature. The effect is more pronounced in the case of lower system pressure settings (typically 5 – 10 Pa), and can result in up to 4.5% difference in the computed primary drying times and up to 2K higher resulting bottom temperatures compared to the results of 0D model without considering the influence of the vial geometry. The obtained results show that the coupled numerical model can be successfully used in studies of the impact of various vial forms as well as stoppers on the lyophilization kinetics in a vial.

Estimation of the state of matter in young impact craters on the Moon based on the orbital observations

Michael Shpekin[1*] and Ricardo Ferreyra[2]

[1] Kazan Federal University, 18 Kremlevskaya str Kazan Russia, MichaelS1@yandex.ru
[2] National University of Cordoba , Avda Velez Sarsfield 1611 Córdoba Argentina, Ricardo.Tomas.Ferreyra@unc.edu.ar

Key Words: *Lunar matter, Impact craters, Orbital observations, State of matter, Estimation of state, Crater structure, Forthcoming expeditions, Applied and fundamental aspects*

The report examines the results of a 3D-survey of the relief in young impact craters based on high-resolution images obtained from lunar orbits. The craters examined included: the Tsiolkovsky and Aitken craters on the far side of the Moon, the Tycho and Ina craters of the visible hemisphere, as well as the Orientale Mare in the marginal zone of the Moon. To build 3D-models, orbital images of the Soviet spacecrafts "Zond-6,-8" and the American spacecraft "Apollo-17" delivered to Earth, as well as images transmitted to Earth from the Lunar Reconnaissance Orbiter (LRO) were used.

The survey of the relief using 3D-models allows us to study the structure of craters from different sides at different angles of view at different scales. This approach, in addition to analyzing single images, opens up new possibilities. In particular, on a 3D-model, it is often possible to detect relief details that are either not visible in single images, or are not clearly visible enough. So, looking through the images from the “Apollo-17” spacecraft, made on different orbit revolutions at different positions of the Sun, which provided different illumination conditions, we found a small volcano on the floor of the Tsiolkovsky crater, surrounded by an oval-shaped depression of soil about 25 km in size [1], which no one had paid attention to before. Further study of the object we found allowed the authors of the work to make an assumption about the presence of a magma chamber under the bottom of the crater. Another example of this approach is associated with the Aitken crater. Comparing our 3D-models of the central peak of Aitken crater with ultra-high resolution images from the LRO, we found a glacier-like tongue crawling out directly from the southwestern slope of the central peak to the crater floor [2]. It was possible for the first time to examine its structure and find similarities with similar objects on Mars. The report provides a detailed analysis of all 5 the above-mentioned objects.

Forthcoming lunar expeditions, creation of lunar bases and mining of minerals presupposes a certain level of knowledge about the lunar surface itself. The state of the matter of lunar craters, the structure of the elements of the lunar relief and the lunar interior is of particular interest in this regard. The results obtained play an essential role in understanding the crater formation process itself, as well as for studying the physics of the extreme state of matter. It is also important to note that the energy of crater-forming events is so high that it is unlikely that it will ever be possible to reproduce it in terrestrial conditions.

Transport of logarithmic potentials versus process duration

Ricardo Tomás Ferreyra [1*]

[1] National University of Cordoba , Avda Velez Sársfield 1611 Córdoba Argentina,
Ricardo.Tomas.Ferreyra@unc.edu.ar

Key Words: *Transport*, *Dynamical Equilibrium, Logarithmic Potentials, Measurements*

Transport phenomena allow us the possibility of understanding and modeling many of the multi-scale dynamics problems of natural sciences and engineering. Particularly, in this work we transport logarithmic potentials such that its parameters are measured in order to match the dynamical balance in a context of a multiplicity of interacting forces where all can be derived from Bayesian theories in close connection with statistical meanings and actual applications. In this scenario, the Gamma function emerges lightly changed from its classical form and plays an important game allowing the time estimation of a process associated to many dynamical models. Although, the Gamma function is associated with a wide variety of applications related to natural numbers, solutions of variable coefficients differential equations, power series, integrals and much more issues in the literature for instance [1-6], this work focuses specifically on the estimation of time of duration in dynamic processes. These processes are possible in scientific experiments but also in the current life, the one people live day by day, at any scale, at any time, period or epoch. So then, three different situations are considered. First, we obtain a non-classical and not common property of the Laplace Transform, in the context of Transport equations and logarithmic potentials. Second, the Gamma function emerges as a balancing solution and it does in an apparently new generic form, so it is worthy to be presented. Third, a formulation for the duration time of a process is provided when we truly predict that the end of the process is reached, successfully. On the other way, some comments related to when we should not wait anymore the end of one process, are given. Hypothetically, this is because from the theoretical approach we should be able to know whether the end of the process will never come. Finally, some related facts are discussed.

Detailed simulations of nozzle-dependent primary atomization in coaxial atomizers

Fabian Fröde*, Temistocle Grenga and Heinz Pitsch

Institute for Combustion Technology, RWTH Aachen University, Templergraben 64 52056 Aachen,
f.froede@itv.rwth-aachen.de

Key Words: Coaxial Atomizer, Primary Atomization, Nozzle Internal Flow, Volume of Fluid

Coaxial atomizers are widely used in industrial spray applications, and it is well known that their high-speed gas flow features, determined by the nozzle geometry, are crucial for the breakup process [1]. As such nozzles often include complex geometry features like sharp edges, computational strategies for simulating primary atomization need to capture the details of the nozzle internal flow. This results in a challenging multiscale problem for computational strategies.
In this work, a simulation approach for detailed simulations of nozzle-dependent primary atomization for a coaxial atomizer is presented. To address the multiscale nature, a one-way coupling approach is used, which divides the entire simulation domain into a single-phase nozzle internal flow simulation domain and primary breakup simulation domain. Coupling between both domains is achieved by imposing the unsteady velocity field at the nozzle outlet plane as inlet conditions for the interface resolving primary breakup simulation. The nozzle internal flow is computed in a large-eddy simulation using the low-Mach solver of the in-house code CIAO. The interface resolving primary breakup simulation is computed as direct numerical simulation with a recently developed 2^{nd}-order conservative unsplit Volume of Fluid method [2], which is coupled to a sharp-interface flow solver [3].
The simulation approach is applied to the coaxial atomizer of the SpraySyn burner and an additional complex nozzle geometry that has been studied in the same context [4]. Both simulations share the same nominal non-dimensional parameters, which allows evaluating the impact of the nozzle geometry on primary breakup. The results show that the simulation approach can capture nozzle-dependent atomization, and the observed qualitative and quantitative results are discussed in the context of the nozzle internal flow features.

Dynamics and Modelling of Spin-affected Droplet Collision

Chengming He[1] and Peng Zhang[2*]

[1] Institute of Mechanics, Chinese Academy of Sciences, Beijing, China,
E-mail: chengming.he@imech.ac.cn
[2] Department of Mechanical Engineering, The Hong Kong Polytechnic University, Hong Kong,
E-mail: pengzhang.zhang@polyu.edu.hk

Key Words: *Droplet collision, Volume of Fluid method, spinning droplet, bouncing, separation*

Droplet collision is closely related to many spray processes in nature and industry, and it has been extensively studied and reviewed[1] in the literature. Modelling of droplet collision is significant for the Eulerian–Lagrangian spray simulation[2]. The Volume-of-Fluid (VOF) method[3] serves as an efficient analysis tools to study the physics and modelling of droplet collision [4, 5].

By far, almost all studies on droplet collision were focused on initially non-spinning droplets. However, in practical situations of dense sprays, the dispersed droplets usually have spinning motions and are highly likely to collide with each other. The spinning motion can be created either from the preceding off-center collisions (owing to the nonzero total angular momentum) or the non-axisymmetric breakup of impinging jets. Droplet spinning motion was neglected in the previous experimental studies probably because it is technically challenging to generate stable spinning droplet and quantitatively characterize the spin velocity. However, it is relatively easy to set up the spinning droplet in a VOF simulation.

In the present study, the significance of droplet spinning motion is numerically verified by quantitatively characterizing the trajectory of mass center and spinning speed of colliding droplets. Then, the relevant canonical phenomena, such as coalescence, bouncing, and separation between spinning droplets, are simulated. For droplet coalescence, a prominent discovery is that the spinning droplet can induce significant nonaxisymmetric flow features and substantially promote the mass interminglement of droplets. For droplet bouncing, a practical modelling of momentum recovery coefficient in determining the post-collision velocities is proposed based on the interchange between the orbital angular momentum and the spin angular momentum during droplet collision. For droplet separation, a unified model of droplet separation (reflexive and stretching separation) was established to analyse the effect of droplet spin chirality on boundary transition. These results enhance our understanding of the dynamics and modelling of droplet collision.

Key Words: *Electrospray, Ionic liquids, Ion emission, Molecular simulation*

Electric-field-driven ion emission from the free surface of a planar room-temperature ionic liquid (RTIL) film was studied by using molecular dynamics simulations. We calculated ion emission rate (j_e) as a function of the electric field normal to the RTIL/vacuum surface (E_n) and found that the logarithm of j_e over the charge density on the surface (σ) is proportional to $E_n^{1/2}$, in agreement with classical ion evaporation theories. The composition of emitted ions includes monomers and dimers. It was found that the monomer has to move across two barriers before emission. The fraction of dimers was found to depend on the external field and ion-ion interactions. We further performed replica exchange molecular dynamics simulations and identified different metastable states of the emitting ion near the liquid film. Our results showed that E_n and molecular details of ion/surface determine the rate and composition of ion emission from RTIL/vacuum surfaces. Fundamental insights revealed in this study form the basis to improve ion evaporation theories and performance of electrospray applications ranging from space propulsion to nanomanufacturing.

Experimental investigation on the spreading progress after droplets impacting on to a vertical vibrating plate at low frequency

Ming zhu[1], Yikai Li[1*] ,Ziming Yang[1], Chenghan Sun[1]

[1] School of Mechanical Engineering, Beijing Institute of Technology, China liyikai@bit.edu.cn

Key Words: *Drop impact, Vibration, Weber number, Spreading, Rim, Inner lamella*

The impingement of fuel droplets on the piston surface would greatly affect the combustion process and emission generation of direct injection diesel engines. In this paper, to mimic the interaction between the droplets and vibrating engine body, the dynamic behaviors of droplets impacting on a vertically vibrating plate were explored experimentally. The main target of this paper is the spreading process from the droplet attaching the plate to it reaching the maximum diameter. Several groups of impacting heights and plate vibrating frequencies were set to obtain a broad range of Weber numbers. The temporal evolutions of the inner lamella and rim after impact were traced by high-speed photography. The results show that the maximum spread time of the inner lamella maintains a relatively stable value, and the whole spreading time depend on the growth time of the rim. The fluctuation range of the growth time of the rim increases under increased vibrating frequency, while decreases with the increase of impacting height. The fluctuation range of the thickness of rim would be smaller with higher impacting height, and the relationship between growth time of rim and impact phase is sinusoidal at the same impacting height and frequency. The existence of air forces plays a key role in the development of the liquid layer. In addition, the maximum spread radius would be smaller for droplets with an impacting height of 15 cm, because the ring-shaped rim would receive more resistance from viscous forces and surface tension than fingers. Finally, an empirical formula based on Srivastava's model was built to accurately predict the maximum spread factor of droplets after impacting on the vibrating plate, in which the influence of the impact phase, vibration frequency and Weber number were incorporated.

Front-Tracking approaches for the modelling of breakup and coalescence

Paul Regnault[1*], Stéphane Vincent[1] and Eric Chénier[1]

[1] Gustave Eiffel University, Multiscale Modelling and Simulation Laboratory, MSME, UMR 8208 CNRS 5 bd Descartes, 77454 Marne-la-Vallée, France, paul.regnault@univ-eiffel.fr

Key Words: Two-phase flows, Front-Tracking, Breakup, Coalescence, Multi-scale

In this work two-phase flows are modelled by a multi-scale approach involving dedicated meshes, one for the interface, mobile and deformable, for the Front-Tracking [1] and called Lagrangian, and the other Eulerian and fixed for the conservation equations of mass and momentum.

These multi-scale models are difficult to achieve numerically because they require managing dynamically in time and space the mesh of the interface (made up of connected triangles). In exchange for this complexity, they offer an explicit description of the interface even in the presence of strong curvatures and a better control of topological changes (coalescence and breakup). The models and algorithms must run in parallel on distributed memory computers to conduct convergence studies, validate academic cases and then tackle more complex configurations.

In order to describe efficiently the thin features of the interface, we implemented an adaptive remeshing procedure with local surface reconstruction. Topological changes are handled geometrically. The volume fraction is calculated with a geometric method: the Ray-Casting with local refinement.

Experimental and numerical configurations from the literature will be used to verify the models and numerical methods. Among them, we can mention the collision of two drops [2].

Fully Compressible Numerical Simulations of Primary Breakup Processes in Dual Fuel Internal Combustion Engines

Yu Jiao*, Steffen J. Schmidt, Nikolaus A. Adams

Technische Universität München, Boltzmannstr. 15, Garching bei München 85748, Germany,
yu.jiao@tum.de

Key Words: *Fully compressible flow; implicit large eddy simulation; duel fuel internal combustion engine; primary breakup; diffuse interface method; continuum surface force model*

Carbon neutrality is imminent and Dual-fuel Internal Combustion Engines (DFICE) using fuel mixtures have the potential to meet stringent emissions regulations. However, there are only few high-resolution studies on the primary breakup process under DFICE conditions. In this work, we develop a numerical algorithm capable of handling DFICE primary break-up and compressibility of all involved phases including surface tension effects. An Implicit Large Eddy Simulation (ILES) approach for compact stencils proposed by Egerer et al. [1] is used, which is based on the Adaptive Local Deconvolution Method (ALDM) by Adams et al. [2] and Hickel et al. [3]. ILES merges sub-grid turbulence with the numerical truncation properties of the scheme. We apply a diffuse interface method (DIM) together with an improved barotropic multi-component fluid model, and a continuum surface force (CSF) model [4] with algebraic interface sharpening treatment, which have recently implemented into our code CATUM. Results from the "recovery from square bubble" case and further standard cases are in very good agreement with reference solutions. A discontinuity sensor switches the cell-face value reconstruction procedure between an upwind-biased and a centered reconstruction scheme, along with proper limiters. Time integration is performed by an explicit, four-stage Runge-Kutta method.

We investigate two different n-dodecane mass flow rates for the "Spray A-210675 model" with an initial pressure of 6MPa and a mixture of 80% Nitrogen and 20% Methane in the chamber. The computational domain is 10D*10D*20D. The computational grid with a smallest mesh size of 0.04μm is applied and the obtained results are analyzed in detail. At high mass flow rate, in-nozzle instabilities and Kelvin-Helmholtz instabilities dominate the primary breakup independent of the surface tension. The disturbance generated by the head of the mushroom jet transmits through the gas mixture to the upstream liquid area and causes the instability to grow in the direction of the liquid core. In case of a low mass flow rate, Rayleigh instabilities become relevant. The results improve our knowledge on how these instabilities develop and contribute into DFICE atomization, providing data on effective designs of DFICE components including Fuel Injection Equipment (FIE) and providing reference data for DFICE primary breakup processes, as detailed experimental measurements and visualizations are insufficiently available.

Influence of Density and Viscosity on Deformation, Breakage and Coalescence of Bubbles in Turbulence

Francesca Mangani[1*], Giovanni Soligo[2], Alessio Roccon[1,3] and Alfredo Soldati[1,3]

[1] Vienna University of Technology, 1060 Vienna, Austria, francesca.mangani@tuwien.ac.at, alfredo.soldati@tuwien.ac.at, https://www.fluid.tuwien.ac.at

Key Words: Bubbles, Bubbles Deformation, Breakage and Coalescence, Density Ratio, Viscosity Ratio

We investigate numerically the effect of density and viscosity differences on a swarm of large and deformable bubbles dispersed in a turbulent channel flow. For a given shear Reynolds number, $Re_\tau = 300$, and a constant bubble volume fraction, $\Phi \simeq 5.4\%$, we perform a campaign of direct numerical simulations (DNS) of turbulence coupled with a phase-field method (PFM) accounting for interfacial phenomena. For each simulation, we vary the Weber number (We, ratio of inertial to surface tension forces), the density ratio (ρ_r, ratio of bubble density to carrier flow density) and the viscosity ratio (η_r, ratio of bubble viscosity to carrier flow viscosity). Specifically, we consider two Weber numbers, $We = 1.50$ and $We = 3.00$, four density ratios, from $\rho_r = 1$ down to $\rho_r = 0.001$ and five viscosity ratios from $\eta_r = 0.01$ up to $\eta_r = 100$. Our results show that density differences have a negligible effect on breakage and coalescence phenomena, while a much stronger effect is observed when changing the viscosity of the two phases. Increasing the bubble viscosity with respect to the carrier fluid viscosity damps turbulence fluctuations, makes the bubble more rigid and strongly prevents large deformations, thus reducing the number of breakage events. Local deformations of the interface, on the contrary, depend on both density and viscosity ratios: as the bubble density is increased, a larger number of small-scale deformations, small dimples and bumps, appear at the interface of the bubble. The opposite effect is observed for increasing bubble viscosities: the interface of the bubbles become smoother. We report that these effects are mostly visible for larger Weber numbers, where surface forces are weaker. Finally, we characterize the flow inside the bubbles; as the bubble density is increased, we observe, as expected, an increase in the turbulent kinetic energy (TKE) inside the bubble, while as the bubble viscosity is increased, we observe a mild reduction of the TKE inside the bubble and a strong suppression of turbulence.

Key Words: Two-phase flows, Volume of Fluid, Breakup, Topology changes

A well-known drawback of the Volume-of-Fluid (VOF) method is that the breakup of thin liquid films or filaments is mainly caused by numerical aspects rather than by physical ones. The rupture of thin films occurs when their thickness reaches the order of the grid size and by refining the grid the breakup events are delayed. When thin filaments rupture, many droplets are generated due to the mass conserving properties of VOF. Thus, the numerical character of the breakup does not allow to obtain the desired convergence of the droplet size distribution under grid refinement. In this work, we present a novel algorithm to detect and perforate thin structures. First, thin films or ligaments are identified by taking quadratic moments of the VOF indicator function. Then, the breakup is induced by making holes in the films before their thickness reaches the grid size. We show that the method improves the convergence upon grid refinement of the droplets size distribution, as well as of enstrophy.

Modeling of Two-Phase Vapor-Liquid Spray with Flash Boiling

Key Words: *Flash Boiling Spray, Phase Change, Speed of sound, Internal Combustion Engine*

ABSTRACT

In internal combustion engines such as diesel and gasoline engines, Flash boiling phenomenon of fuel spray has a significant effect on the liquid atomization process and the mixture formation process. There are many experimental reports on the phase change process in spray formation with flash boiling, however, the phenomena remains unclear and quantitative prediction of the phenomena is difficult. Flash boiling is a phase change process from liquid to vapor that occurs when the pressure drops below the saturated vapor pressure of the liquid caused by a sudden pressure change. In the nozzle, the rapid phase change is due to the heterogeneous nucleation and bubble growth process caused by the air in the fuel liquid. The phase change from liquid to vapor requires energy, which is due to the enthalpy of the liquid itself, and the fuel flow in the nozzle seems to involve a temperature drop in addition to the phase change. The speed of sound for liquid is different from the speed of sound for vapor, and the speed of sound for a mixture of vapor and droplet is significantly lower than the speed of sound for both. Therefore, even if the jet velocity is below the speed of sound condition of the liquid, flash boiling spray is underexpansion state in the near-nozzle region, as seen in supersonic jets. In this study, the mass conservation and energy equations of the flash boiling spray were analyzed, and the phase change of the fuel spray at the nozzle exit was quantitatively predicted. In addition, the underexpansion state of the flash boiling spray was analyzed by calculating the speed of sound in the mixture of vapor and droplet from the results of the phase change analysis.

Key Words: *Phase field model, Machine learning, Drop impact, Air bubble*

One of the fundamental requirements of painting and coating technologies is the controlled and homogeneous deposition onto a solid surface. However, an uncontrolled air bubble entrapment under the deposited liquid layer could deteriorate the quality and durability of a film, and in some cases may cause significant damage. It is challenging to directly monitor the flow details during painting and coating under practical operation conditions. However, simple photographs of a deposited product could shed light on a potential failure, thus allowing to foresee future painting/coating degradation. Predicting such an undesirable air bubble entrapment in advance under real conditions is an imperative step in ensuring high quality painting/coating films. In this contribution, we present a combined multi-physics and deep-learning approach validated by our own experimental measurements to detect air bubble formation during drop impact onto solid parafilm surfaces.

The multi-physics modeling approach is based on the phase-field modeling (PFM) and the Navier-Stokes equations. The PFM is validated against our own experimental measurements in terms of the drop's maximum spreading and rebound height. Then, several cases with varying Weber and Froude numbers are considered to study air entrapment. The PFM results reveal that air may be entrapped under water drops during the initial deposition, as well as during its retraction after maximum spreading. The volume of the entrapped air bubble varies during both processes, significantly affecting drop spreading and rebound height. Furthermore, the simulation results reveal a significant pressure build-up in the entrapped air (up to an order of magnitude higher than that in the surrounding water phase), which has a detrimental effect on drop deposition. Based on our predictions and experimental results a map in the Weber vs. the Froude number plane describing the air entrapment domain is established and discussed.

Using the experimental and multi-physics modeling results, we have further developed a deep-learning approach based upon the VGG16 convolutional neural network (CNN) to predict air bubble entrapment. Hyperparameter optimization is performed to improve the accuracy of the model. It was observed that the CNN, trained based on the experimental images, reveals better predicting capabilities than the one trained based on the simulated images. In addition, for both data sets the prediction is more accurate when training the model using side views rather than the top views. Thus, the present combined deep-learning modeling approach and experimental measurements allow for a fast and precise prediction of air bubble entrapment during drop impact onto solid surfaces.

Novel Spray Breakup Model with Multi-hole Nozzle in Port Fuel Injection SI Engine

Kanako Nishiura[1*], Dai Matsuda[1], Eriko Matsumura[1] and Jiro Senda[1]

[1] Doshisha University,
1-3 Tatara Miyakodani, Kyotanabe-shi, Kyoto, 610-0394, Japan

Key Words: *Port Fuel Injection SI Engine, Fuel Spray Atomization, Breakup Model*

Recently, the electrification of automotive powertrains has been accelerating to achieve a decarbonized society. Meanwhile, it is important to improve the efficiency and low pollution of internal combustion engines, considering that Well to Wheel emissions of CO_2 are lower than those of electric vehicles, and that internal combustion engines are expected to account for 80% of vehicle sales in 2050 [1][2].

Numerical simulations are widely used in the research and development of automotive engines. Spray breakup models in the numerical simulation are important because spray atomization has a significant influence on the subsequent wall impingement behavior and mixture formation. Therefore, the purpose of this study is to investigate the spray atomization process and predict the breakup process in multi-hole nozzle spray for port fuel injection SI engine.

In this study, novel spray breakup model for gasoline spray injected from plate type multi-hole nozzle is developed [3]. This model is considered the liquid sheet breakup based on the phenomenological sheet breakup theory [4]. In this report, this novel breakup model is applied to numerical simulation of fuel spray and predict the spray formation. The validation of the model was carried out by comparing the spatial distribution and the droplet diameter distribution of the fuel spray with experimental results.

ABSTRACT

In fuel injection process in diesel engines, the internal nozzle flow has a significant effect on the spray characteristics such as droplet diameter distribution and concentration distribution. Numerical analysis of diesel sprays, the calculation of spray behavior is often carried out without calculating the flow in the nozzle, and the effect of the flow in the nozzle needs to be analyzed as an injection model to predict the spray injection near the nozzle hole. However, almost injection models ignore the unsteady state flow in the nozzle and require the input value of spray angle measured value in the quasi-steady state. Therefore, it is necessary to develop an injection model that can accurately predict the spray injection behavior with internal nozzle flow. The flow in the nozzle has been analyzed experimentally by visualizing the inside of the nozzle and numerically by using commercially fluid simulation code. The behavior of the spray near the nozzle hole has also been investigated by taking magnified images of the spray near the hole. These results indicate that the spray angle increases in the initial stage of the spray due to the effect of swirling flow and string cavitation in the nozzle. In addition, the X-ray spray analysis indicates that a hollow cone spray is formed when the spray angle increases in the initial stage of injection. In this study, a new spray injection model is developed to predict the spray injection behavior near the nozzle hole and the hollow cone spray in the initial stage of injection by considering the flow in the nozzle with minisac type. In the initial stage of injection, the seat throttle mainly affects the injection rate, and after that, the nozzle hole throttle affects the injection rate. Therefore, our one-dimensional model considerd the seat and nozzle hole throttling. By using this model, the pressure in the sac and the angular velocity of the swirling flow in the sac were estimated, and the injection velocity and injection angle were calculated. The initial droplet diameter was calculated by considering the liquid film thickness in the case of hollow cone sprays, and the diameter of the nozzle hole and the contraction flow in the case of solid sprays. The timing of hollow cone sprays was estimated by analyzing the results of sheet scattered light photography of diesel sprays. In addition, the model was applied to KIVA3V, one of the most popular codes for engine in-cylinder analysis, to analyze the diesel spray behavior. The results of the analysis using KIVA3V were compared with the results of diesel spray visualization using sheet scattered light photography, and the accuracy of the model was evaluated.

Key Words: *Atomization, Thin layers, Manifold death, Basilisk*

The atomization of thin liquid layers in closed channels is a process closely related to aerosols generation in several scenarios, such as the respiratory system during coughing and sneezing. This problem has regained relevance lately due to its relation with Covid-19 transmission [1].

In this work, we study the deformation and atomization of a thin liquid layer subject to a rapid air stream in a closed rectangular channel. We run numerical simulations of this setup using the Volume-of-Fluid (VOF) method with octree Adaptive Mesh Refinement (AMR) to capture local small-scale phenomena related to turbulence and breakup. Regarding the latter, we control the impact of grid resolution by applying breakup control by means of a Manifold Death algorithm [2].

We consider different flow regimes, defined by the gas velocity and the liquid viscosity. We compare the droplet-size distribution of these cases with data from experiments with an analogous setup and with measurements taken from real cough experiments. The atomization mechanisms observed in this problem are similar to those of multiphase mixing layer experiments and simulations, resulting in Log-Normal distributions replicated in the experiments. We also report the droplet velocity distribution, analyzing the acceleration of the drops at early atomization stages.

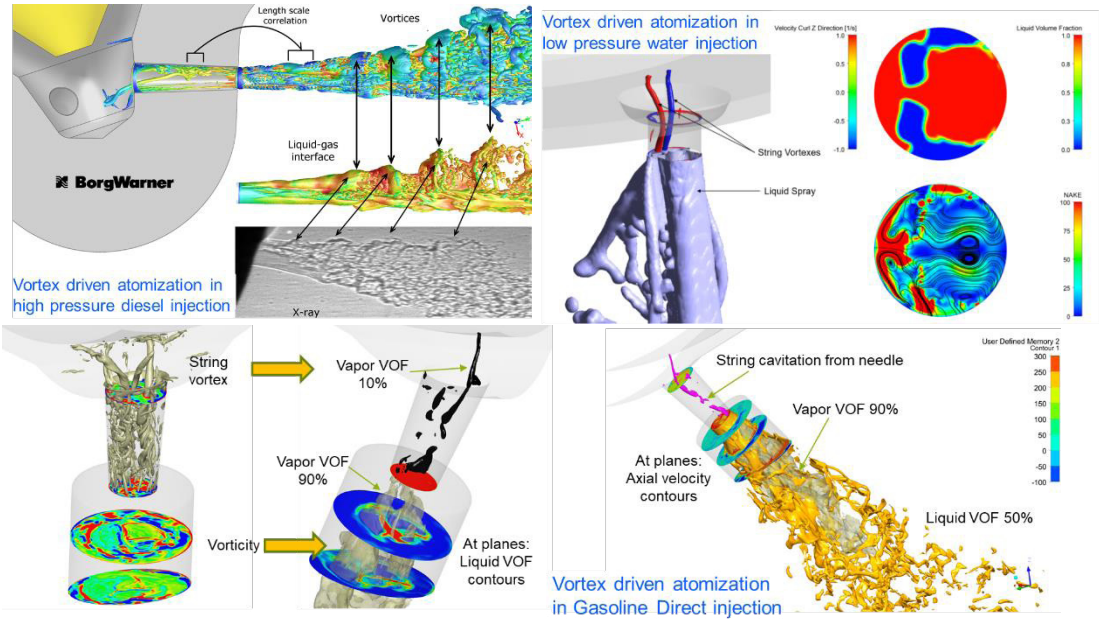
Vortex driven liquid fragmentation in pressurized liquid injection from multi-hole nozzles

Junmei Shi*, Ramesh Venkatasubramanian, Eduardo Gomez Santos, Pablo Aguado Lopez, Guy Hoffmann

BorgWarner Luxembourg Automotive Systems S.A., Avenue de Luxembourg,
jushi@borgwarner.com,
https://www.borgwarner.com/technologies/fuel-injection-systems

Key Words: *High Pressure Fuel Injection, Low Pressure Water Injection, SCR, Level Set, VOF, LES, Large Scale Vortices, Atomization, Spray Correlation*

Multi-hole pressure atomizers find wide applications in internal combustion engine systems, including high pressure diesel fuel injection (up to 3000 bar), gasoline fuel direct injection (up to 500+ bar), low pressure gasoline port fuel (4-6 bar) or water injection (5-10 bar), and AdBlue injection in the exhaust gas aftertreatment device (5- 10 bar). For all these atomizers, the injection nozzle design has a crucial influence on the engine combustion and exhaust emission performance. Knowledge driven atomizer design requires a understanding of fundamental physics behind the spray formation phenomenon and a continuous search of innovative atomization mechanism. This paper is to present a summary of our research progress on this topic over the past 9 years using Scale-Resolve-Simulation and high resolution micro-visualizations. Although these different applications operate in very different atomization regimes according to established knowledge in literature, they have one thing in common, namely the vortex dynamics in the nozzle flow triggers the liquid jet deformation and ligament formation as an important mechanism driving the near nozzle spray development. Examples will be presented to demonstrate the link between vortex structures, dynamics and the spray structures in the primary breakup regime for the above mentioned different atomizers (e.g. see Figures below). The influence of nozzle design on the vortex flow and spray will also discussed. On the basis of Scale-Resolve Simulations, correlations have been developed between spray penetration, droplet size and nozzle geometry or nozzle flow using URANS simulations and tests.



A Preliminary Numerical Simulation for Flows through Oblique Detonation Engines based on Less Dissipative Schemes and Machine Learning

YI-Jhen Wu , Chi-Heng Ting and Yang-Yao Niu

Department of Aerospace Engineering, Tamkang University,
New Taipei City, Taiwan, ROC

Key Words: Oblique Detonation Engines, Detonation Wave, Shock wave, Machine Learning, Detonation Engine.

In this study, an interfacial variable interpolation of ATM (Average of THINC-EM and MUSCL), a hybrid method with the MUSCL interpolation method with the THINC-EM schemes, is proposed to achieve the less numerical dissipative solutions of smooth profile and discontinuities. The main idea of the hybrid approach of ATM is to reconstruct the right and left cell interfacial data by the weighting function of pressure or primitive variable gradients. To determine the optimal weighting parameter settings in the ATM, the Q-learning Q-table method in reinforcement learning is performed on the benchmark test case of the two colliding waves. In addition, the ATM method is extended to solve the stiffened Euler equations to achieve accurate simulation of the detonation waves, shock waves, and the expansion fans for the detonation flow problems. The further performance analysis of the oblique denotation engines will be performed.

A Time Consistent Method by Preconditioning of the Diffusion Term for Unsteady Gas-Liquid Two-Phase Flows

Tianmu Zhao[1*] and Byeong Rog Shin[2]

[1] University of Miyazaki, Miyazaki 889-2192, z370701@student.miyazaki-u.ac.jp
[2] University of Miyazaki, Miyazaki 889-2192, brshin@cc.miyazaki-u.ac.jp

Key Words: *Gas-Liquid Two-Phase Flow, Time Consistent Preconditioning, Roe Upwind Scheme, Riemann Problem*

Gas-liquid multiphase flow often happens in hydro machines. In cavitating flow as an example of typical gas-liquid two-phase flow, when its bubble occurs and collapses near body surfaces, it causes the noise, vibration, and damage to the hydro devices. In the sense of reducing these unfavorable effects, in order to clarify and understand the behavior of cavitating flow, several efforts to propose cavitating flow model and numerical method have been made [1,2]. However, due to its strong and complicated unsteady flow phenomenon such as phase changes and the co-existence of compressible and incompressible flow nature, the mathematical model and numerical method is not established yet. Recently, Shin et al. [3] has proposed a preconditioned dual time-stepping method based on a homogenous cavitation model to treat cavitation problems. This method has solved many gas-liquid two phase flow problems associated with wide range of speeds of sound, but relatively it takes time to get the unsteady solution.

In this study, a time consistent preconditioning method for gas-liquid multiphase flows is proposed. A finite-difference 4th-order Runge-Kutta method and a Roe-type flux splitting method with the 3th-order MUSCL TVD scheme are employed. The artificial viscous terms in the flux splitting are modified by using the preconditioning matrix to enhance the numerical stability and accuracy of unsteady computation for compressible and incompressible flow with arbitrary Mach numbers. By using the concept of the homogeneous equilibrium model, gas-liquid two-phase flow is modeled to a pseudo single-phase flow, taking into account the compressibility of the mixed medium. From the above, the present method permits simple treatment of the whole gas-liquid two-phase flow including wave propagation, large density changes, and compressible and incompressible flow characteristics.

As numerical examples, Riemann problems of gas-liquid two-phase shock tube problem were applied to investigate the validity of the present method. From the computation, it showed a good prediction of pressure, density, velocity and void fraction distributions in comparison with Roe's approximate solutions, and quite well simulates unsteady phenomena of the shock wave including the propagation of both compression and expansion waves. The reliability and applicability of the present method to arbitrary Mach number flow problems were confirmed as consequence. Detailed observations of shock and expansion wave behaviors in the gas-liquid media and comparisons of predicted results with exact solutions are provided and discussed.

Key Words: Two-fluid model, high speed flow, Interface-sharpening

This paper present a single-pressure-field two-fluid model with finite volume discretization to solve the motion of compressible multiphase flow. To resolve both smooth and discontinuous profiles of flow quantities, we proposed a generalized sharpening technique that combines the conventional monotonic upstream scheme for conservation law (MUSCL) and tangent of hyperbola interface capturing (THINC) schemes. A slope-ratio parameter is devised to determine the proportion of values obtained by MUSCL and THINC automatically. Fluxes across cell faces are evaluated by the so called "hybrid AUSMD-type algorithm", where the mass flux and pressure on cell faces are calculated using primitive variable Riemann solver (PVRS). The accuracy and robustness of the proposed scheme are validated by a series of high-speed multiphase flows, where complex wave structures are involved. Unlike the existing scheme (e.g., MUSCL), which usually suffers from numerical diffusion, the proposed scheme significantly sharpens the fluid interfaces and captures more details of wave patterns including shock waves and rarefaction fans. Moreover, for the problem in which surface tension is important, the proposed method shows good capability in increasing the accuracy of curvature estimation. Finally, simulations of a three-dimensional example of the liquid jet crossflow are conducted. The proposed scheme shows more details of the fluid interface, including the interfacial instabilities on the windward side of the liquid jet and droplet formation due to the breakup phenomenon in the downstream of the crossflow, than the existing schemes

Key Words: General pressure equation, phase field method, two-phase flow

The general pressure equation-based method[1] is fully explicit, and the method does not require either solving the pressure Poisson equation nor executing sub-iteration for incompressible flow simulation. In this work, general pressure equation based method is used to conduct numerical simulations of two phase flows using phase field method[2] coupled with level set method[3]. Several test problems are used to demonstrate the capability of the current approach. The simulations are conducted on GPU cluster using MPI and CUDA[1, 4].

Folding Instabilities in Viscoplastic Sheets

Anselmo Pereira, Romain Castellani*, Arthur Hochedez, Louis Simon, Elie Hachem and Rudy Valette

MINES Paris, PSL University, Centre de mise en forme des matériaux (CEMEF),
CNRS UMR 7635, CS 10207 rue Claude Daunesse 06904 Sophia Antipolis Cedex, France,
romain.castellani@minesparis.psl.eu

Key Words: *viscoplastic fluids, yield stress, folding instabilities, rheology*

In this work, we investigate viscoplastic effects on the development of folding instabilities in non-Newtonian viscous sheets of fluid which viscosity is given by a Herschel-Bulkley constitutive equation. Such instabilities are trigged by compression stresses acting on viscous sheets that comes out of a channel at a very small initial velocity, fall, and then hit a solid surface or a fluid substrate. Our study is conducted through a mixed approach combining direct numerical simulations, energy budget analyses, scaling laws, and experiments.

The numerical results are based on an adaptive variational multi-scale method for multiphase flows, while Carpobol gel, ketchup and mayonnaise sheets are used for the lab experiments. Three folding regimes are observed: (1) the viscous regime; (2) the plasto-gravitational; and (3) the visco-gravitational one. Interestingly, only the second and the third mentioned regime are affected by non-Newtonian manifestations within the material. In short, when gravity is balanced by viscoplastic forces along the non-Newtonian viscous sheet, both the folding amplitude and the folding frequency are given by a Herschel-Bulkley function of the sheet slenderness, the Galileo number (the ratio of the gravitational stress to the viscous one), the Bingham number (the ratio of the yield-stress and the gravitational one) and the flow behaviour index of the constitutive law. Highly plastic materials develop large amplitude (and low frequency) instabilities, which, in contrast, tend to be suppressed by shear thinning effects, and eventually cease. Lastly, non-Newtonian effects on folding onset/cessation are also carefully explored. As a result, non-Newtonian folding onset and cessation criteria are presented.

Key Words: kinetic transport, mathematical modeling, fluid dynamics, partial differential equations

While the kinetic theory of monatomic gases is complete, modelling the kinetic transport of polyatomic gases remains challenging. This is mostly due to the much more complicated particle interaction which is modeled as simplified relaxation to equilibrium in most kinetic equations nowadays, e.g., in [3].

Based on a continuous internal energy state variable, we propose an explicit, fully non-linear Boltzmann collision operator for the evolution of distribution function describing a polyatomic gas with constant heat capacity [1]. The particle interaction is a polyatomic generalization of the variable hard sphere model, used in a recent rigorous mathematical analysis [2], and includes frozen collisions. The model is consistent with the monatomic case and allows easy evaluations for moment equations and the Chapman-Enskog expansion. Using a specifically tailored computer algebra code, which is publicly shared, we can explicitly compute nonlinear production terms for macroscopic systems of moments. The range of Prandtl number values recovers the Eucken formula for a specific choice of parameters. The new collision model allows on the one side to study differential cross sections and how the dependencies on relative velocity and internal energies of the polyatomic particles influences macroscopic fluid properties.

On the other side moment equations as in [3] can be derived with explicit production terms obtained from the new collision operator. We will discuss preliminary results from the polyatomic hierarchical moment cascade for heat conduction in the spirit of [4].

Key Words: Fokker-Planck-Landau, Type Equations; Boltzmann Equation; Numerical Schemes; Conservative Spectral Methods; Error Estimates; Numerical Analysis

Error estimates are rigorously derived for a semi-discrete version of a conservative spectral method [1,2] for approximating the space-homogeneous Fokker-Planck-Landau (FPL) equation modeling a probability density function associated to hard potentials [1]. The analysis, inspired by the work in [4], consists in showing properties of the semi-discrete scheme is consistent, conservative, it has a unique semi discrete solution with bounded moments depending on the initial data and the computational domain, and local time stability converging to the approximating stationary state given by the global Maxwellian probability density distribution. In addition, the derivatives of such solution, up to any order, also remain bounded in Sobolev spaces for three dimensional local velocities and globally in time. The estimates depend on the initial model data and the computational domain, as expected to be for kinetic collisional models.

These estimates, combined with control of the spectral projection, are enough to obtain error estimates to the analytical solution and convergence to equilibrium states. It is noted that this is the first time that an error estimate has been produced for any numerical method which approximates FPL equations associated to any range of potentials. Simulations of the space dependent and homogeneous showing the accurate decay to equilibrium for hard potentials and Coulomb interactions will be presented.

Extending the BGK model: velocity dependent collision frequency and quantum description

Marlies Pirner[1*]

[1] University of Wuerzburg, Emil-Fischer-Str. 40, marlies.pirner@mathematik.uni-wuerzburg.de, https://www.mathematik.uni-wuerzburg.de/en/fluidmechanics/team/marlies-pirner/

Key Words: BGK approximation, velocity-dependent collision frequency, entropy minimization

The fundamental model I am considering is the so called Bathnagar-Gross-Krook (BGK) equation:

$$\partial_t f + v\nabla_x \cdot f = \nu(M(f) - f)$$

where f is the distribution function of the gas, $M(f)$ the equilibrium distribution (in the classical case a Maxwell distribution) and ν describes the collision frequency. The BGK equation is an approximation of the Boltzmann equation which has the same main properties as Boltzmann (conservation of properties, H-Theorem and the same shape of the equilibrium) and is much more efficient in numerical simulations. Therefore, in many applications, this approximation is used. However, the standard BGK equation is too simple in real applications. Therefore a recent open question is if it is possible to equip this approximation with more physics to describe more complex phenomena but still try to keep the numerical efficiency.

In this talk, I will focus on including a velocity dependency into the collision frequency and quantum effects. In both cases the Maxwell distribution has to be exchanged by a different function which leads to difficulties in the proof of the conservation properties and the H-Theorem.

Finally, I will give an outlook for extending this strategy to cover a large class of BGK models including for example the quantum BGK model with velocity dependent collision frequency, the relativistic BGK model with velocity dependent collision frequency, BGK models for gas mixtures and BGK models for polyatomic molecules.

This is joint work with S. Yun, G. Bae, (Sungkyunkwan University), J. Haack (Los Alamos National Laboratory), C. Hauck (Oak Ridge National Laboratory) and C. Klingenberg, S. Warnecke

Numerical Analysis of a Slow Rarefied Gas Flow past a Circular Disk

Takuma Tomita[1*], Satoshi Taguchi[2] and Tetsuro Tsuji[3]

[1] Kyoto University, Kyoto 606-8501, Japan, tomita.takuma.83s@st.kyoto-u.ac.jp

[3]Kyoto University, Kyoto 606-8501, Japan, tsuji.tetsuro.7x@kyoto-u.ac.jp

Key Words: Rarefied Gas, Non-Continuum Flows, Method of Characteristics

The slow uniform flow past an object is one of the fundamental problems in rarefied gas dynamics and plays a vital role in MEMS and aerosol transport. In the case in which the obstacle is a spherical body, a hybrid scheme for the Boltzmann equation, combining the finite difference method and the method of characteristics, was successfully applied, and detailed flow structures were clarified (e.g., [1]). On the other hand, the analysis of the flow past a three-dimensional object with a sharp edge, such as a disk, is much less developed. In this case, the high dimensionality and the complex structure of the velocity distribution function (VDF) make the hybrid method impossible to apply in practice.

In this study, we consider a uniform flow of a rarefied gas past a circular disk. More precisely, we investigate the steady behavior of the gas around the disk based on the Bhatnagar–Gross–Krook (BGK) model of the Boltzmann equation and the diffuse reflection boundary condition under the linearization. Our strategy is to solve an integral equation for an unknown function (VDF) derived by applying the method of characteristics. At first glance, this approach seems inefficient as compared to the finite difference method. However, it provides more flexibility in generating the mesh for numerical integration, which is important for capturing the discontinuity in the VDF, as demonstrated in moving boundary problems [2] and time-dependent problems [3].

The numerical solutions are obtained for various values of the Knudsen number, i.e., the ratio between the mean free path of the gas molecules at the reference equilibrium state and the radius of the disk. The details of the macroscopic profiles and the precise value of the drag will be presented in the talk. The present study shows that the numerical analysis based on the method of characteristics is now feasible for three-dimensional external flow problems with sharp edges with reasonable computational resources.

On scientific machine learning of kinetic theory and fluid dynamics

Tianbai Xiao[1], Martin Frank

Karlsruhe Institute of Technology, Karlsruhe 76131, Germany

In this talk, I will introduce the momentum built by machine learning methods in computational sciences. Specific attention will be paid on the usage of deep neural networks as building blocks in a numerical method to solve the Boltzmann-type kinetic equations. This is a particularly interesting topic since the high-dimensional integro-differential equation possesses an intricate structure that a numerical method needs to preserve. As universal function approximator, artificial neural networks might be beneficial but cannot be used out-of-the-box. The ongoing project is dedicated to touches upon the applications point of view of deep learning with a focus on interpretability and robustness, and on the mathematical methodologies point of view to solve partial differential equations. The following figures show the preliminary work on this research topic.

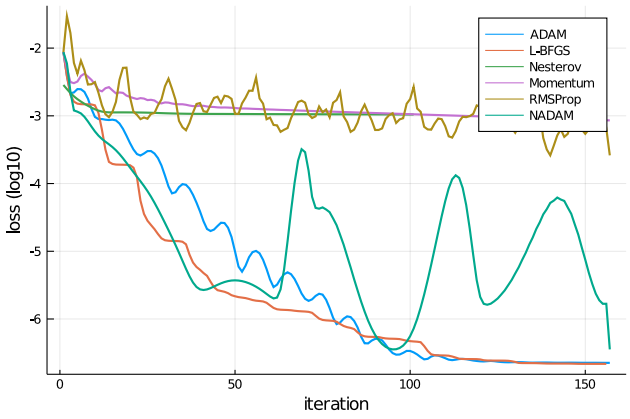

Figure 1: Iterations of loss with different optimizers.

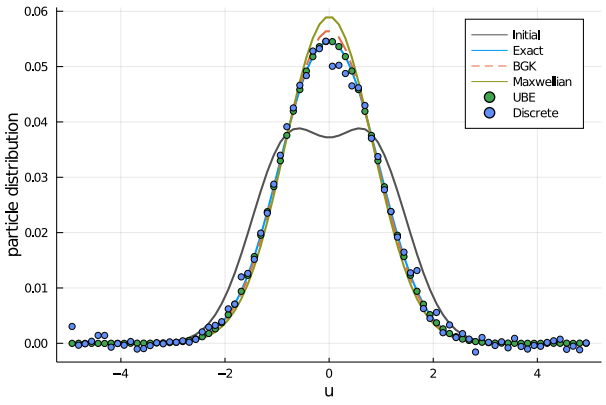

Figure 2: relaxation of non-equilibrium particle distribution.

On the kinetic model for a polyatomic gas: the Cauchy problem and moment equations

M. Pavić-Čolić
University of Novi Sad, Serbia & RWTH Aachen University, Germany

This talk focuses on the Boltzmann equation that models a polyatomic gas by introducing one additional continuous variable, referred to as microscopic internal energy [1, 2]. We will discuss the existence and uniqueness theory in the space homogeneous setting for the full non-linear case, under an extended Grad assumption on transition probability rates, that comprises hard potentials for both the relative speed and internal energy with the rate in the interval (0, 2], which is multiplied by an integrable angular part and integrable partition functions [3].

The Cauchy problem is resolved by means of an abstract ODE theory in Banach spaces, for an initial data with finite and strictly positive gas mass and energy, finite momentum, and additionally finite $k*$ polynomial moment, with $k*$ depending on the rate of the transition probability and the structure of a polyatomic molecule or its internal degrees of freedom. Moreover, we will prove that polynomial and exponential moments associated to the solution are both generated and propagated.

Based on this kinetic model, we will build moment equations. The transition probability rate proposed in [3] is shown to provide an accurate macroscopic theory and to recover physical properties such as the Eucken formula for the Prandtl number and experimentally observed viscosity dependence upon temperature [4–6].

[3] Oden Institute for Computational Engineering & Science,
The University of Texas at Austin, TX 78712 U.S.A., gamba@math.utexas.edu

Key Words: Quasilinear Theory, Mean Field Theory, Finite Element Method

Quasi-linear diffusion of magnetized fast electrons in momentum space results from stimulated emission and absorption of waves packets via wave-particle resonances. Such model consists in solving the dynamics of a system of relativistic kinetic diffusion processes described by the balance equations for electron probability density functions (electron pdf) coupled to the time dynamics waves (quasi-particles) in a quantum process of their resonant interaction. Such description results in a Mean Field model where diffusion coefficients are determined by the local spectral energy density of excited waves whose perturbations depend on flux averages of the electron pdf, introduced in [1], [2], [3].

We will discuss the model and a mean field iteration scheme that simulates the dynamics of the space average model, where the energy spectrum of the excited wave time dynamics is calculated with a coefficient that depends on the electron pdf flux at a previous time step; while the time dynamics of the quasilinear model for the electron pdf is calculated by the spectral average of the quasi-particle wave under a classical resonant condition where the plasma wave frequencies couples the spectral energy to the momentum variable of the electron pdf. Recent numerical simulations will be presented showing a strong hot tail anisotropy formation and stabilization for the iteration in the relativistic 3 dimensional cylindrical coordinates model.

Exterior calculus is a generalization of vector calculus to manifolds of arbitrary dimension. Discrete exterior calculus (DEC) [1] is the discrete version of exterior calculus. In DEC, physical fields are discretely expressed as *k*-forms representing the integration of the physical quantity on k-dimensional primal/dual mesh objects. DEC ensures that vector calculus properties are discretely satisfied. In addition to preserving the mathematical properties it allows for conservation of secondary quantities, such as kinetic energy and vorticity for an inviscid flow [2]. DEC is coordinate independent, and convenient for investigating flows over curved surfaces.

We present a framework for computing flows on surfaces based on a DEC discretization of Navier-Stokes (N-S) equations on simplicial meshes. The framework incorporates rotational and primitive formulations of the NS equations and allows for different time integration methods including those which feature energy conservation [3]. Other features of the framework consist of the inclusion of the Coriolis force term to investigate flows on rotating surfaces, and phase-field based interface tracking methods for multiphase flows. Moreover, we have enhanced our DEC framework to build hybrid DEC-FD and DEC-FFT discretizations which are useful for the investigation of convection in spherical shells and aerodynamic flows, respectively. The method is second order accurate on structured triangular meshes, and first order on otherwise unstructured meshes. It demonstrates the conservation of inviscid invariants such as kinetic energy and enstrophy over an extended period of time [4].

We present simulation results for a variety of physical configurations including the flow past a circular cylinder and airfoils, multiphase flows, vortex dominated flows on surfaces with and without rotation, and convection in spherical shells.

Key Words: *Large eddy simulation(LES), Stress blended eddy simulation(SBES), Improved delayed detached eddy simulation(IDDES) CFD, Heat transfer, Pin-Fin matrix,*

The pin-fin matrix is adopted representatively in heat exchanger, turbine blade and nuclear reactor to improve the performance of heat transfer. The structure of the pin-fin matrix seems to be simple, but heat and flow structure are complicate. In this reason, many researchers have investigated the heat transfer phenomenon. First of all, Ames et al.[1] conducted an heat transfer experiment on staggered pin-fin matrix with hot wire and infrared camera. Reynolds number 3,000, 10,000 and 30,000 were investigated. Benhamadouche et al.[2] conducted numerical simulation for staggered pin-fin matrix with 4 turbulence model (k - ω SST, ϕ - model, EB-RSM, LES).

In present work, two hybrid RANS/LES models and one LES model are adopted to study heat transfer and fluid flow on staggered pin-fin matrix at Reynolds number, 10,000. Two hybrid RANS/LES modes are an improved detached eddy simulation (IDDES) and a stress-blended eddy simulation (SBES). The LES model is based on dynamic Lily model. 3D vortical flow structures and turbulnece properties were compared depending on the adopted models. Also heat transfer properties including averaged Nusselt number at each surface was presented with comparison of experimental data[1].

Hydrothermal oxidative decomposition is one of methods for detoxification of polychlorinated biphenyls (PCBs, $C_{12}H_{(10-n)}Cl_n$), which are decomposed into water (H_2O), carbon dioxide (CO_2) and sodium chloride (NaCl) by dechlorination with sodium carbonate (Na_2CO_3) and oxidative decomposition with liquid oxygen (O_2) under high temperature 370 °C and high pressure 26.5 MPa [1]. In these reactor vessels, wall thinning due to corrosion was observed on bottom inner wall. At present, the reactors have been safely maintained and operated by adding a bottom partition to prevent chemical sinking and supplying hot water to the reactor vessel bottom to control the temperature. Thermal fluid analysis of the hydrothermal oxidative destruction reactors is necessary to clarify the corrosion mechanism.

A finite volume analysis solver chtMultiRegionTwoPhaseEulerFoam of OpenFOAM [2] is used to perform a multi-regionally coupled analysis of the internal fluid flow and heat conduction in the reactor vessel considering the conjugate heat transfer on the solid-liquid interface. The internal fluid is two-component fluid, PCB and water, with different densities without chemical reaction. Advection equation for the volume fraction of two fluids, compressible Navier-Stokes equation with gravity term, and energy equation are staggeringly solved for unsteady thermal fluid analysis. The Reynolds-averaged Navier-Stokes equations based on the standard k-ε model are used for turbulent flow analysis. Temperature dependent thermo-physical properties of PCB and water such as specific heat, thermal conductivity and viscosity, and equation of state of density, are employed as polynomial equation of temperature.

As a result of the analysis, the density difference flow of the two fluids was confirmed. To evaluate the integrity of the hydrothermal oxidative destruction reactor vessel, corrosion risk was evaluated based on the results obtained from the analysis such as temperature, volume fraction of PCB and wall shear stress on the solid-liquid interface.

Numerical Study of the Heat Transfer Process in a Wind Tank

Rafael Marulanda[1*] **and Omar López**[2]

Key Words: Heat Transfer, CFD, Thermal Comfort, Wind Tower, Wind Tank

In regions with a warm climate, the demands for thermal comfort also imply high consumption of electrical energy. The actual enviromental situation and the climate change impose a challenge in using renewable sources of energy in order to achieve thermal comfort for living spaces located in regions of hot/warm climate such as the tropics.

A solution that uses renewable energy is a wind tank; which is a structure located in the upper part of a living space (e.g: a house) with a compartment for water storage and with lower lateral openings that allow the air flow through water distribution line pipes acting like heat exchangers to cool the living space [4]. With the use of elevated tanks acting like wind towers [2], thermal comfort would be improved at times of the day with higher temperatures when the wind is favorable. To achieve the above, it is necessary to know the relevance of airflow [3] and heat transfer [1] through the installed water distribution lines that act as heat exchangers. A three-dimensional CFD simulation was performed to study the distribution of temperature, velocity and pressure due to the wind tank in a test room; three different wind tanks were analyzed varying their height above the roof. The natural tendency of the air to flow through the wind tank and its exit through the room windows is confirmed; the internal velocities reached acceptable average values, and heat transfer from air to water distribution lines allows cooling the room to acceptable levels for thermal comfort. The presence of heat exchangers causes drops in circulating air pressure but leaves enough fresh air inlet. A sensibility study was realized to find the influence of water temperature in living space thermal comfort.

Optimal Cooling Design of Gamma-ray Converter with Venturi Structure Based on Multi-physics Analysis

Hiroto Yamamoto[1*] and Tetsuo Oya[2]

[1] Keio University, 223-8522, H.yamamoto171205@keio.jp
[2] Keio University, 223-8522, oya@sd.keio.ac.jp

Key Words: *Multi-physics analysis, Particle accelerator, Venturi structure*

In recent years, a new method to produce Mo-99 with a particle accelerator, which emits less amount of nuclear waste than nuclear reactor, gets a lot of attention [1]. In this method, accelerated electron beam is generated, converted into gamma-ray, irradiated onto the specimen and then Mo99 is obtained. Here, it is important to cool the gamma-ray converter made of copper alloy plates, which are exposed to large heat loads. For more efficient cooling, forced convection of water is adopted, where the converter itself is used as the flow channel.

To enhance the cooling effect, higher Reynolds number and large surface area are effective. However, the converter channel has design constraints on flow rate and the volume irradiated by the beam. For this reason, we focused on the flow control using venturi structure. There are few studies that applies venturi structure to cooling design. Hatami et al. [2] numerically investigated the effect of venturi tube on the cooling performance of nanofluid.

Venturi structure is composed of two sections: nozzle section and diffuser section. In the nozzle section, the width of the channel gradually decreases, and the flow velocity increases. In the diffuser section, the width is restored to the original value, and turbulence is more likely to occur. Applying this structure to the upstream, local turbulence with high flow velocity can hit the heated part of converter.

Venturi structure has three design parameters: nozzle length l_n, nozzle equivalent diameter d, diffuser length l_d. By experimental design, various combinations of these design variables are prepared. Then, each design proposal is analysed using multi-physics analysis of LS-DYNA R12. The conjugate heat transfer between structure and fluid is calculated, and the maximum temperature of each design is extracted as the objective variable. In the analysis, constant volumetric heat generation is imposed on the heated part of converter, and the flow rate is set constant.

As a result, a design proposal with stepped-shape diffuser ($l_d = 0$) showed the highest cooling performance. The optimal design effectively accelerates the flow and guide the high-velocity turbulent flow to hit the surface of heated part. This leads to 6.2 % decrease of the maximum temperature when the converter is irradiated by 10 kW electron beam, compared to the base design with flat channel.

The article describes a multistage modelling methodology proposed by the author for the modelling of emergency core cooling processes. The methodology is based on the best practice guidelines presented by the IAEA, it is applied to a specific scenario of emergency core cooling during a loss of coolant accident[1] with an effective break diameter of 20mm.

A 3D thermohydraulic analysis was performed as the first step in the solution process, where the transient changes in the pressure, velocity and temperature fields within the reactor pressure vessel were studied [2]. The transient CFD analysis simulated the fluid structure interaction between the coolant and the reactor pressure vessel wall. This interaction focused on the thermal field and the unsteady cooling processes. The primary knowledge learned when processing the results of the first step, was the presence of an oscillating cold coolant stripe in close proximity to the pressure vessel wall.

The next step in the methodology consisted of a three-dimensional thermo-mechanical analysis of the reactor pressure vessel [3]. In this step, pressure thermal shock induced critical zones of mechanical loading were identified and the influence of the oscillatory character of the cold stripe on the pressure vessel was studied.

Accelerating Structural and Fracture Mechanics Simulations with Localised Phenomena through Matrix Compression and Sub-Structuring

Konstantinos Tatsis[1], Konstantinos Agathos[2], Konstantinos Vlachas[1], Eleni Chatzi[1]

[1] ETH Zürich, Zürich, Switzerland, {tatsis, vlachas, chatzi}@ibk.baug.ethz.ch,
[2]University of Exeter, Exeter, UK, k.agathos@exeter.ac.uk

Key Words: model order reduction, localised damage, Hierarchically Off-Diagonal Low Rank (HODLR) approximation, dynamic substructuring

Several problems in structural and fracture mechanics involve stationary or evolving localised features, such as cracks and damage. A repetitive solution of the forward equations of these problems is often required, to track for instance the evolution of damage for different system configurations, or as part of an inverse problem solution. In such settings, that are often encountered in the realms of Structural Health Monitoring (SHM) and reliability assessment, significant benefits are attained from the use of model order reduction, to decrease the associated computational cost. However, conventional projection-based techniques, which are often preferred for reduction, would not be effective for such problems due to the infeasible size of the resulting parameter spaces, which should account for all possible feature locations and configurations [1], as well as additional parameters, such as environmental and operational conditions.

In the present work, an alternative approach is proposed, where low-dimensional spaces, created for the original system, in the absence of localised features, are enriched with appropriately selected columns of the flexibility matrix of the system. While it can be shown that this approach exactly recovers the solution of the full order problem in the static case, its application for general localised features requires the computation of the full flexibility matrix of the system, which can quickly become intractable in terms of memory. This issue is mitigated by using a Hierarchically Off-Diagonal Low Rank (HODLR) representation for the involved system matrices [2], while the computational cost, which depends on the size of the flexibility matrix, is further reduced by means of dynamic substructuring [3]. This allows to effectively scale the computational time by only extracting the flexibility matrices of the sub-structures, whose size is much more reduced than the one of the full-order system. The efficiency of the resulting scheme is demonstrated through a series of numerical applications, involving large-scale structural dynamics models with localised damage.

Key Words: *Stochastic Differential Equations, Splitting Methods, Generalized Langevin Equation, Memory Kernel, Error Analysis, Harmonic Oscillator*

We study numerical methods for the generalized Langevin equation (GLE) with a positive Prony series memory kernel, in which case the GLE can be written in an extended variable Markovian formalism. We propose a new splitting method that is easy to implement and is able to substantially improve the accuracy and robustness of GLE simulations in a wide range of the parameters. An error analysis is performed in the case of a one-dimensional harmonic oscillator, revealing that all but one averages are exact for the newly proposed method. Various numerical experiments in both equilibrium and nonequilibrium simulations are also conducted to demonstrate the superiority of the newly proposed method over popular alternative schemes in interacting multi-particle systems.

Key Words: *adaptive multigrid, molecular mechanics, large scale optimization, a posteriori*

We present several efficient adaptive multigrid strategies for large-scale molecular mechanics optimization. The oneway multigrid method is used with inexact approximations at every coarse level and the adaptive quasi-atomistic approximation and the adaptive blended ghost force correction (BGFC) method are considered as the coarse-grid problems. Mesh refinements based on the gradient-based a posteriori error estimator can obtain better approximations on the coarse-grained levels. Sublinear complexity is observed numerically when the BGFC method is used for crystals with defects, like vacancies, micro-crack and dislocation. For systems with more than ten millions atoms, this strategy has a fivefold acceleration in terms of CPU time on average.

Adaptive Parareal Algorithms for Molecular Dynamics Simulations

Frédéric Legoll[1]

[1] ENPC and Inria, 6 et 8 avenue Blaise Pascal, 77455 Marne la Vallée Cedex 2 (FRANCE),
frederic.legoll@enpc.fr

Key Words: Molecular dynamics simulation, Stochastic differential equations, Parallel-in-time algorithms, Long time integration

In this talk, we introduce parareal algorithms in the context of molecular dynamics, where we couple a fine propagator based on the reference potential energy landscape with a coarse propagator based on a surrogate potential. Although the parareal algorithm, in its original formulation, always converges, it suffers from various limitations in the context of molecular dynamics. In particular, it is observed that the algorithm does not provide any computational gain in terms of wall-clock time (compared to a standard sequential integration) in the limit of increasingly long time-horizons. This numerical observation is backed up with theoretical discussions. We then introduce a modified version of the parareal algorithm wherein the algorithm adaptively divides the entire time-horizon into smaller time slabs [1]. We numerically show that the adaptive algorithm overcomes the various limitations of the standard parareal algorithm, thereby allowing for significantly improved gains. Several numerical examples will be discussed, including the simulation of defects in tungsten using LAMMPS.

Key Words: Dislocations, particle system, SDE, mean-field limit, discrete-to-continuum limit

We focus on the connections between four stochastic and deterministic models for the motion of straight screw dislocations. Starting from a description of screw dislocation motion as interacting random walks on a lattice, we prove explicit estimates of the distance between solutions of this model, an SDE system for the dislocation positions, and two deterministic mean-field models describing the dislocation density. The proof of these estimates uses a collection of various techniques in analysis and probability theory, including a novel approach to establish propagation-of-chaos on a spatially discrete model. The estimates are non-asymptotic and explicit in terms of four parameters: the lattice spacing, the number of dislocations, the dislocation core size, and the temperature. This work is a first step in exploring this parameter space with the ultimate aim to connect and quantify the relationships between the many different dislocation models present in the literature.

Coarse-graining of Markov chains

Bastian Hilder[1], **Upanshu Sharma**[2*]

[1] Lund University, bastian.hilder@math.lu.se
[2] Freie Universität Berlin, upanshu.sharma@fu-berlin.de

Key Words: Coarse-graining, continuous-time Markov chains, fast-slow systems

Various physical phenomenon, such as Markov state models in molecular dynamics, stochastic chemical kinetics for a chemical-reaction system and agent-based models in social dynamics are modelled by jump processes. Coarse-graining of such models has received considerable attention from practitioners in recent years – for instance to perform a data-driven identification of the transition-rate matrix for a reduced set of stable configurations in a molecular system or to deduce subnetwork dynamics from large-scale biochemical systems. Typically in these settings, coarse-graining is characterised by a projection onto a smaller subset of states, which captures the essential slow-behaviour of the model. Inspired by the conditional-expectation closures introduced in coarse-graining of diffusion processes, in this work we propose an *effective dynamics* for continuous-time Markov chains. The central aim of this work is to understand if and when this effective dynamics is indeed a good lower-dimensional approximation of the full stochastic jump process. Using entropy techniques we provide sufficient conditions under which this effective dynamics stays close to the original system and provide quantitative bounds on the approximation error. Furthermore, we connect the effective dynamics to the averaging literature which deals with multi-scale problems in jump processes.

Key Words: Model reduction; Koopman operators; Mori-Zwanzig formalism; nonlinear time series analysis; system identification

The Mori-Zwanzig (MZ) projection operator formalism provides a general framework for constructing reduced models for chaotic and stochastic dynamical systems, particularly in situations without sharp scale separation and hence significant memory effects. In this talk, I will report on an approach to data-based model reduction for stochastic and random dynamical systems using the NARMAX (Nonlinear Auto-Regressive Moving Average with eXogenous inputs) representation of stochastic processes, widely used in time series analysis and data-driven modeling. I will explain how the NARMAX approach may be formally derived from the original dynamical model using a discrete-time version of the MZ formalism. These ideas are illustrated on a stochastically-forced PDE. Time permitting, I will also discuss our recent efforts to improve the efficiency and scalability of our data-based modeling procedure.

Discretizing Atomistic Dynamics with Markov Renewal Processes

Danny Perez[1*]

[1] Theoretical Division T-1, Los Alamos National Laboratory, PO Box 1663, Los Alamos, NM, 87544, USA, danny_perez@lanl.gov

Key Words: *Long-time dynamics, jump processes, coarse-graining*

Atomistic simulations with methods such as molecular dynamics are extremely powerful tools to understand nanoscale dynamical behavior. The resulting trajectories, by the virtue of being embedded in a high-dimensional configuration space, can however be difficult to analyze and interpret. This makes low-dimensional representations, especially in terms of discrete jump processes, extremely valuable. This simplicity can however come at the cost of accuracy, as tractable representations often entail simplifying assumptions that are not guaranteed to be realized in practice, no matter how the discrete states are defined. We describe a discretization scheme for continuous trajectories that enables an arbitrarily accurate representation in terms of a Markov Renewal Process over a discrete state space. The accuracy of the model converges exponentially fast as a function of a continuous parameter that has the interpretation of a local correlation time of the dynamics, for any state definition.

[4] Dipartimento di Chimica e Chimica Industriale, Univerista di Pisa, I-56124 Pisa, Italy

Key Words: Grassmann extrapolation, ab-initio molecular dynamics, QM/MM

Simulating ab-initio molecular dynamics is in general numerically very expensive due to the large non-linear eigenvalue problem that needs to be solved at each time step of the dynamics. This problem is usually solved by means of a self-consistent field algorithm, in which the accuracy of the initial guess strongly influences the number of iterations to perform, and therefore the overall cost of the method.

In this talk, I will present a method for computing accurate initial guesses for the density matrix initiating a self-consistent field algorithm in a Born-Oppenheimer molecular dynamics, based on density matrices at previous time steps. To perform the extrapolation, we introduce a locally bijective map between the manifold where the density matrix is defined and its tangent space so that it is possible to perform linear extrapolation in a vector space, keeping the correct physical properties for the initial guess. I will then illustrate the method with numerical simulations on a few molecules, demonstrating the low computational cost and accuracy of the proposed method.

Large Deviations for Model Coarse-graining: Metastable Atmospheric Jets

Tobias Grafke[1]*, **Nayef Shkeir**[1]

[1] University of Warwick, United Kingdom, T.Grafke@warwick.ac.uk

Key Words: Slow-fast systems, large deviation theory, rare events, metastability, atmospheric flows

In stochastic systems with time-scale separation the average behavior of the effective slow variables can be computed rigorously by stochastic averaging and homogenization. The result is a law-of-large-number type result describing the limiting evolution equation in the limit of infinite time-scale separation. Similarly, typical fluctuations around this most likely behavior can be quantified through a central limit theorem, so that effective stochastic dynamics for the slow degrees of freedom can be derived.

Here we show that these considerations do not contain extremely long-time behavior, such as metastability on the slow time scale, which necessitates macroscopic fluctuations of the slow variable away from its typical behavior [1]. Classical results [2] prove that the corresponding large deviation principle (LDP) involves an Hamilton-Jacobi equation whose Hamiltonian is related to the leading eigenvalue of the generator of the fast process, and is typically non-quadratic in the momenta—in other words, the LDP for the slow variables in fast-slow systems is different in general from that of any stochastic differential equation (SDE) one would write for the slow variables alone. In short, large fluctuations of the slow variables cannot be described by classical Freidlin-Wentzell theory of SDEs.

This situation is not only of mere theoretical interests, but occurs in real-world systems such as atmospheric flow: Here, the slow evolution of atmospheric jets is driven by fast fluctuations of the turbulent flow, and can be approximated by quasi-linear theory. In certain parameter regimes, different arrangements of planetary jets are simultaneously locally stable, and rare fluctuations can drive the system between these states on very long time-scales.

Key Words: Model reduction, renormalization, multiscale

While model order reduction is a promising approach in dealing with multi-scale time-dependent systems that are too large or too expensive to simulate for long times, the resulting reduced order models can suffer from instabilities. We have recently developed a time-dependent renormalization approach to stabilize such reduced models. In the current work, we extend this framework by introducing a parameter that controls the time-decay of the memory of such models and optimally select this parameter based on limited fully resolved simulations. First, we demonstrate our framework on the inviscid Burgers equation whose solution develops a finite-time singularity. Our renormalized reduced order models are stable and accurate for long times while using for their calibration only data from a full order simulation before the occurrence of the singularity. Furthermore, we apply this framework to the 3D Euler equations of incompressible fluid flow, where the problem of finite-time singularity formation is still open and where brute force simulation is only feasible for short times. Our approach allows us to obtain a perturbatively renormalizable model which is stable for long times and includes all the complex effects present in the 3D Euler dynamics. We find that, in each application, the renormalization coefficients display algebraic decay with increasing resolution, and that the parameter which controls the time-decay of the memory is problem-dependent [1].

Key Words: Eigenvalue PDE, Metastable Diffusion Process, Artificial Neural Network

Abstract: In this talk, we consider the eigenvalue PDE problem of the infinitesimal generators of metastable diffusion processes. We present a numerical algorithm based on training artificial neural networks for solving the leading eigenvalues and eigenfunctions of such high-dimensional eigenvalue problem. The algorithm is useful in understanding the dynamical behaviors of metastable processes on large timescales. We demonstrate the capability of our algorithm on a high-dimensional model problem, and on the simple molecular system alanine dipeptide. This talk is based on joint work with Tiejun Li and Christof Schütte.

Tensor-valued Atomic cluster expansion for inference of dynamical systems

Christoph Ortner[1], **Matthias Sachs**[2*]

[1] University of British Columbia, Department of Mathematics, cortner@math.ubc.ca
[2*] University of British Columbia, Department of Mathematics, msachs@math.ubc.ca

Key Words: Atomic cluster expansion, Dynamical systems, Tensor-valued functions, equivariant basis construction

Complex physical systems are commonly parametrized by tensor-valued coefficients that are functions of the current state of the system. For example, rigorous derivation of the dynamics via the Mori-Zwanzig projection formalism of coarse-grained atomistic systems typically results in a (generalized) Langevin equation with configuration-dependent friction and diffusion coefficients. Learning the dynamics of such systems from data and simulating the inferred model requires efficient parametric representations of such tensor-valued functions. More specifically, such representations should allow for computationally efficient evaluation and data-efficient estimation of their parametrization from data.

The framework of the recently proposed Atomic Cluster Expansion (ACE) [1, 2] has been successfully used for inference of potential energy surfaces and force fields of atomistic systems from data. In this talk, I will present some recent work that was performed in collaboration with C. Ortner which extends the framework of the Atomic Cluster Expansion to equivariant tensor-valued functions. I will discuss the derivation of the resulting basis expansions for matrix-valued and vector-valued functions. Moreover, I will present the results obtained by applying our approach to atomistic trajectory data.

A Variational Approach based on Perturbed Eigenvalue Analysis for Improving Spectral Properties of Isogeometric Multipatch Discretizations

Thi-Hoa Nguyen[1*], René R. Hiemstra[1], Stein K. F. Stoter[2] and Dominik Schillinger[1]

[1] Institute of Mechanics, Technische Universität Darmstadt, Franziska-Braun-Straße 7, 64287 Darmstadt, Germany
[2] Multiscale Engineering Fluid Dynamics, Eindhoven University of Technology, PO Box 513, 5600 MB Eindhoven, The Netherlands

Key Words: Isogeometric analysis, outlier frequencies, outlier modes, perturbed eigenvalue analysis, multipatch discretizations, explicit dynamics, critical time step

A key advantage of isogeometric discretizations is their accurate and well-behaved eigenfrequencies and eigenmodes. For degree two and higher, however, the so-called optical branches formed by spurious outlier frequencies and modes may appear due to boundaries or reduced continuity at patch interfaces [1, 2]. The outlier frequencies are significantly overestimated, which unnecessarily reduce the stable critical time-step size in explicit dynamics calculations. Moreover, the outlier modes behave in a spurious manner and may have a negative impact on the solution accuracy and robustness, particularly in hyperbolic problems [3]. In this talk, we present (a) a variational approach based on perturbed eigenvalue analysis to improve the spectral properties of isogeometric multipatch discretizations; and (b) a scheme for estimating optimal scaling parameters of the added perturbation term such that the outlier frequencies are effectively reduced and the accuracy in the remainder of the spectrum and modes is not negatively affected; and (c) how to cast this scheme into a pragmatic iterative procedure that can be readily implemented in any isogeometric analysis framework. We verify numerically via spectral analysis of second- and fourth-order problems that the proposed approach improves spectral properties of isogeometric multipatch discretizations in the one- and multidimensional setting. For exemplary membrane and plate-like structures, we confirm that our approach maintains spatial accuracy and enables a larger critical time-step size. We also demonstrate that it does not depend on the polynomial degree of spline basis functions.

Auxiliary Splines Space Preconditioning for B-Splines Finite Elements: The case of $\boldsymbol{H}(\mathbf{curl},\Omega)-$elliptic problems

Abdeladim El Akri[1*], **Khalide Jbilou** [2] **and Ahmed Ratnani** [3]

[1] Mohammed VI Polytechnic University, Morocco, abdeladim.elakri@um6p.ma
[2] University of Littoral Côte d'Opale, France, khalide.jbilou@univ-littoral.fr

Key Words: Auxiliary space preconditioning, IGA, $H(\boldsymbol{curl},\Omega)$, Preconditioning.

Despite the large success of the IsoGeometric Analysis (IGA), dealing with higher-order B-spline functions generate matrices that are denser than the finite element matrices. In general, this leads to a condition number that is not uniformly bounded with respect to discretization parameter h and can even grows rapidly when h goes to zero. As a consequence, the employing of standard numerical solution methods for IGA discrete systems may fail and preconditioning is necessary to obtain convergence in a reasonable amount of time. To overcome the difficulties given by the observed ill-conditioning, in this work we propose the use of what is called the *Auxiliary Space Preconditioning method* [2], ASP method for short, to derive an optimal and robust preconditioning strategy for the linear $H(\boldsymbol{curl},\Omega)$-elliptic problem, on unit square/cube domains, in the case of regular B-Splines finite elements.

From the theoretical side, we have derived a uniform, stable and regular decomposition of the IGA discrete space $V_h(\boldsymbol{curl},\Omega)$, then we have proved the mesh-independent effectivity of the preconditioners by using the abstract theory developed by R. Hiptmair and J. Xu [1]. For the application's part, some sample simulations are developed to test the strategy proposed by our theoretical results in view of further applications. Simulations are conducted on two and three spatial dimensions through three tests. We have first solved the preconditioned linear system, using *Conjugate Gradient (CG)* method, relying on *Jacobi* and on the *Gauss-Seidel* smoothing, then we have investigated the behavior of the preconditioner with respect to the degree refinement, showing in particular that the resulting algorithm can be easily extended to a p-stable algorithm.

The numerical tests show that our preconditioning method has been a very effective cure to the ill-preconditioning of the approximate problem, in the sense that the spectral condition number is sufficiently small and is hardly dependent on the mesh parameter, the number of conjugate gradient iterations necessary to achieve the convergence is essentially independent of the discretization parameter as well as of the B-spline degrees.

Efficient and Fast Mesh Adaptation Method on more General Geometries using Isogeometric Analysis

BAHARI Mustapha[1*] **and RATNANI Ahmed**[2]

[1] Mohammed VI Polytechnic University, Green City, Morocco, mustapha.bahari@um6p.ma
[2] Mohammed VI Polytechnic University, Green City, Morocco, ahmed.ratnani@um6p.ma

Key Words: Moving Mesh Method, r-Refinemet, Monge-Ampere Equation, Optimal Transport, B-spline, Fast diagonalisation

Adaptive meshes is fundamental for the numerical simulation of the various problems. Thus, the book published by Huang and Russell [1] contains most of the techniques that exist in the literature. However, one that is based on the optimal transport problem is quite powerful because of the guaranteed mathematical properties. Thus, by following the current, we generate a new efficient and accurate sketch of mesh adaptation, especially when we are interested in more general geometries. Hence, inspired by the work of Delzanno et al [2], our idea is based also on the resolution of the Monge-Ampere equation (MAE), but still, in our case, we solve just Poisson equation in each few iterations using the second method introduced by Benamou at al. [3]. Simplifying a lot of computation, we calculate the optimal one-to-one mapping using isogeometric analysis tools to ensure the regularity we need C^1 (or even C^2) and instead of the mesh adaptation on each geometry as presented in the sketch proposed by Delzano et al, which requires a resolution of (MAE) on each deferent geometry, we have simplified this by what we call the inverse image of the adapted mesh on the unit square (single patch domain) and thus always solve (MAE) in the unit square, where the desired adaptive meshes in the physical domain are no other than the image by the initial mapping of this new unit square mesh. From this and using the fast diagonalisation method proposed by Sangalli et all [4] our method is quite really efficient and (fast).

Immersed Finite Element and Isogeometric Analysis Using Approximate Lagrange Extraction

John A. Evans[1*], Nils Wunsch[1], Kurt Maute[1], Jennifer Fromm[2], Ru Xiang[2], Han Zhao[2], and David Kamensky[2]

[1] University of Colorado Boulder, Boulder, CO, USA, john.a.evans@colorado.edu

Key Words: Immersed Finite Element Analysis, Immersed Isogeometric Analysis, Lagrange Extraction

In this talk, we present a new approach to immersed finite element and isogeometric analysis. In our approach, finite element or spline basis functions defined on a non-body-fitted background mesh are first interpolated onto a Lagrange basis defined on a body-fitted integration mesh, and these background basis function approximations are then employed for immersed finite element or isogeometric analysis. Much like spline basis functions can be represented element-wise in terms of Bernstein shape functions in body-fitted isogeometric analysis [1], the background basis function approximations in our approach can be represented in terms of Lagrange shape functions over each element in the body-fitted integration mesh using Lagrange extraction operators. Consequently, one can transform a classical finite element analysis code into an immersed finite element or isogeometric analysis code with minimal implementation effort using our approach. Namely, one only needs to provide a classical finite element analysis code with Lagrange extraction operators, a connectivity array relating local and global degrees of freedom, and the ability to compute the values and derivatives of the background basis function approximations using the Lagrange extraction operators. In this talk, we will present a stability and convergence theory for our approach for a simple model problem, and we will illustrate the efficacy of our approach using a number of example problems from structural mechanics and fluid dynamics. Finally, we will discuss how we were able to enable immersed finite element analysis within the popular open-source finite element analysis platform FEniCS using our approach [2].

Finite element analysis is widely used for the detailed design of civil engineering structures. However, finite element analysis of curved members has the problem of generating shape errors when we use the non-curved shape elements. Therefore, it is effective to introduce Isogeometric Analysis [1] into the structural analysis of civil engineering structures. This study developed a new two-dimensional curved Bernoulli-Euler beam element using the NURBS basis function. We aim to use our new IGA beam element for the Isogeometric Analysis of thin curved members such as arch ribs and beam string structure.

Several formulations of curved beam elements suitable for IGA have been proposed [2] [3], including the deflection angle as an unknown variable. On the contrary, Weeger et al [4] developed a nonlinear Bernoulli-Euler beam element using only displacements as an unknown variable. In the article, they focused on the spline functions that can automatically maintain continuity of deflection angles between elements. Therefore, we also developed a curved Bernoulli-Euler beam element with only displacement as an unknown variable.

In the present study, we adapted the definition of strain based on the theory of two-dimensional curved Bernoulli-Euler beams [5] and discretized using a finite element method based on the Galerkin method. The trial function consisted of a linear combination of NURBS basis functions and displacement on each control point. Finally, we found that the convergence rate of the relative error to the exact solution decreased with decreasing element length. Furthermore, we evaluated the proposed curved elements with varying curvatures. As a result, our proposed element could solve any curved beams with high accuracy.

Key Words: *Cavitation, Stabilized formulation, Isogeometric Analysis, Navier-Stokes-Korteweg*

Cavitating flows are ubiquitous in engineering and science applications. Despite their significance, a number of fundamental problems remain open; and our ability to make quantitative predictions is very limited. The Navier-Stokes-Korteweg equations constitute a fundamental model of cavitation [1], which has potential for predictive computations of liquid-vapor flows, including cavitation inception —one of the most elusive aspects of cavitation. However, numerical simulation of the Navier-Stokes-Korteweg equations is very challenging, and state of the art simulations are limited to very small Reynolds numbers, open flows (no walls), and in most cases, micrometer length scales [2-3]. The computational challenges emerge from, at least, (a) the presence of third-order derivatives in the governing equations, (b) a complicated eigenstructure of the spatial partial-differential operators in the governing equations, which prevents the use of standard finite volume techniques, and (c) the need to resolve the liquid-vapor interface, which without special treatment, has a thickness in the order of nanometers. Here, we present a stabilized isogeometric discretization scheme that permits, for the first time as far as we are aware, large-scale simulations of wall-bounded flows with large Reynolds numbers. The proposed stabilization scheme is a residual-based approach that emanates from the eigenstructure of the equations and vastly outperforms standard stabilization schemes for advection-dominated problems. We feel that this work opens possibilities for predictive simulations of cavitation.

Optimization of the dimensioning of structural structures is gaining momentum. FEM, evolutionary, and other methods are found that are transformed by algorithms into computer simulations of construction models. Using existing methods and interconnecting and merging these structures yields a new, seemingly complicated, but simple method that computers can easily support with software loops. By setting the geometric characteristics of constructive lattice systems in equation lines, formulas are obtained that replace even trigonometric equations. The Ritter-Križaić iterative method for one-sided gratings with a flat lower band is also defined. This method paves the way for new methods to define different types of grids. By solving demanding models, i.e., by defining an iterative model with oblique rod belts sticks, the definition of spatial variables necessary for static dimensioning of structures is accelerated. As a result, the approach of simple n-polygonal structural modeling of truss continuous construction with combination direction coefficients and defining differential equations of a grid's continuum in displacement with the Mathcad toolset is developed.

Calibration and Validation of DEM and CFD-DEM Models of Industry-Relevant Systems using Evolutionary Optimisation and Positron Emission Particle Tracking

Kit Windows-Yule[1*], Leonard Nicuşan[1], Dominik Werner[1], and Hanqiao Che[1]

[1] School of Chemical Engineering, the University of Birmingham, Edgbaston, Birmingham, B15 2TT, UK

Key Words: *Discrete Element Method, Industrial Applications, Calibration, Validation*

The discrete element method (DEM) is a powerful tool capable of predicting the dynamics of diverse particulate systems with quantitative accuracy. However, if not correctly calibrated, the results of DEM simulations can be inaccurate or even unphysical. As such, the calibration and validation of DEM simulations is an important task, but one which carries significant complexity. In particular:

1. DEM models require details of *microscopic* quantities (sliding and rolling friction coefficients, restiution coefficients...), but conventional powder characterisation measure only *macroscopic* quantities (internal friction angle, yield stress...) making the rigorous determination of accurate calibration values highly challenging.
2. The meaningful validation of DEM models requires the detailed, multi-point comparison with experimental results. As many industrial systems are metal-clad and thus optically-opaque, the use of common imaging techniques such as PIV is precluded.

In this talk, we detail solutions to both of these challenges developed at the University of Birmingham. Regarding the former, we briefly introduce the recently-developed ACCES (Autonomous Characterisation and Calibration using Evolutionary Simulation) technique which uses evolutionary algorithms to backcalculate the microscopic parameters of particulate media from measurements of their bulk behaviours. Regarding the latter, we discuss how Positron Emission Particle Tracking, a technique capable of extracting high-resolution, three-dimensional data from optically-opaque systems, may be leveraged to provide rigorous, detailed validation of DEM and coupled CFD-DEM simulations of industry-relevant systems.

Modelling of keyhole dynamics and melt pool flow in selective laser melting additive manufacturing

Erlei Li[1*], Zongyan Zhou[1], Lin Wang[1] and Aibing Yu[1]

[1] ARC Research Hub for Computational Particle Technology, Department of Chemical Engineering, Monash University, Clayton, VIC 3800, Australia, erlei.li@monash.edu

Key Words: *selective laser melting, additive manufacturing, keyhole, fluctuation, melt pool flow, recoil pressure*

As one of the promising additive manufacturing (AM) technologies, selective laser melting (SLM) fabricates metal components layer-upon-layer using laser beams to fuse metallic powder. The keyhole is produced commonly at high energy density (high laser power or low scanning speed) during the SLM process. However, the dynamics of keyhole and melt pool, and their relationship with forces remain unclear. Here, through the developed three-phase volume of fluid (VOF) model [1], the quasi-stable keyhole dynamics and metal powder melting process are captured. Results show that the keyhole life cycle experiences steps of formation and drilling, fluctuation, and disappearance. Pores are generated from the gas void in the powder bed, keyhole protrusion, and the end eroded gas bubbles. During the laser-on period, an anticlockwise vortex is generated at the tail, and the liquid travels in a clockwise path ahead of the melt pool. The stability of the keyhole depth is disturbed by the powder layer thickness variation, and it oscillates repeatedly until the laser is off. The centrifugal flow at the tail body of the melt pool is driven at the combined action the surface tension and Marangoni force. The rear keyhole is compressed dominated by the surface tension while the front rim is expanded controlled by the recoil pressure. The present study enhances the further understanding of multi-physics in SLM process.

Numerical analysis of debris-like flow using an extended CFD-DEM method based on micropolar fluids

Lian Wang, Xihua Chu*

*Wuhan University, Wuhan, Hubei, China, Chuxh@whu.edu.cn

Key Words: *Micropolar fluids, discrete particle, debris-like flow, micropolar parameters*

Debris flow, a multiphase system containing multi-scale particles, often occurs in geological hazard, causing serious economic losses and casualties. Therefore, it is important to deeply understand the mechanism of the debris flow and establish an effective scheme to monitor and prevent its large-scale occurrence. But, researches on the occurrence and movement of the debris flow is difficult to be carried out by experiment due to the complexity of geological conditions. Thus, numerical simulation could be a main approach to predict the movement of the debris flow, and the selection of mathematical model for describing the debris flow movement is the guarantee of the effectiveness of the simulation. In this study, based on the physical mechanism of microstructure effect considered in the micropolar fluids model [1], and its application in suspension system [2]. We established a coupling computation model (MVD model) considering the micropolar fluids to describe the mixed system with small particles and VOF (volume of fluid) method to track the free surface of liquid and discrete element method (DEM) to describe the movement of larger particles and their interaction. The main works include (1) the solution and verification of the MVD model under single particle sedimentation test [3], (2) the comparison of the debris-like flow morphology with DEM, classical fluid-particle coupling model and MVD model, (3) the analysis of the debris-like flow under different micropolar parameters, particle volume fraction, particle size distribution and slope gradient based on the MVD model. Numerical results indicate that the fluid with microstructure plays a significant role in the occurrence and movement of the debris-like flow and other factors have a certain effect on the movement characteristics of the debris-like flow.

Key Words: *DEM-CFD Method, Signed Distance Function, Immersed Boundary Method*

A solid-fluid multiphase flow including large particle size variations is ubiquitous in industries. In this system, large sized objects and small sized particles are mixed. Since understanding of the large particle size variations is not sufficient, application of numerical model is desired. In the present study, we develop a new model to simulate the large sized object which is mixed with small sized particles. In this model, the contact force is simulated by the linear spring model and the drag force is computed by combination of the signed distance function (SDF) [1] with the immersed boundary method (IBM) [2]. The small sized particle is calculated by the discrete element method (DEM) [3]. The new model is incorporated into our in-house code which is referred to as FELMI [4]. In order to show adequacy of the new model, we perform a validation test. In the validation test, we employ the fluidized bed system, where a large sized object is mixed with the small sized particles. Herein, the object position is compared between the computational and experimental results after fluidization is terminated. The large-sized object position well agreed between the computation and the experiment. Hence, Adequacy of the new model is proved through the validation test.

Study on rolling resistance model of discrete element method based on material elastic hysteresis theory

Zhengguo Gao, Yajun Zhang, Jun Wang, Becaye Cissokho Ndiaye

School of Transportation Science and Engineering, Beihang University, Beijing, 100191, China, Gaozg@buaa.edu.cn

Key Words: *Granular material; Rolling resistance; Elastic hysteresis; Speed independent; Discrete element*

In this paper, the mechanism of particles' rolling resistance caused by elastic hysteresis in collapsing elastic granular materials is studied at the meso-scale. A rolling resistance model applicable to the discrete element method is proposed.

Firstly, we analyze the rolling resistance behavior due to the material's elastic hysteresis during the rolling process of an elastic, round particle under different compression and relaxation pressures at the front and rear areas of the contact surface. Subsequently, the mechanical model of rolling resistance caused by material elastic hysteresis is established.

Then, the particle material's elastic hysteresis constitutive curve under compression (loading)and relaxation pressures (unloading) is measured by experimental method. The particle material's elastic hysteresis parameters are obtained, and a formula of particle rolling resistance for the discrete element method is proposed.

Finally, the formula is applied to the discrete element model to simulate the rolling process of an elastic circular particle on a rigid surface, and the simulation results are verified by a physical experiment. The results show that the rolling resistance model based on the material elastic hysteresis theory can effectively reproduce the rolling resistance behavior of elastic particles in granular materials.

Adaptive Computations for Biot System Based on A Posteriori Error Estimate with Mixed Finite Element Method for Flow

Key Words: *Error Estimate, Mixed Finite Element Method, Biot System, Iterative coupling*

Coupling Geomechanics to flow has greatly improved the accuracy of subsurface modeling. In this paper, we present an adaptive mesh refinement and iteration stopping algorithm based on a posteriori error estimates for solving the Biot system. The mechanics system is approximated by conforming Galerkin method (CG) while the flow is solved by mixed finite element method.

The Biot system commonly appears in geosciences and biosciences for modeling carbon sequestration (Lu and Wheeler 2020) and tissue deformation during subcutaneous injection (Leng, Lucio and Gomez 2021). Previous works have indicated that ensuring local mass conservation for the flow (Choo and Lee 2018) is crucial to the accuracy of the simulation, making Enriched Galerkin (EG) (Girault, Lu and Wheeler 2020) and mixed finite element method attractive options. Here we restrict our work to solving the flow with mixed finite element method and fixed-stress split for resolving the Biot system. A posteriori error estimates are derived for such algorithm to quantify different error components. The error estimators provide a novel adaptive stopping criterion, which balances algorithmic error from fixed-stress split and discretization error in space and time, for the fixed-stress iterations. We also demonstrate adaptive mesh refinement guided by the error estimators for simulating fractured reservoirs.

Efficient Implicit-Explicit Time Integration for Multiscale Simulations Using Hybridized Finite Element Methods

Bryan Reuter[1]*, **Timothy Wildey**[1]

[1] Sandia National Laboratories, Albuquerque, NM, {bwreute,tmwilde}@sandia.gov

Key Words: Multiscale methods, multinumerics, hybridized finite elements, time integration methods

Hybridized finite element methods have grown in popularity over the past 20 years, primarily for implicit time integration schemes with higher-order spatial discretization because the global linear system is much smaller than that of comparable methods. In addition, hybridized methods can be derived as variational multiscale methods [1], but have additional benefits due to the flexibility provided by the mortar grid. This perspective is well-suited for multiphysics problems and naturally allows for different resolutions and numerics throughout the computational domain [2]. For hybridized methods, the decomposition can be pushed to the element level, effectively providing such flexibility at the element-by-element level.

Recently, there has also been an interest in developing explicit and implicit-explicit (IMEX) methods to bolster the applicability of hybridized methods [3, 4, 5]. For wave propagation applications, explicit methods are attractive when the timestep required for stability is similar to that required for accuracy. However, for many practical problems, subgrid scale physical features in the medium render explicit integration prohibitively expensive; therefore, IMEX schemes based on domain decomposition become an attractive alternative. In this work, we explore the stability, accuracy, and performance of generalized IMEX methods for hybridized finite element methods in massively parallel computational environments. We will include applications in shallow water and wave propagation through heterogeneous media.

Key Words: Heart Modeling, Multiphysics Problems, Computational Fluid Dynamics, Variational Multiscale Methods, Large Eddy Simulation, Stabilization Methods

Computer-based numerical simulations of the heart and blood circulation represent a valuable tool to analyze the cardiac function and to enhance the understanding of cardiovascular diseases. In this talk, we introduce a Computational Fluid Dynamics (CFD) model for the numerical simulation of the whole heart hemodynamics, by accounting for all the physical processes that influence cardiac flows: moving domain and interaction with electromechanics, transitional-turbulent flows, cardiac valves and coupling with the external circulation. We employ the Navier-Stokes (NS) equations in Arbitrary Lagrangian Eulerian (ALE) framework and the Resistive Immersed Implicit Surface (RIIS) method to model the presence of valves in fluid. To impose a physiological displacement of the domain boundary, we employ a cardiac electromechanical model obtaining thus a multiphysics one-way coupled electromechanics-fluid dynamics model [1]. To better match the 3D CFD with blood circulation, we also couple the 3D NS equations to a 0D closed-loop circulation model. We obtain a multiphysics and multiscale coupled 3D-0D fluid dynamics model that we solve via a segregated numerical scheme [1]. We use a Variational Multiscale - Large Eddy Simulation (VMS-LES) method [2] to get a stable formulation of the NS-ALE-RIIS equations discretized by means of FE Method, to stabilize the advection-dominated regime, and to account for turbulence modeling within the framework of LES. Finally, we propose the ehnancement of residual-based stabilization methods via Artificial Neural Newtorks (ANNs). By considering numerical tests for the simpler case of advection-diffusion PDEs with SUPG stabilization method, we show that our ANN approach yields more accurate solution than using the conventional SUPG method [3].

Simple Models for Linear and Singular Losses for Periodic Flow

Guillermo Hauke[1*]

[1] Area de Mecanica de Fluidos, Escuela de Ingenieria y Arquitectura, C/Maria de Luna 3, 50018 Zaragoza, ghauke@unizar.es

Key Words: Finite element methods, hydraulic losses in periodic flow

Many attention has been paid to the losses in pipes and singular elements of fluid systems for stationary flow [1]. However, some systems found in engineering, biology and nature are based on pulsatile flow and/or periodic flow. This is the case of the circulatory system or the design and testing of dampers based on hydraulic circuits. In this work, based on the theory of dynamical systems, dimensional analysis and computational fluid dynamics, a simple model for the losses of various elements as a function of frequency is developed [2,3].

Streamline-Upwind Petrov-Galerkin formulation for the analysis of hypersonic flows in thermal non-equilibrium

David Codoni, Craig Johansen, Artem Korobenko*

Department of Mechanical and Manufacturing Engineering, University of Calgary, Calgary, AB T2L1Y6, Canada

* Presenting author: artem.korobenko@ucalgary.ca

Key Words: *Compressible flows, Stabilized methods, Shock capturing, Finite elements, Reacting flows, Thermal non-equilibrium, Hypersonic flows*

This work presents a Streamline-Upwind Petrov-Galerkin (SUPG) framework with finite elements discretization for the prediction of non-ionized hypersonic flows in thermal non-equilibrium. The formulation is enhanced with a residual based discontinuity capturing (DC) operator. The numerical framework solves the set of Navier-Stokes equations for the compressible reacting flows with an additional equation for the vibrational-electronic energy conservation. The set of equations, which involves one continuity equation for each chemical species considered, is solved in the pressure-primitive variables. The framework was recently validated for the non-reacting hypersonic flow problems in [1]. The numerical framework capabilities are assessed through several benchmark cases, including validation of the chemical model and its coupling with the two temperatures model in the context of critical flow features such as shock-shock and shock-wave boundary layer interactions. The first test case presented is 0D nitrogen reactor case which is a transient evolution of reacting nitrogen in vibrational non-equilibrium. The next case is the 2D cylinder case immersed in a Mach 12.7 flow of a 5-species reacting air mixture in thermal non-equilibrium. The last two cases are the 3D axisymmetric hollow cylinder extended flare (HCEF) and the double cone. Detailed measurements of the surface pressure and heat flux for the HCEF and the double cone in high-enthalpy flows have been obtained during a series of experiments carried out in the LENS XX expansion tunnel facility. The accuracy of the results is assessed through the comparison with the numerical and experimental data available in the literature for all the test cases presented. The numerical results demonstrate the suitability of the formulation in predicting non-ionized reacting hypersonic flows in thermal non-equilibrium.

Variational-Multiscale Discontinuous-Galerkin Method: Application to Additive Manufacturing

Arif Masud*, Ignasius Wijaya
Department of Civil and Environmental Engineering
University of Illinois at Urbana-Champaign, Urbana, IL, 61801-2352
amasud@illinois.edu

Abstract

This talk presents mathematical constructs underlying the Variational Multiscale Discontinuous Galerkin (VMDG) method [1,2,3]. It results in a robust finite element approach for mathematical problems with weak and strong discontinuities, and also facilitates a unified framework to derive interface transmission conditions. The method accommodates non-matching discretizations and optimal error convergence rates are presented.

The method is applied to extrusion-based layered printing with cementitious materials [4]. The evolution of mechanical properties as the printed material cures and stiffens results in non-physical reduction in the magnitude of elastic strains when standard constitutive models are employed. This elastic recovery of the printing induced deformation contradicts the experimentally observed behavior of the printed cementitious materials that harden at a nearly-frozen deformed state. A thermodynamically motivated constraint on the evolution of elastic strains is imposed on the constitutive model to remedy the non-physical bounce-back effect. An algorithm that is based on a strain-projection technique for the elastic part of deformation is developed that complements the inelastic response given by the Drucker-Prager model A ghost mesh method is proposed for continuous layer-wise printing of the material without the need for intermittent mesh generation technique or adaptive remeshing methods. The model is validated via comparison with experimental data and representative test cases are presented that investigate the mathematical and computational attributes of the proposed model.

Key Words: *fuel cell, heat transfer simulation, water management*

Hydrogen is a secondary clean energy for sustainable development, and fuel cell is the main way to use hydrogen energy [1]. Proton exchange membrane fuel cell (PEMFC) directly converts the chemical energy of hydrogen into electrical energy through electrochemical reaction, which avoids the limitation of Carnot cycle and has a huge market prospect.

Water will be produced during the operation of oxyhydrogen fuel cells. The accumulation of water will accelerate carbon corrosion and reduce the performance of the battery [2]. On the other hand, if the fuel cell is dry for a long time, the proton exchange membrane fuel cell will dry and break, which will also cause damage to the fuel cell [3]. The temperature distribution of the battery has a great influence on the output power and indirectly affects the water content [4]. Uneven temperature distribution will lead to serious degradation of the membrane and catalyst layer, thus shortening the battery life [5]. The coupling relationship between water and heat management can not be ignored.

In this study, COMSOL was used to establish the simulation model of proton exchange membrane fuel cell, and the heat and mass transfer process in the cell was coupled with electrochemistry. The results show that by simulating the real-time state of the battery and adjusting the parameters, the irreversible damage to the battery can be avoided and the battery life can be effectively prolonged.

Key Words: *Pressure Poisson equation, Deep neural network, Deep Residual Iteration Method, Fluid simulation*

In the SIMPLE algorithm for incompressible flows, solving the pressure Poisson equation is usually one of the key steps with the longest time consumption. In this study, a method based on deep neural network is proposed to accelerate this process: first, the equation is transformed into multiple independent tridiagonal subproblems based on the Fast Fourier Transform, and the subproblems are solved in fast parallel using a deep residual network. For the problem with more than 100,000 grids, this optimized SIMPLE algorithm has more than 10 times efficiency improvement in GPU platform compared to traditional methods. In addition, the algorithm effectively overcomes the shortcomings of neural networks in terms of interpretability and accuracy compared to other neural network methods, and has high numerical accuracy in typical cases such as driven cavity flow and backstep flow, and provides a promising means of implementation for large-scale direct numerical simulation.

BDD Preconditioner for A Diagonal-scaled Schur Complement System

Masao Ogino[1*]

[1] Daido University, 10-3 Takiharu-cho, Minami-ku, Nagoya 457-8530, m-ogino@daido-it.ac.jp

Key Words: *Balancing Domain Decomposition, Non-overlapping Domain Decomposition, Schur Complement, Diagonal-scaling Preconditioner*

Many of actual problems in science and engineering fields have multiple different materials and are modelled with large-scale unstructured mesh. The Domain Decomposition Method (DDM) based on the iterative methods is well-known as an effective parallel finite element method, however, solving such problems will suffer from slow convergence rate or no convergence. In order to achieve high performance in both convergence rate and parallel efficiency, it is necessary to apply an effective preconditioner for the DDM.

The Balancing Domain Decomposition (BDD) preconditioner [1] is an effective preconditioner for its very fast convergence rate. However, in considering composition of very different materials for actual problems, the convergence rate of the BDD is also shown to be worse. Some studies extended the BDD preconditioner to such problems with jumps in coefficients [2][3], but these are not suitable for cases of complex shape and composite materials. On the other hand, some numerical experiments show that a BDD-DIAG method [4], which uses a diagonal-scaling preconditioner instead of the Neumann-Neumann one, has robust convergence for the multi-materials.

In this study, to accelerate convergence of BDD preconditioner for the multi-materials, a BDD method combined with diagonal scaling preconditioner is considered and some numerical examples are demonstrated.

Key Words: *Viscoelastic Model, PTT, Network Theory, Planar Poiseuille Flow*

A number of investigations of linear or nonlinear viscoelastic fluid models have been proposed. Examples are Upper-Convected-Maxwell fluid model [1], Oldroyd-B model [2], Giesekus model, FENE model and many others. A new viscoelastic model among these is the Phan-Thien–Tanner (PTT) model for which one can reasonably hope to obtain the analytical and numerical solutions. The constitutive equation of the PTT model was derived using network theory [3,4]. This model has advantages over others because it includes not only shear viscosity and normal-stress differences but also an elongational parameter ε. Therefore it reproduces many features of the rheology of polymer solutions and non-Newtonian liquids.

Micro-macro models of polymeric viscoelastic fluids that arise from statistical physics are based on coupling Navier-Stokes system to conservation equation of network theory. In the model polymer molecules are idealized as linear or unbranched chains, connected by junctions to constrain chains so that the connected points move together for at least a certain minimum length of time. Network is formed by a set of chains connected by junctions such that every junction is linked by at least one unbroken macro-molecular path to a boundary point.

This research derives a new PTT model for compressible fluids. The elastic extra stress tensor $\mathbf{T}$ and polymer density η are contained in the governing equations derived from polymer network theory and combined with compressible Navier-Stokes equations the non-Newtonian elastic extra stress tensor is rederived. Planar Poiseuille flow is simulated based on the compressible PTT model and the accuracy of model is validated by numerical results compared with the analytical results.

Key Words: *High-Frequency Electromagnetic Field - Heat Conduction Coupled Analysis, Parallel Computing, Finite Element Method, Hierarchical Domain Decomposition Method, Human Body Model*

In order to evaluate an effect of cancer treatment by hyperthermia quantitatively, we have been studying its high-frequency electromagnetic field – heat conduction coupled analysis in a parallel environment. In our study, the NICT numerical human body model [1] is analyzed. This model uses a binary data format wherein types of organs are encoded using voxels. The diameters of cancers treated with hyperthermia are several millimeters; thus, elements must be refined to obtain sufficient accuracy. However, there are approximately 1 trillion degrees of freedom (DOFs) provided that the element sizes are 0.1 mm. In addition, smoothing techniques to reduce numerical noise increase the DOFs further. The efficient parallel computing method for large-scale finite element analysis (FEA) that we have been studying is the iterative substructuring method in the form known as the domain decomposition method (DDM) based on the iterative method [2]. It is expected to obtain scalable parallel efficiency on distributed memory parallel computers with the implementation of a Hierarchical Domain Decomposition Method (HDDM) [3]. The HDDM has been applied to the large-scale FEA of electromagnetics, and high-frequency electromagnetic field problems have been solved with 130 billion DOFs [4]. As the next step, a parallel coupled analysis is considered. In this presentation, the numerical human body model involving 220 million DOFs is analyzed in the parallel environment.

Key Words: *Smoothed Particle Hydrodynamics; Numerical analysis; Computational fluids dynamics; Domain decomposition; Multi-section division; Fast neighbor search; Hashed-Tree method; High-performance parallel computing;*

As a new generation of CFD scheme for complex hydrodynamics problems, the SPH (Smoothed Particle Hydrodynamics) numerical method was developed in the late 1970s. After being subsequently tailored to the modelling of elastic media, particularly for the calculation of the very large strains and the fracture phenomenon, it was repeatedly improved before being applied, as of the early 1990s, first to weakly compressible hydrodynamics, then to strongly compressible[1] and truly incompressible[2] hydrodynamics.

As an interpolation method, the accuracy of the SPH method often depends on the number of particles in the support domain. In theory, when the number of particles approaches infinity, the computational accuracy will be very close to reality. However, as an adaptive method, SPH has to run a large amount of computation at each time step, which is quite time-consuming and limit the development of the method[3].

This paper reports our high-performance smoothed particles hydrodynamics solver on distributed parallel computational system. In the solver, a highly efficient domain decomposition method based on multi-section division and the sampling method was proposed which could make the distributed computing system achieve load balancing with negligible work. For the search for neighbouring particles, an algorithm called Hashed-Tree Method was implemented to accelerate the initialization of the hierarchical data structure with well parallelization. The actual performance of the solver was assessed in detail through numerical simulations at various scales. Not only the weak scaling performance could be almost linear speed up but also high efficiency is achieved for strong scaling tests.

Key Words: Parallel Finite Element Method, Domain Decomposition Method, Inactive Element Method, Damage Analysis, Additive Manufacturing Analysis

The domain decomposition (DD) method is a powerful parallel computing technique for finite element analysis of solid mechanics problems at large scales. Although various DD methods have been proposed so far, the present study uses the balancing domain decomposition (BDD) method [1] and the BDD with diagonal scaling (BDD-DIAG) method [2].

In the DD methods, the analysis model should be decomposed into subdomains for parallel computing, before the linear system of equations is solved. In many solid mechanics problems, the analysis model does not change throughout the analysis with time steps. This means that the analysis model is decomposed only once at the beginning of the analysis. However, in some problems such as severely large-deformation problems, crack propagation problems and machining problems, regeneration of the domain-decomposed analysis model is necessary at every time step or every few time steps.

Furthermore, one can find another type of problem that is the focus of the present study. In this type, the analysis model involves inactive elements that are finite elements having zero stiffness. For example, multi-pass welding analysis and additive manufacturing analysis use the inactive elements to model the region to be solidified. Moreover, in damage analysis, the inactive elements can be found when the damage variables reach unity. For these problems, we adopted the one-time decomposition approach, in which the DD process is performed once at the beginning of the analysis. To adopt this approach, we need to formulate an implementation method to constrain floating degrees of freedom caused by the inactive elements.

In the present study, we present an implementation method for the BDD and BDD-DIAG solvers with the inactive elements. Moreover, its applications to damage analysis and/or metal additive manufacturing analysis will be demonstrated in the presentation.

ACKNOWLEDGMENT

Key Words: *Assembly Structure, Mortar Finite Element Method, Balancing Domain Decomposition Method, Dual Lagrange Multiplier, Multipoint Constraints, Weak Form, Background Cell*

Incorporation of a set of linear multipoint constraints (MPCs) in finite element analysis is important for performing realistic structural simulations. Miyamura[1] proposed a method to incorporate MPCs into the balancing domain decomposition (BDD) method (BDD-MPC method).

In the mortar finite element method, constraints to connect structural components are imposed in a weak form with a surface integration. The constraints can be represented by Lagrange multipliers that are interpolated using a set of shape functions. In the dual Lagrange multiplier method[2], the Lagrange multiplier is interpolated using a set of biorthogonal shape functions. After the surface integration for the constraints is conducted, a constraint matrix with respect to nodal displacements is obtained, that is, the constraints in a weak form are represented as a set of MPCs. In general, mesh patterns of two surface patches of two meshes to be connected are inconsistent. Sando et al.[3] proposed a method that uses integral cells generated by triangulation on the constraint surfaces for the integration of the weak form. In this study, the Gauss integration is performed in square cells called background cells, which are arranged in a grid pattern. The pattern is independent of the mesh patterns of two patches to be connected.

Examples of simple assembly structures whose constraint conditions in weak form can be integrated using only one cell were presented in the previous study[4]. In this study, examples of constraint conditions that are integrated using multiple cells are shown. The analyses are performed using the BDD-MPC method, and the convergence properties of the method are also investigated.

Key Words: *Large Scale Magnetostatic Problems, Preconditioning, The Coarse Problem*

Until now, we have considered the Balancing Domain Decomposition DIAGonal scaling (BDD-DIAG) preconditioner as a preconditioner of non-overlapping domain decomposition analysis of 3-dimensional magnetostatic problems taking the magnetic vector potential as an unknown function. One interesting fact is that the direct solver can be used in many cases for solving the coarse problem in BDD-DIAG. In this paper, we show a sufficient condition for positive-definiteness of the coarse matrix in BDD-DIAG of a perturbed maganetostatic problem. Though our numerical results are got in many cases of the original magnetostatic problem, we mainly consider the well-known perturbed problem in this paper. A conjecture is also given for the original magnetostatic problem.

Key Words: *Machine learning, real-time control, neural network, stable integrators, data-driven*

Online control and prediction of controller behaviour is often a tricky issue, especially when it comes to sensitive tasks requiring control within few milliseconds. Previous works used dynamic mode decomposition approach (DMD) to build a digital twin, learning therefore a stable correction and integrator of the controller [1]. Moreover, regularization is used to train a stable time integrator using DMD method.

On the other hand, DMD can be extended to nonlinear settings, where DMD is trained locally, which leads to the need of training multiple local integrators and then select the most appropriate in operation depending on the location in the phase space.

In this work, we train a non-linear integrator, using machine learning techniques and recurrent neural networks. Multiple models are trained and used in this work. The result is first a real-time controller behaviour prediction in fraction of milliseconds. Second, a stable real-time integrator is trained to perform real-time controller simulations. Both models are tested against data sets never used in the training.

Key Words: Reduced Order Models, CFD, Turbulence, Industrial Applications

The complexity associated with geometrically parametrised flow problems represents a limitation to the application of conventional, or high-fidelity, techniques. On the other hand, on such applications reduced order models (ROM) show great potential, allowing for the efficient solution of complex systems. This work presents a hybrid strategy to build a reduced model applicable in industrially-relevant applications. The methodology combines data-driven and projection-based techniques. It consists of constructing the reduced basis by means of the well-established proper orthogonal decomposition (POD) [1], and a Galerkin projection of the Navier-Stokes problem for the evaluation of the parametric coefficients. The eddy viscosity, and in effect the turbulent contribution is approximated via an interpolation scheme, i.e. POD-I, significantly improving the versatility of the methodology.

Aiming towards industrial applications, this work considers the most commonly-employed methodologies, i.e. the Finite-Volume Method (FVM) and the Reynolds-Averaged Navier-Stokes equations (RANS). For improved implementation, the sampling procedure and the calculation of the reduced operators in the offline phase use OpenFOAM's [2] open-source libraries, while the data separation and the online problem are solved using Python.

Finally, the capabilities of the proposed strategy are tested by approximating the turbulent flow around a NACA aerofoil with parametrised angle of attack, expanding the work presented in [3] to turbulent problems.

Key Words: Dimensionality reduction, Topological and geometrical characterization, Interpolation, Optimization

Those last years have seen a growing maturity in optimization tools, particularly topological optimization [1]. Nevertheless, those methods do not take the accumulated knowledge of industrial manufacturers into account. Moreover, they face substantial limitations to include all the various constraints that govern the realization of industrial products.

We wish to ally discovery tools from IA and optimization ones in this project. A key question is that the amount of design of a given industry is very low and thus it is not possible to use deep-learning approaches for this purpose. Therefore, among the possible tools we have elected those allowing to infer, if possible, a reduced manifold of the existing design. If the latter is of low dimension optimization my then be performed in this manifold. The second question is what type of descriptors and classification are the most appropriate to perform the dimension reduction and to interpolate properly within the existing design. Those tools combine reduced modelling and manifold learning approaches (like Locally Linear Embedding) [1], geometrical characterization (Level set [2]), Topological Data Characterization [3] and optimal transport [4]. Those tools are today of easy access through dedicated libraries.

Those basic concepts will be illustrated with 2D examples mimicking bumpers. At the present stage, it seems that we are capable of defining the geometrical manifold of bumpers and interpolate following the manifold. We are looking to incorporate mechanical information such as von Mises maps to enrich the description of the manifold.

Our present focus, which we hope to be able to illustrate during the conference, is to make use of the enriched manifold to be able to optimize along the variety of "validated design', that is, to create know-how optimization tools.

Acknowledgements: O. Allix would like to thank the French National University Council and ENS Paris-Saclay for supporting his sabbatical at UPV, which made it possible to closely interact with the colleagues from I2MB-UPV.

Key Words: *Finite Element Method, Digital Twin, Informed Machine Learning, Hybrid model*

A hybrid model combining the Finite element method (FEM) and neural network is introduced for forward and inverse problems. The model uses the discretized form of the governing equation as the loss function of the neural network. As mentioned above, the requirement for the target variable for the neural network's training is avoided, resulting in an unsupervised learning approach. The hybrid model falls in informed machine learning [1] and introduces a new direction to combine FEM and neural network.

The proposed hybrid model can create a surrogate model for forward solving of Partial Differential Equations. The FEM will provide the discretized system matrix and force vector, whereas the neural network predicts the solution vector. The matrices, along with the prediction, are used inside the loss function of the neural network. The calculated loss is backpropagated through the neural network to optimize the network parameters. A digital twin can use such trained networks for real-time simulation.

The same algorithm can be used for inverse problems as well. The unknown parameters are modeled using a neural network and assembled to the system matrix using FEM principles. Using the measured response and known forces, a similar loss function as that for the forward problem is formulated and backpropagated to optimize the parameters of the neural network. The trained neural network can then be used as the model for unknown parameters of the model.

Both the forward and inverse problems are demonstrated with the examples. Forward solving is demonstrated for the wind load on a high-rise building [2]. The application of the surrogate model is shown with the help of an uncertainty quantification problem using the Monte-Carlo method.

The inverse problem is demonstrated in finding the bearing parameters of fluid bearing in a rotor dynamics problem. The speed-dependent stiffness coefficients of the fluid bearing are modeled using a neural network and trained using the vibration measurement and known unbalance in the test rig.

Key Words: Geometric Deep Learning, Structure-Preserving Neural Networks, GENERIC

Deep learning-based artificial intelligence success in computer science has encouraged many authors to transfer this new technology to the physical simulation field. The challenging task of those research lines is to adapt state-of-the-art deep learning tools into physics and engineering, two disciplines with centuries of experimental and theoretical background. In our work, we develop a deep learning framework to predict the evolution of complex physical systems using that knowledge in a form of several inductive biases, which guide the learning algorithm to find the physically consistent target function.

The first inductive bias enforces the metriplectic structure of dissipative dynamics via the GENERIC formalism [1]. This formulation imposes the physical consistency by using thermodynamics, describing the system as a sum of a conservative term (related to conservative energy and Hamiltonian mechanics) and a dissipative term (related to entropy and the irreversible physics of the system). Furthermore, the degeneracy conditions of this formulation ensure the energy conservation and the entropy inequality, fulfilling the first and second laws of thermodynamics respectively.

Learning this specific mathematical structure is a challenging task for a standard neural network, as physical systems may have complex local interactions based on geometrical constraints. Thus, we develop a graph-based architecture to take advantage of the structured mesh information and make computations over the topology of the domain [2]. The use of geometric deep learning is also convenient for introducing symmetries to the problem, such as permutation or translational invariance, which decrease the data consumption of the method. The combined use of the metriplectic and geometric bias is tested with several nonlinear examples of solid and fluid mechanics.

Key Words: Scientific machine learning, dissipative systems, inductive biases, GENERIC.

Soon after the widespread interest in applying deep learning technology to the field of computational mechanics appeared, our community has realized that it is of utmost importance to enforce the fulfillment of physical laws to guarantee that the obtained predictions comply to the physical reality. In general, this is done through the employ of inductive biases of various types.

In some of our previous works [1, 2] we have employed the enforcement of the metriplectic structure of dissipative problems through the so-called GENERIC formalism [3]. Using GENERIC as an inductive bias ensures the satisfaction of the first and second principles of thermodynamics (conservation of energy in closed systems and non-negative entropy production, respectively). This enforcement is done in a soft way in our works, although recent approaches to the same problem have chosen to do it in a hard way [4, 5].

In this work we will discuss about the statistical mechanics of machine learning, the implications of choosing GENERIC as the inductive bias and the appealing of the results it gives.

Key Words: Surrogate model, Proper orthogonal decomposition, Numerical simulations, Solid oxide fuel cell, Electrochemical potential

The capability of solid oxide fuel cell (SOFC), which generates electricity using hydrogen as a fuel, is determined by not only the electrochemical performance but also the mechanical durability, for which predicting the transient nature of the electrochemical potentials is of paramount importance. To this end, Terada et al.[1] and Muramatsu et al.[2] proposed the numerical analysis method to evaluate the time-varying electrochemical potential distributions under various start-and-stop control environments. However, due to the highly nonlinear behavior such as the environment-dependent physical properties, fairly fine time step should be taken to stably obtain the results with high accuracy.

To overcome this issue, we propose a method of surrogate modeling with proper orthogonal decomposition (POD) that is capable of predicting the non-stationary distributions of electrochemical potentials in an efficient way. First, a series of *offline* numerical analysis is carried out under various target conditions taken, e.g., for design purposes. Second, POD is applied to the obtained data matrix that stores all the results following certain rule of thumb to represent each simulation result by a linear combination multiplied by the corresponding coefficients. Third, the coefficients are interpolated within the parameter space specifying the prepared analysis conditions to construct the surrogate model that enables us to realize *online* numerical analysis under an arbitrary condition. A representative numerical example is presented to demonstrate the capability of the constructed surrogate model, and for verification purpose the predicted results are compared with some of the *offline* analysis results that are not contained in the original data matrix used for POD.

In reinforcement learning (RL), an agent learns from the contact with the environment to perform a certain task. Such systems generalize experiences so that previously acquired knowledge is employed in new, but similar, goals. Model-based reinforcement learning helps to predict the output of actions based on simulations. In this scenario, the bottleneck of the approach is the model's accuracy to match reality. The correction of the model can be part of the RL optimization to learn an appropriate replica of the world.

We introduce a RL approach to correct fluid dynamics from the interaction with reality. We propose as a source model a data-driven physically informed digital twin of a glass full of a liquid based on the GENERIC formalism [1][2] to ensure the thermodynamical consistency of the simulation. The integration is performed in realtime from the solely evaluation of the free surface of the liquid, detected by computer vision techniques. From its study with recurrent neural networks we unveil the not measured information of the dynamics to perform the simulation.

The digital twin becomes a hybrid twin that learns to correct the deviations in the free surface reconstruction to maximize the similarity with the ground truth. The error is backpropagated through only a few activated layers of the whole architecture to preserve the patterns and useful insights already learnt from full field information. As a result, the reduced order space and the simulator are both adapted to the new, computational and real, liquids perceived.

A Bending Consistent Meshfree Formulation for Reissner-Mindlin Plates

Yen-Ling Wei, Tsung-Hui (Alex) Huang*
Department of Power Mechanical Engineering, National Tsing Hua University, Hsinchu, Taiwan.
*thhuang@mx.nthu.edu.tw

The Reissner-Mindlin plate theory is attractive as it considers shear deformations through the thickness of a plate that can be applied to a broad range of engineering structures. However, it also suffers from the notorious "shear locking" when the plate thickness approaches the Kirchhoff limit. In the meshfree method, the employment of the nodal smoothing technique, as well as the higher-order reproducing kernel (RK) approximation, can easily satisfy the bending exactness (BE) and Kirchhoff mode reproducing condition (KMRC), which leads to a locking free meshfree solution [1]. Nevertheless, it is computationally inefficient due to the introduction of the smoothing cells and the larger kernel support size. To address this issue, in this study, we present a bending consistent Galerkin formulation that aims to fulfill the BE and KMRC efficiently. We first utilize the idea in the variationally consistent integration (VCI) [2] to correct the test function such that the residual of BE is automatically minimized. In this way, the smoothing procedure is bypassed, which speeds up the simulation. Then, to enable the use of a smaller support size, we introduce the quasi-consistent approximation technique in [3] with proper error control to avoid the moment matrix singularity in the RK approximation when a quadratic basis is used with smaller support size. In this way, the RK approximation still meets the KMRC, but the approximation construction is more efficient. For the stabilization of low energy instability in the proposed nodal integration framework, a variational multiscale stabilized (VMS) method [4] is used to eliminate the spurious oscillatory modes. The proposed framework is validated by solving various numerical examples, and the numerical results are locking-free and are more efficient than the conventional approaches.

A Coupled Meshfree and Infinite Element Approach for Non-Fourier Heat Conduction Problems

Kuan-Chung Lin [1*],

[1] National Chen Kung University, No.1 University Road, Tainan 70101, Taiwan,
kclin@gs.ncku.edu.tw

Key Words: *meshfree methods, infinite element methods, non-Fourier heat conduction, infinite domain, naturally stabilized, variational consistency conditions*

In this research, a stable and efficient meshfree/infinite element approach is introduced for solving a half-space with a heat source. The non-Fourier heat equation is used to obtain the finite thermal propagation speed. The unbounded properties of the semi-infinite domain defined as the far-field are simulated by infinite elements [1, 2]. Utilizing the infinite elements can reduce the size of the numerical model to save computing time. For the near field, a nodally-integrated reproducing kernel particle method (RKPM) is used. Meshfree methods are friendly for avoiding mesh issues such as mesh entanglement and mesh distortion. The nodally integration method is used in this research, and this method usually provides poor accuracy and unstable results in meshfree methods. These issues have been addressed using the naturally stabilized nodal integration [3] and variational consistency conditions [4]. The responses without a self-oscillation frequency are investigated. In addition, corresponding analytical solutions have been derived in the frequency domain. Finally, some conclusions are made and discussed by comparing the results obtained with the corresponding analytical solutions.

A Stabilized Galerkin Mixed Formulation for Nearly Incompressible Material

Chia-Lien Chao, **Tsung-Hui Huang***

Power Mechanical Engineering, National Tsing Hua University, Hsinchu, Taiwan

Key Words: *Mixed Formulation, Stabilized One-Point Integration, Strain Smoothing, Variational Multiscale Method*

The conventional numerical methods in modeling nearly incompressible materials usually suffer from "volumetric locking." Although the usage of the mixed formulation can alleviate the locking issue, the pressure oscillation occurs due to the violation of the LBB condition. Besides, low energy instability exists in conventional nodal integration methods in meshfree and mesh-based methods, such as SCNI [1] and SFEM [2]. This research develops a stabilized Galerkin mixed formulation within a one-point integrated framework for modeling nearly incompressible materials that bypass the abovementioned issues. The variational multiscale (VMS) formulation [3] is introduced to circumvent the low energy modes and LBB instability in the conventional Galerkin formulation. The multiscale decomposition of the variational equation results in a residual-based stabilized Galerkin framework. The derived fine-scaled terms act as a stabilization that mitigates the hourglass instability and pressure oscillation. The strain smoothing and strain divergence smoothing method is employed to ensure the satisfaction of the integration constraint in the new Galerkin formulation. A series of numerical examples under the incompressible limit are examined to verify the effectiveness of the new formulation. In numerical testing, the proposed method outperforms other conventional stabilization approaches [4].

Iso-geometric Analysis Method for Thermal Fatigue of Wafer Level Chip Scale Package

Hao Yu Wang[1*], Pai chen Guan[1]

[1] National Taiwan Ocean University, Department of Systems Engineering and Naval Architecture, No.2, Beining Rd., Zhongzheng Dist., Keelung City 202, Taiwan, Paichen@ntou.edu.tw

Key Words: *Solder Ball, Iso-geometric Analysis, Optimization, Constitutive Model, Thermal Fatigue, Fatigue Model*

The failure of electronic packaging often starts from the failure of solder. Solder balls are soldering materials used for chip-size ball-grid array package. The reason for the failure of the solder is that when the solder ball is subjected to thermal loading, the thermal stresses concentration occurs at the solder boundary due to the coefficient of thermal expansion (CTE) mismatches between different materials. This cyclic stress loading will produce irreversible deformations such as creep and plastic deformation. When the permanent deformation reaches a certain level, fatigue crack will propagate along the solder ball boundary and leads to failure. The current accuracy of evaluating the reliability of electronic packaging depends on the material constitutive model, finite element model and fatigue life prediction model. In this research, we use the optimized iso-geometric analysis (IGA) method for numerical simulation of thermal-mechanical coupled problem. The IGA method uses non-uniform rational B-splines (NURBS) as the shape function, which is a combination of B-spline and weight coefficients. In computer-aided design, due to the introduction of weights used to describe irrational functions, NURBS can accurately describe the geometry of solder balls. Compared with the finite element method, the IGA method can reconstruct the geometric field with fewer points. In the physical field, we introduce the optimization method, which treat both control values and weights as nodal variables. Therefore, we proposed an alternating iteration scheme, which uses the Galerkin weak form of governing equation to solve the control values, and then we update the weights by the least square method and Newton's method. The control values should also be updated for the new weight functions to obtain better physical solution. The constitutive equation used in this research is Anand model [1]. Anand model is mainly used to describe the nonlinear deformation behavior of solder balls. To calculate the Anand model, nine parameters must be determined and its stress and deformation resistance must be nonlinearly iterated [2]. Thermal fatigue refers to a progressive degradation of a material due to cyclic fluctuations in temperature. The fatigue model we chose is Coffin Manson's plastic strain-based model to predict low cycle fatigue, and Basquin's elastic strain-based model to predict high cycle fatigue. The results of this research found that the IGA method can reconstruct geometric and physical fields with fewer points than finite element method. Since there are fewer points, the calculation time can also be reduced.

Key Words: *radial basis function; weighted essentially non-oscillatory; WENO-AO; RBF-WENO-AO; hyperbolic equation*

We develop a framework for finite volume radial basis function (RBF) approximation of a function u on a stencil of mesh cells in multiple dimensions. The theory of existence of the approximation is given. In one dimension, as the cell diameters tend to zero, numerical evidence is given to show that the RBF approximation converges to u to the same order as a polynomial approximation when the RBF is infinitely differentiable. Specific multiquadric RBFs on stencils of 2 and 3 mesh cells are proven to have this convergence property. A two-level RBF based weighted essentially non-oscillatory (WENO) reconstruction with adaptive order (RBF-WENO-AO) is developed. WENO-AO reconstructions use arbitrary linear weights, and so they can be developed easily for RBF approximations, even on nonuniform meshes in multiple dimensions. Following the classical polynomial based WENO, a smoothness indicator is defined for the reconstruction. For one dimension, the convergence theory is given regarding the cases when u is smooth and when u has a discontinuity. These reconstructions are applied to develop finite volume schemes for hyperbolic conservation laws on nonuniform meshes over multiple space dimensions. The focus is on reconstructions based on multiquadric RBFs that are third order when the solution is smooth and second order otherwise, i.e., RBF-WENO-AO(3,2). Numerical examples show that the scheme maintains proper accuracy and achieves the essentially non-oscillatory property when solving hyperbolic conservation laws.

Solving large-scale engineering problems by ghost point method and domain decomposition method

Key Words: *meshless methods, ghost point method, domain decomposition method*

In this study, a meshless numerical model, based on ghost point method and domain decomposition method (DDM), is proposed to analyze large-scale engineering problems. The ghost point method is one of the newly-developed meshless methods, which can avoid the time-consuming tasks of mesh generation and numerical integration. The ghost points method adopted the concept of ghost points to improve the conventional Kansa's method by separating the collocation points and the source points and extending the source points to a covering domain region. As a result, this simple process of the ghost point method can significantly increase the stability and accuracy of the Kansa's method. In order to determine the optimal shape parameter of the radial basis function, the modified Franke's formula and the leave-one-out cross-validation (LOOCV) algorithm are adopted in this study. However, the full-populated system of linear algebraic equations in the ghost point method limits the applicability to solve large-scale engineering problems. In this study, the ghost point method cooperates with the DDM to reduce the requirements of huge computers resource when the large-scale engineering problems are considered. Several numerical examples will be provided to verify the feasibility, accuracy, and stability of the ghost point method combined with the DDM to solve large-scale engineering problems.

Key Words: 2nd order consistency, Laplacian, Mixed derivative

Smoothed Particle Hydrodynamics(SPH) and Moving Particle Simulation(MPS), which are both mesh-free particle method with the Lagrangian description, have high potential for simulating free-surface flows. Both SPH and MPS have weakly incompressible and incompressible schemes, but weaknesses may remain especially in the second-order differential model with Laplacian operator and mixed derivatives. Although the gradient operator in SPH uses a renormalization to overcome the weakness in the case of non-uniform particle distribution, the conventional Laplacian operator in both SPH and MPS loses accuracy in the case of non-uniform particle distribution.

Recently, the Least-Square MPS(LSMPS) [1] gives consistent higher-order differential operators, and the convergence profiles of these operators show good results not only for uniform particle distributions, but also for non-uniform particle distributions. A similar corrections for Laplacian and mixed derivative operators in SPH have been proposed by Fatehi and Manzari [2] and Lian et. al. [3], but there is no clear discussion of their similarities and differences.

In this study, we reformulate the second-order derivative operator including the Laplacian and the mixed derivative using the consistency of the Taylor expansion in order to preserve the predicted truncation error. The convergence of the Laplacian and mixed operators is verified for several influence radii of SPH, and the relationship between the existing and proposed models is shown.

Key Words: *Isogeometric analysis; MPS method; Coupling algorithm; Fluid–structure interaction*

A two-way coupling method of the three-dimensional (3D) isogeometric approach and the least-square moving particle semi-implicit method (LSMPS) is presented for handling the fluid–structure interaction problems. This method takes advantages of isogeometric analysis (IGA) for structure deformation, e.g. the exact representation of the structure geometry and high accuracy for solution fields with relatively few elements, and that of the LSMPS method for fluid flow, e.g. its consistent discretization for both internal particles and boundary conditions. When the fluid is solved by the LSMPS method, the NURBS (Non-Uniform Rational B-Splines) surfaces provide boundary conditions for the LSMPS method. Afterward, the pressure on the NURBS surface is first evaluated from the pressure and the corresponding derivatives at the LSMPS particles by using the Taylor series expansion, and then integrated to determine the pressure force at the virtual points on the NURBS surface by using the Newton–Cotes method. Subsequently, the pressure forces at the virtual points are distributed onto the control nodes (i.e. control points) of the IGA elements so that the structure deformation can be analyzed by using the IGA method. The coupling algorithm is based on a Lagrangian framework and can handle the boundary conditions and the fluid–structure interactions accurately and easily. Finally, three examples, i.e. fluid flowing in a rigid pipe, fluid-tank, and fluid-torus interactions in the elastic regime, are simulated to demonstrate the accuracy and validity of the proposed coupling method.

A Multiphase Axisymmetric Model of Moving Particle Semi-implicit Method

Jinchen Gao[1], Gen Li[2*] and Junjie Yan[1]

[1] State Key Laboratory of Multiphase Flow in Power Engineering, Xi'an Jiaotong University, Xi'an 710049, China

[2] School of Electric Power Engineering, South China University of Technology, Guangzhou, 510641, China, genli@scut.edu.cn

The moving particle semi-implicit method (MPS) is a mesh-free particle method, which has great advantages in dealing with large deformation problems due to the Lagrangian nature. However, for the MPS method, the neighbor particle list is updated in each time step, thereby resulting in extensive calculation. Given the significant increase of particle number for the 3D simulation, the high computational cost of the original MPS method limits its application in handling the 3D axisymmetric problem. To improve the computation efficiency of the particle model, scholars have explored the axisymmetric model suitable for the smoothed particle hydrodynamics (SPH) method. These axisymmetric SPH models [1] have been proved to have the ability to significantly reduce the calculation cost. Nevertheless, an axisymmetric model applicable to the MPS method has not been published in the literature.

In this study, a multiphase axisymmetric-MPS model based on the Cartesian coordinate system was developed to deal with 3D axisymmetric problems. In the proposed model, as shown in Fig. 1, the virtual rotating particles are applied to supplement the neighbor particles of the particles of the 2D plane for considering the hoop stress and the Langrangian interpolation characteristics. The divergence, gradient, Laplace operator, and PPE models are re-established to consider the interaction among virtual rotating particles and rotating surface particles. To test the accuracy and stability of the model, the case of the cylindrical capillary jet breakup [2] is simulated.

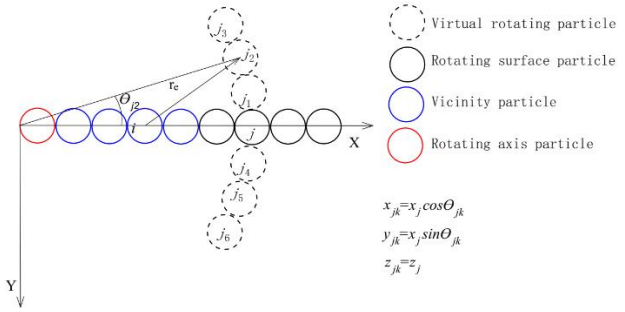

Fig. 1. The initial particle distribution of the axisymmetric-MPS model

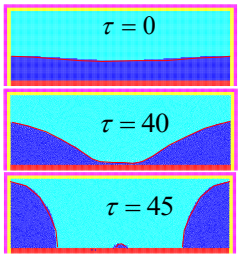

Fig.2. Comparison of the present instantaneous interface with reference results[2] (red line)

The initial configuration of the long cylindrical capillary jet details in Ref. [2]. At the density ratio $\rho_2 / \rho_1 = 0.8$, the disturbance wave number $k = 0.7$, viscosity ratio $\mu_2 / \mu_1 = 0.01$, and Reynolds number $Re = 1$, Fig. 2 shows the instantaneous interface of the capillary jet in the 2D rotating axial section simulated by the method proposed herein. The good agreement shown in Fig. 2 indicate that the perfect reproduction of the procedure of the capillary jet breakup tests the accuracy and stability of the model.

Key Words: *Particle Method, Linear Complementarity Problem, Incompressible Fluid, Rigid bodies*

In this study, we propose a method to achieve strongly coupled calculations of incompressible fluids and rigid bodies using the particle method. The proposed method is based on the authors' previous study [1] and adopts a velocity-based formulation and derives a linear complementarity problem as an equation to obtain the pressure due to the requirement that no attractive force is generated between particles. This linear complementarity problem is also used for contact between rigid bodies, and by solving the constraint conditions for incompressibility and contact between rigid bodies, as well as the constraint conditions for the interaction between rigid bodies and incompressible fluid in the same way, strong coupling between incompressible fluid and rigid bodies is accomplished.

Furthermore, we introduce velocity-based constraint conditions that generalize the nature of the constraint conditions required to perform the strong coupling calculation using the same method, and propose a more flexible and versatile system for the strong coupling calculation that can be applied to other than incompressible fluids and rigid bodies.

In order to validate the method, we show examples of calculations performed to confirm that the method correctly calculates the behavior of a rigid body, the behavior of an incompressible fluid, the interaction between a rigid body and an incompressible fluid, and the strong coupling. The examples include calculations for scenes consisting only of rigid bodies, hydrostatic pressure calculations, calculations for dam break problems, and calculations for buoyancy forces, etc.

Key Words: Particle method, Multi-resolution, Particle addition/deletion, Error estimation

Particle methods are well-suited to model complex fluid phenomena such as multiphase and free-surface flow. In recent years, several successful multi-resolution particle implementations have been proposed based on prescribed high- and low-resolution sub-domains. However, speed-ups are limited for many applications, such as for multiphase and free-surface flows, where the high-resolution regions are moving in time.

In this study, an adaptive multi-resolution scheme is considered based on error estimation. Specifically, the error estimation is defined by the local truncation error for the LSMPS spatial discretization of velocity. In [1], particles were resized based on the error estimation. This technique gave accurate and stable results for a two-dimensional rotating cylinder problem with a small clearance. However, the application is limited to when the critical regions changes slowly in time. To increase applicability, particle addition and removal schemes have been incorporated to handle faster resolution changes. To reduce pressure fluctuations, particle addition and removal occur over several time-steps by using a time-dependent weight function. Its performance has been evaluated for Karman vortices.

Time-marching schemes for particle methods are seldom fully implicit. Therefore, the time-step length is typically restricted by the smallest particle sizes. To handle this issue, time-step length restrictions are applied to the fluid particles individually. This enables the use of longer time-step lengths for most particles. The main challenge with the multi-time-stepping is the implicit pressure calculation at intermediate time-steps when not all particles are updated. In this study, the pressure is either assumed to be constant during a time-step or that only the low-frequency part of the pressure field changes. The latter option can be implemented by using a multigrid solver with high-frequent smoothing only over updated particles.

Key Words: *Particle method, Melt spreading, Nuclear Severe Accident, Solidification,*

During a postulated nuclear severe accident, molten material called corium spread on the containment floor at Primary Containment Vessel (PCV). Moving Particle Hydrodynamics method (MPH method) [1,2] which is a new particle method has advantages to simulate the melting and solidification, where the solid and the liquid coexist. In this paper, the corium spreading behaviours were analyzed with the MPH method.

The 2 different experiments were analyzed with the MPH method. The calculation geometry was summarized in Fig.1. In Fig.1 (a), the low-viscosity molten metal discharged from the vessel and spread on the stainless plate with a flat surface. In Fig.1 (b), the high-viscosity molten material spread on a ceramics plate.

The simulation result using the low-viscosity material was shown in Fig.2. The molten metal drastically spread in short time with a flat surface and the solidification started from the edge of the metal. The molten metal solidified in circle shape. Fig.3 is the results of the highly viscous spreading behavior [3]. Unlike Fig.2, the molten corium spread gradually on the ceramics substrate and solidified due to the radiation from the free surface. The results indicated that the MPH method was capable of simulating the corium spreading behavior in the nuclear severe accidents.

Key Words: *Particle methods, MPS, MPH, SPH, CFD, Fluid Lubrication*

Nowadays, energy and resource saving is significantly required in order to realize a sustainable society. In that context, fluid film lubrication of machine elements such as bearings, which leads to smooth movement by avoiding metal-to-metal contact and wear, is essential to operate a mechanical system in well-functioning conditions. As for the fluid film lubrication, lowering friction loss and extending bearing life are strongly demanded for the sake of energy and resource saving. The straightforward approach is to achieve the fluid film lubrication with small amount of lubricant to reduce stirring and sliding friction losses in bearings. Therefore, it is important to understand and predict the detail of lubricant behaviour and distribution in an entire bearing. And the computational fluid dynamic (CFD) is expected to be a promising approach to realize that.

Considering practical machine elements such as bearings, a meshless, Lagrangian, particle-based method is considered to be a promising approach since it is more suitable to model free surfaces, moving or deforming boundaries, multi-phase flows, and complex geometry than the conventional grid methods such as the finite volume method. In this study, a physically consistent particle method, the moving particle hydrodynamics (MPH) method,[1] was applied to the fundamental fluid lubrication problems: the wedge film and the squeeze film in order to confirm its capability. The compressible version of the MPH method, so-called MPH-WC,[2] was employed here. The computed pressure profiles induced in the wedge and squeeze films were validated against analytical solutions based on the classical Reynolds equations[3] and good agreements were confirmed.

Key Words: *MPS method, Multiphase flow, Interface Tension, Potential Model*

Background and Objective

For capturing the complicated dynamics of surface, Moving Particle Semi-implicit (MPS) method has been increasingly utilized in diverse fluid problems. As one of the major types of methods to model surface tension, potential model [1][2] has been widely applied to the relatively complex surface dynamics thanks to its simplicity and stability. Recently, a new potential model to consider the "interface tension" between fluid-fluid interface as well as ordinary surface tension has been developed [3]. However, in the preceding potential models, the potential force acts not only on the surface/interface particles, but also on the particles inside the fluid bulk, leading to "particle clumping" involving the unrealistic hindering of fluid flow. Moreover, the preceding potential models require surface tension coefficients of fluids even when only fluid-fluid interface is considered, and no surface exists [3].

In this study, a new potential model has been developed for the fluid problem involving only interfaces, and no surface. With this model, potential force acts only on the particles on the vicinity of interfaces, avoiding the particle clumping and unnecessary requirement of surface tension coefficients of each fluid.

Developed Method and Validation

Based on the methodology proposed by Kondo et, al. [2], a new interface tension model with a new concept of "interface potential" has been introduced. The interface potential is defined only effective when particle i and its neighbor particle j belong to different fluid phases and is calculated with a coefficient determined only by the interface tension coefficient between these two phases. In this way, the potential force, which is derived as the negative of spatial derivative of interface potential, acts only on the particles on the vicinity of the interface of different phases.

The current model has been validated against the Taylor's shear flow problem and the result has been compared with the Zhu's existing interface potential model [3]. Since Zhu's model require surface tension coefficients of each fluid, which theoretically does not influence the prediction of Taylor's shear flow problem, they were determined arbitrary. However, in Zhu's model, the particles of the fluid bulk clumped due to the attractive force calculated by arbitrarily determined surface tension coefficients, leading to the failure to correctly model the influence of interface tension. On the other hand, the current model, which is based only on the interface tension coefficient, does not involve such particle clumping and the result relatively agreed with theoretical value.

Abstract: Based on the moving particle semi-implicit method (MPS), an elastic structure model and coupled solvers for fluid structure interaction is developed. The elastic structure model adopts Lagrangian kernel function and is discretized in Lagrangian system to ensure that the simulation process is more in line with the physical reality and avoid tensile instability. And Euler kernel function is used in fluid calculation. The fluid-solid coupled process is realized by sharing the load, velocity and position information of the solid boundary. The developed models are verified by the free oscillation of cantilever beam, violent sloshing test and dam break with elastic gate.

Development of Parallel Parametric Analysis System Using Coupling-Matrix-Free Iterative S-version FEM for Design of Structure with a Hole

Hiroki Suwa[1*] and Yasunori Yusa[2]

Key Words: *Parametric Study, S-version FEM, Parallel Computing, Message Passing Interface*

Operators of the V-bending process have sometimes been injured because of broken pieces of a die. To prevent this accident, a structure of the die that is tough to break is required. In the previous study [1], we performed parametric studies of the V-bending die with a hole using the Coupling-Matrix-Free Iterative s-version FEM (CMFI s-FEM) [2]. In this method, because the mesh for the whole analysis domain and the mesh in the vicinity of the hole were created separately, it was not necessary to perform remeshing in a parametric study of the hole coordinates. However, there were two issues. The first one was computation time. Such parametric study needs several hundred thousand cases of analyses. Thus, the analyses took a very long computation time. The second issue was that it required a considerable amount of effort to perform the analyses manually.

In this study, to overcome these issues, we developed a parallel parametric analysis system. We implemented this system based on the Message Passing Interface (MPI), to perform a parametric study on a distributed-memory parallel computer such as supercomputers and PC clusters. In the parallel parametric analysis system, each analysis with a parameter such as the coordinates of a hole is assigned to an MPI process. Every analysis in the parametric study is computed completely in parallel.

A structure with a hole was analyzed for a demonstration of the parallel parametric analysis system. The shape of the hole was assumed to be an ellipse. As parameters of the parametric study, the central coordinates, the semi-major axis, the semi-minor axis and the angle of the elliptical hole were used. We evaluated the parallel performance, the computation time, and the convergence performance of the iterative solver of the parallel parametric analysis system based on CMFI s-FEM.

ACKNOWLEDGMENTS

The authors greatly appreciate Prof. Takashi Kuboki for helpful advices. The present study was supported by The Amada Foundation and JSPS KAKENHI Grant Number JP19K14871.

Development of snow accretion analysis method for railway vehicles

Kohei Murotani[1*], Koji NAKADE[2] and Yasushi KAMATA[3]

Key Words: *Snow accretion analysis, Airflow analysis, Coupled analysis, Railway vehicles*

In case where a train travels on the snow covered tracks, snow accretes to train bogies and grows up. When the accreted snow drops off the train bogies, it might damage the railway ground facilities along the tracks, the train devices, etc. To establish countermeasures against such snow accretion damage, we have developed a snow accretion analysis method in order to understand the snow accretion process.

The “snow accretion analysis method” developed by this research consists of an “airflow calculation”, a “trajectory calculation” and a “snow accretion calculation”. In the snow accretion analysis method, airflow velocity is obtained by the airflow calculation, trajectory of flying snow particles is calculated by the equation of motion for gravity and drag using the airflow velocity, snow accretion determination for objects is performed by the snow accretion calculation. When a certain amount of snow accretes to the objects, the accretion shape was suitably taken into consideration in the airflow calculation. We calculate again the airflow velocity using the updated accretion shape and the snow accretion growth using the updated airflow velocity.

In the snow accretion calculation, the theoretical principle is not yet established in the snow accretion phenomenon, and there are many unexplained parts. Therefore, in this research, we are developing the snow accretion determination algorithm by the experimental method. It has been confirmed by the snow accretion experiment that the snow accretion shape has a snow accretion angle according to the speed and property of the flying snow particles. In order to incorporate these experimental results, a snow accretion determination algorithm by the velocity and collision angle of the flying snow particles have been developed.

In this research, two kind of validations are performed using a snowfall wind tunnel. First, a snow accretion analysis on a cubic model is performed, and it was confirmed that the snow accretion analysis reproduces the snow accretion experiment with a relative error of 6%. Next, each snow accretion analyses on two railway car-body models are performed, and it was confirmed that the snow accretion distributions were similar with the experiments. As this result, it became possible to consider places and causes where snow accretion occurs for the railway car-body models by the snow accretion analysis.

Key Words: *Material point method, Extended B-spline basis function, F-bar projection, nearly incompressibility, Nitsche's method*

A novel computational method incorporating the F-bar projection method into extended B-spline-based implicit material point method (EBS-MPM) is proposed to avoid not only volumetric locking but also stress oscillations. MPM with the standard B-spline basis functions is capable of suppressing the cell-crossing error caused by particles crossing background grid boundaries and reducing the quadrature error. Furthermore, EBS-MPM enables us to avoid both stress oscillations arising from inaccurate numerical integration and ill-conditioning of their resulting tangent stiffness metrices thanks to extended B-splines (EBS) which are active on the background grid containing smaller number of material points than interior ones. In addition, boundary conditions are imposed arbitrarily by the application of the Nitsche's method, while the capability of conventional MPMs is limited [1]. Although the applicability of EBS-MPM to nearly incompressible and plastically incompressible material problems was investigated, it has been confirmed that volumetric locking was avoided by higher-order EBS, but stress oscillation was not [2]. Various countermeasures against incompressibility have been proposed, but incompressible constraints are interpolated by basis functions lower than those for displacement in most of them. Since higher-order EBS are preferably utilized to suppress the cell-crossing error in EBS-MPM, it is necessary to reduce the order of basis functions appropriately. Therefore, we incorporate the $\bar{\mathbf{F}}$ projection method into EBS-MPM in this study, which showed the efficacy to solve nearly incompressible problems with a pure displacement formulation using higher-order basis functions [3]. This is expected to be a novel stabilizing scheme for MPM which is able to avoid volumetric locking as well as stress oscillations due to incompressibility. In the presentation, several representative numerical examples are presented to demonstrate the performance of the proposed method.

Key Words: Discrete Element Method, Granular, Event-Driven, Impulse-Based Simulation

The Discrete Element Method (DEM) models collision of particles as a spring-dashpot system[1]. The eigen frequency obtained from the oscillation equation defines an upper limit of the time steps in DEM. Since higher stiffness of the spring for accurately modeling the collision requires smaller time step, DEM-based computations tend to require high computational cost. In other hand, the event-driven algorithm, which adopts an impulse-based expression of the collision and solves all binary collisions by analytically determining the trajectory of particle motions, is developed in studies on molecular dynamics[2]. It represents the time evolution by varying time steps according to the collision events, and there is no upper limit of the time steps for stability of computation such as DEM. However, the time steps become zero when the collision frequency is very high. In addition, this algorithm has the inherent sequential nature which prevents parallelization unless special implementation.

In this study, we propose Impulse-Based DEM (IB DEM). We locally applies the event-driven algorithm to achieve stable and accurate simulation with relatively large time steps. Our proposed method determines the motion of each particle based on known values of its neighboring particles in the previous time step, which are inside the local region centered on the particle. The event-driven algorithm is applied to the calculation in the local region assuming that velocities of particles are constant in the time step. Moreover, our proposed method can be parallelized because each particle is calculated independently. We show results of analyzing bead mills by IB DEM.

Key Words: *Material point method, Saturated soil, Extended B-splines*

Extended B-spline-based implicit material point method [1] is developed for the coupling analysis of a saturated soil with the aim to simulate a collapse process of ground structure, which is mainly caused by seepage flow in a long time scale and involves transition processes from a solid to flowing mixture. The governing equations are formulated based on the full formulation [2] of the theory of porous media, in which primary variables are solid displacement, fluid velocity, and fluid pressure. This formulation realizes the simulation of pore fluid flow in a highly permeable porous structure as shown after collapsing the structure skeleton. The continuum body of the solid skeleton is discretized with a set of Lagrangian material points that possess the information of the solid and liquid. In order to improve the robustness and efficiency in comparison with the previous studies, we apply an implicit scheme enhanced by extended B-splines (EBS) [3]. At the same time, with the aim to weakly impose an arbitrary boundary condition of saturated soil, such as permeable/impermeable surface, Nitsche's method is introduced with boundary points. Also, the stabilized method based on the variational multiscale method is utilized for the stabilization of the pressure fields without losing continuity characteristics of B-spline basis functions. Several numerical examples are simulated to demonstrate the performance and capability of the proposed method in stably solving the large deformation of solid skeleton and flow of pore fluid.

Modelling of Interface Tension using Multi-resolution MPS Method with Polygon Boundary

Jing Zhang[1*], Jinbiao Xiong[2]

[1] Shanghai Jiao Tong University, Shanghai, China, zhang-jing@sjtu.edu.cn
[2] Shanghai Jiao Tong University, Shanghai, China, xiongjinbiao@sjtu.edu.cn

Key Words: *MPS (moving particle semi-implicit) method, Polygon wall, Multi-resolution, Surface tension*

Simulation of severe accident in nuclear reactor involves multiphase flow phenomena with free surface or component interfaces. The moving particle semi-implicit (MPS) method [1] waives the topological mesh which has been extensively employed in multiphase simulation. In the traditional MPS method, the uniform-size particles are utilized, which leads to high computation cost when high spatial resolution is demanded in the region of interest, e.g., near the phase interfaces [2]. Meanwhile, a large number of wall particles are employed to model the wall boundaries, which further increases the computation resource.

In order to improve the computation efficiency and accuracy, the multi-resolution method [3] and polygon boundary [4] are implemented into the MPS method. In order to accommodate with the non-uniform particle size, several basic models of the MPS method are modified, including particle effective radius, gradient operator model, Laplace operator model, and free surface identification model. Based on dam-break simulation, it is verified that utilization of multi-resolution particles can capture more complex free surfaces. The polygon boundary eliminates the wall particles. The wall distance and background grid are introduced to calculate the contribution of the boundary to fluid particles. The zero-pressure gradient at the wall is realized with the virtual mirror particles about the wall. For the verification of the polygon algorithm, the static pressure in a water column is simulated. The discrepancy between the pressure at the monitoring point and the theoretical value is 6.25%.

In this paper, potential force interface tension model [5] is improved to expand its application to multi-resolution particles. Four sets of coefficients are calculated when the particles are in two sizes, namely large-large, large-small, small-large, and small-small coefficient. After selecting the corresponding coefficient, the potential force can be calculated between fluid particles. Regarding the wall contact cases, temporary wall particles are set in the range of the effective radius of the particle. To verify the accuracy of the contact angle, a floating droplet is simulated which shows accurate prediction between fluids. In addition, the wall contact angle is simulated and the predicted value agrees well with the theoretical one. Therefore, the improved interface tension model can be applied to the multi-resolution simulation.

Key Words: *Mesh-Free Particle Method, MPS Method, Boundary-Fitted Coordinate Transformation*

We propose an effective numerical method for simulating ocean waves based on a mesh-free particle method with a bottom boundary-fitted coordinate transformation. While particle methods such as the smoothed particle hydrodynamics (SPH) and the moving particle semi-implicit/simulation (MPS) method have been applied to simulations of free-surface flows including tsunamis [1, 2], they have difficulty in handling curved boundary such as seabed. Though an existing study has proposed the curvilinear SPH [3], which adopts a coordinate transformation corresponding to bottom boundaries, the curvilinear SPH has mainly focused on simulation of inviscid flow ignoring the viscous term.

This study proposes a bottom boundary-fitted coordinate transformation for the Navier–Stokes equations considering the viscous term. We adopt the explicit MPS method as a mesh-free particle method, where pressure field is explicitly computed instead of solving the pressure Poisson equation. We derive a mixed derivative model of the MPS method since the coordinate transformation of viscous term generates the mixed partial derivatives. Our proposed method including the derivative model is verified by the simulation of a hydrostatic pressure problem with round-shaped bottom.

Key Words: *Particle method, Viscoelastic fluid, Weissenberg effect, Oldroyd-B model*

The polymer industry is interested in free-surface flow of viscoelastic fluids. Normal stress differences cause unique behaviors known as Weissenberg effect and so on. In this study, a new particle method was developed to predict the behavior, free-surface flow under normal stress differences. Up to the present, a number of numerical methods haves been developed for free-surface flows. In this study, the moving surface mesh-incorporated particle method developed by Matsunaga *et al*. [1] was used. In this method, the free-surface boundary can be more rigorously treated by using a surface mesh. The LSMPS scheme [2] was used as the spatial discretization method. Oldroyd-B model [3] was adopted as a viscoelastic model, with which an analytical solution can be derived for the test case considered in this study.

To examine the accuracy of the proposed method, problems where the Weissenberg effect occurs were simulated. The Weissenberg effect, also known as rod-climbing effect, is a typical phenomenon of viscoelastic fluids. Surface shape computed by proposed method with coarse spatial resolution didn't match the curve calculated by a finite element method in the previous study [4]. On the other hand, the shape computed with fine spatial resolution was close to the curve of previous study. Thus, it is implied that the result obtained by using the proposed method with the fine resolution has a comaparable accuracy to the previous study. To compare climbing heights between numerical results and theoretical solution [5], numerical simulations were performed at several Weissenberg numbers. Numerical results were in good agreement with theoretical solutions in lower Weissenberg numbers. Reproducibility of theoretical solution reduced as the Weissenberg number increases. However, it was confirmed that the results with fine resolution is close to theoretical solution. Through several basic problems, the proposed method is found to have the capability to reproduce Weissenberg effect. Hence, it is expected that the proposed method is able to predict other behaviors of free-surface flow caused by normal stress differences.

Key Words: *MPS method, Weakly-compressible MPS, Bubble rising, Pressure discontinuity, Large density ratio*

Bubble dynamics are common encountered in a wide range of engineering applications. However, abrupt density and pressure drop would occur at the interface due to the discontinuity of fluid properties, e.g., density, viscosity and surface tension. Owing to the mathematical discontinuity, numerical simulation of bubble dynamics, especially for large density ratio, is always challenging.

The Lagrangian particle methods, such as the Moving Particle Semi-implicit method (MPS) [1], have attracted great attentions in simulating free surface and multiphase flows due to its distinct advantage in tracking moving interfaces.

This study presents a new coupled particle method for bubble dynamic with large density ratio. The proposed scheme couples the incompressible MPS and Weakly Compressible MPS [2], representing the liquid and gas phases, respectively. The liquid-gas phase interface is explicitly represented by a moving interface mesh, consisting of discrete nodes. The stress balance equations at the interface are adequately enforced on these interface nodes. The surface tension is considered as pressure jump at the interface [3] rather than treated as volume force. Without applying the smoothing or averaging scheme, the density and viscosity are preserved discontinuous across the interface. Benefiting from the least squares scheme [4], axisymmetric formulation is straightforwardly introduced. To save computational cost, a multi-time step algorithm is developed further. Moreover, to maintain quasi-irregular particle distribution and control the multi-spatial resolution dynamically, a user-defined particle shifting scheme is proposed.

Several benchmark tests are conducted to verify the accuracy and efficiency of the developed method. Satisfying agreements are obtained by comparing with reported numerical solutions and experimental data.

Multiple solvers for implicit temperature calculation of plate heat conduction with MPS method

Sijun Li, Xinkun Xiao, Qinghang Cai, Yubao Zhong, Ronghua Chen, Kailun Guo, Wenxi Tian, Guanghui Su, Suizheng Qiu

In this study, an implicit algorithm and different solvers for temperature calculation were used to reduce the computation time of a plate heat conduction. The method used is based on the Moving Particle Semi-Implicit(MPS) method. The original MPS method uses explicit method for temperature calculation and is limited by time increment due to diffusion number especially in some cases with high thermal diffusivity. In this paper, the heat conduction of plate with Dirichlet boundary condition and Neumann boundary condition are studied. Furthermore, we contrast with steady state and transient heat conduction. The calculation time and accuracy of explicit and implicit calculation of plate heat transfer cases are compared. In addition, different algorithms and existing solvers are used to calculate the implicit temperature equation, and the calculation time and accuracy of different algorithms and solvers are compared. Consequently, it is shown that the temperature obtained using implicit algorithm agrees well with that obtained using the original explicit algorithm and the steady state equation, the computation time of implicit algorithm is shorter than that of explicit algorithm. In addition, the coefficient matrix of implicit temperature calculation equation is similar to the Pressure Poisson Equation(PPE), the optimal solver can also be extended to the solution of PPE.

New Spar Type Floating Wind Power Plant Behavior Simulation by SPH Method

Key Words: *Particle Method, Smoothed Particle Hydrodynamics, Wind Power Plant.*

It is important to stabilize behaviors for the efficiency of the floating wind power plants. And it is necessary to consider safety in the case of a design for the floating wind power plant about the natural disasters such as tsunamis. To predict behaviors of floating wind power plants in the ocean are very important for the safety and the ability of efficiency for power generation by numerical simulations. The particle methods which are the smoothed particle hydrodynamics (SPH) method [1] and the moving particle semi-implicit (MPS) [2] method are recently applied to fluid dynamics analyses for predictions for behaviors of structures under natural disasters such as Tsunami.

The SPH method including the artificial viscosity coefficient and the artificial density diffusion coefficient are proposed by M.Antuono et al.[3] and D.Molteni et al.[4] that is the δ-SPH method. The numerical correction terms are added to the momentum conservation equation and mass conservation equation in the δ-SPH method respectively. The 3-dimensional δ-SPH method analyses are applied to calculate the behaviour of new spar type wind power plant models. The calculated results are compared with the experimental results of the new models of the experiments.

Key Words: *MPS, SPH, Ship-wave Interaction, Wave Force, Computational Cost*

We developed a numerical analysis method that can predict the wave pressure acting on a ship in a short computation time [1]. The method is based on the overlapping particle technique for the multi-resolution simulation of particle methods [2] and ellipsoidal particles [3]. The spatial resolution can be changed in three levels in the simulation domain. The spatial resolutions of this simulation can be set more flexibly than conventional single- and two-level spatial resolutions. In addition, OpenMP, which is a parallelization library, was used to parallelize the simulation program.

Using the developed method, the wave pressure acting on the ship bow under short regular waves was numerically analyzed. The results revealed that the wave pressure values obtained by the numerical simulation was close to the experimental values. The total number of required particles was reduced by approximately 99%, compared to the case where the multi-resolution method was not applied. Future issue is simulation under long waves, where ship motion should be considered.

Key Words: *SPH Method, Cold Spraying, Deposition, Interfacial Force Model*

Due to the characteristics of high velocity, high pressure and small size, it is difficult to observe the particle deposition process of cold spraying in the experiment, so the numerical simulation called virtual experiment becomes more important tool. In this paper, smoothed particle hydrodynamics method is used to simulate the particle deposition process of cold spraying. Based on SPH theory, related numerical techniques and conservation equation of continuum mechanics, a dynamic impact model of cold sprayed particles impinging on substrate is established. With the help of the L-J atomic potential model, a new interfacial force was proposed, which can be successfully used to predicted the critical velocity of particle deposition according to the increase of surface temperature, to eliminate the rebound of the deposition particles. The effects of several particle shapes and subsequent impact position are also discussed. Result shows that, compared with elliptic particles, circular particles are more conducive to deposition, and different positions of subsequent particle impact have significant effects on coating quality. In this paper, the model of cold spray particles impinging on the substrate established by SPH method can well reproduce the experimental phenomenon, which is helpful to understand the mechanism of particle deposition.

On the bound solution property of the Node-based Smoothed Point Interpolation Methods (NSPIMs) in coupled problems of porous media

Arman Khoshghalb* **and Ashkan Shafee**

The School of Civil and Environmental Engineering, UNSW Sydney*, Sydney, NSW, 2052, Australia*, Arman.khoshghalb@usnw.edu.au

Key Words: *Coupled analysis, Saturated porous media, poro-elasticity, Node-based smoothed point interpolation method, upper bound*

An outstanding feature of the node-based smoothed point interpolation methods (NSPIMs) in solid mechanics problems is their potential to yield softer stiffness matrices compared to those of the linear finite element method (FEM). In particular, it has been shown that the NSPIM with linear shape functions yields the upper bound of the exact solution in energy norm in elasticity problems in contrast to the lower bound property of the solutions obtained using the linear FEM. Accordingly, the solution of the NSPIM with linear shape functions together with the solution of the linear FEM can bound the exact solution in solid mechanics problems. In this study, bound properties of the NSPIMs and linear FEM are examined in plane-strain coupled problems of porous media, to explore how the presence of pore water pressure affects this feature of the NSPIMs and linear FEM. The bound properties of the solution of three popular NSPIMs and linear FEM in poro-elasticity problems are then thoroughly investigated. The results show that the upper bound solution property of the NSPIMs is lost in coupled problems of poro-elasticity due to the coupling effects of the fluid phase.

Particle Method Simulation of the Eutectic Liquid Formation in Sn-Bi system using PHALSER Code

Kenta Inagaki[1*], Shota Ueda[2] and Masahiro Kondo[3]

Key Words: *Particle method, Simulation, Eutectic liquid, PHALSER*

Particle method is suitable for the simulation of melting, relocation and solidification of materials in a severe accident analysis of nuclear power plant and it has been applied for simulating various phenomena such as the candling of fuel rods, melt spreading of corium, molten-corium-concrete interaction (MCCI), and so forth. In those severe accident phenomena, liquid phase is formed even below the melting temperature of the material by eutectic reaction which occurs at the interface of different materials. In the boron-carbide control rods, for example, eutectic liquid is formed at the interface of the boron-carbide and SUS, which significantly affects the following accident scenario [1]. Therefore, development of a model to predict the behavior of the eutectic liquid formation is important for severe accident simulation.

In the present study, a test was conducted to investigate the dynamic behavior of the eutectic liquid formation. In the eutectic melting test, a solid cylinder of tin was soaked in a eutectic liquid pool of Sn-Bi which was maintained at a constant temperature slightly above the eutectic temperature. The solid cylinder was rotated to form a flow field in the pool and the weight of the solid was recorded to evaluate the rate of the eutectic melting. The test was conducted with changing the size of the cylinder or the rotation speed. It was observed that the rate of the eutectic melting at the solid surface is significantly dependent on the surrounding flow conditions and it can be explained by a film mass diffusion theory [2] when the flow is in the Laminar range.

On the basis of these observations, a eutectic reaction model was developed and implemented in a particle method code PHALSER [3] to perform the numerical simulation of the eutectic melting test. In the simulation, the tin cylinder and Sn-Bi pool was modelled using solid particle and fluid particle, respectively. The mass concentration of tin and bismuth was given as variables to both types of particles and their concentration over time due to diffusion was evaluated. The mass transfer at the interface between solid tin and Sn-Bi liquid was defined to be proportional to a mass transfer coefficient k_m, which was measured by the eutectic melting test. The solid tin particle was transformed to the Sn-Bi liquid particle when the mass concentration of bismuth exceeded a threshold value.

The simulation result was compared with the test results to investigate the validity of the present eutectic model and to clarify the issued to be solved for more realistic modelling of the eutectic reactions.

Key Words: *MPS Method, Lubrication, soft EHL, Computational Cost*

In this study, we developed a numerical method for simulating fluid lubrication [1] based on the moving particle simulation (MPS) method, which is a particle method. The overlapping particle technique (OPT) for the multi-resolution simulation of particle methods [2] was improved by applying an implicit algorithm to a viscosity calculation. Additionally, OPT was applied to the developed method to reduce the required number of particles and computational time. The implicit algorithm for the viscosity calculation eliminates the restriction in the time increment due to the diffusion number. In addition, we enabled the particle size to be changed significantly between sub-domains in the OPT. As a result, the pressure obtained by the developed method agreed well with the semi-theoretical solution of the Reynolds equation. The computational time of the developed multi-resolution simulation was significantly shorter than that of a single-resolution simulation.

Moreover, we developed a soft elasto-hydrodynamic lubrication (EHL) simulation method [3] based on the MPS method and OPT. In the soft EHL method, the viscosity does not depend on the pressure because the latter is relatively low. The elastic deformation of a cylinder was simulated by solving the elastic deformation equation [4] in the MPS simulation. The surface tension and cavitation were ignored when comparing the results with the semi-theoretical solutions. The results indicated that the pressure and deformation of the cylinder obtained by the developed method agreed well with the semi-theoretical solutions. It was also demonstrated that the improved multi-resolution method reduced the required number of particles and computational time while maintaining accuracy.

Key Words: *Seepage flow, internal erosion, Smooth particle hydrodynamics, constitutive model*

Internal erosion is a common phenomenon occurring in porous media caused by seepage water flow. When this phenomenon occurs, fine particles are removed from the porous media, causing significant changes in properties of porous media, including a reduction in the shear strength, an increase in compressibility and hydraulic conductivity. Consequently, the stability of geoengineering applications and adjacent structures are significantly affected. Therefore, predicting the occurrence of internal erosion in porous media is very important. In this study, an innovative smooth particle hydrodynamics (SPH) computational framework is proposed to predict the occurrence of internal erosion and its effects on the stability of geoengineering structures. In this framework, the porous media is represented by a set of Lagrangian material points, which consists of five phases, including a stable solid skeleton, erodible fine particles, fluidized particles, water, and air. Governing equations are then developed for these five phases based on the mixture theory. The mechanical response of soil during the internal erosion process is captured by a robust suction/erosion dependent softening constitutive model. The proposed framework is first employed to predict the behaviour of the classical 1D consolidation in order to demonstrate its capability in dealing with coupled flow-deformation problems. Subsequently, different erosion tests are conducted to exam the capability of the proposed modelling framework in capturing the effect of internal erosion on the mechanical and hydraulic responses of the soil structure. Comparisons between the predicted results and data available in the literature testify to the accuracy and robustness of the proposed frameworks. More importantly, the proposed framework is able to predict the entire internal erosion process, from particle separation to large deformation and failure of geoengineering structures, which demonstrates that this framework is an efficient tool to solve erosion problems that are normally difficult to be tackled by traditional mesh-based methods.

Key Words: *MPS method, Overlapping Particle Technique, Tsunami, Computational Cost*

In this study, a two- and three-dimensional coupled multi-resolution particle method was developed based on the moving particle semi-implicit method [1] and overlapping particle technique for the multi-resolution simulation of the particle method [2], to reduce the computational cost of a tsunami simulation. By coupling the sub-domains, the developed method resolved the three-dimensional phenomena near a coastal structure in a three-dimensional subdomain and the tsunami propagation far from the structure in a two-dimensional sub-domain. The reason for coupling is that the simulation cost of two-dimensional simulations is much lower than that of three-dimensional simulations. Each sub-domain had an independent spatial resolution. The two-dimensional sub-domain had vertical and horizontal coordinates. In the tsunami propagation region, a tsunami was regarded as the two-dimensional phenomenon in which a long water wave propagated toward the coast at an angle of incidence of 0°. The three-dimensional sub-domain was composed of a middle and high-resolution sub-domains. The ellipsoidal particle model [3] that enabled the use of a lower resolution in particular directions was adopted in the three-dimensional middle-resolution sub-domain to further reduce the required number of particles. Additionally, the conventional spherical particle model was used in the three-dimensional fine-resolution sub-domain.

A tsunami was simulated using the developed method, and the wave pressures acting on the front and back walls of a coastal structure were validated. Results revealed that the wave pressures acting on the structure obtained by the present method agreed with the experimental values. It was also confirmed that the present method was effective in reducing the computational cost of the tsunami simulation by the particle method.

A GPU-accelerated SPH method for modeling wave breaking problems

Huashan Zhang[1*], Moubin Liu[2]

[1] Peking University, Beijing 100871, P.R.China, zhanghuashan@stu.pku.edu.cn
[2] Peking University, Beijing 100871, P.R.China, mbliu@pku.edu.cn

Abstract: Smoothed particle hydrodynamics (SPH) is a meshless method with Lagrangian characteristics that is suitable for modeling incompressible flows with free surfaces [1-2]. However, the conventional SPH is limited by its low computational efficiency so that it poses great challenges for SPH to perform large-scale simulations. In this paper, we present an improved SPH method based on Graphics Processing Unit (GPU) through multi-threading to enhance the computational performance in terms of efficiency and scale. In addition, a repulsive force model that is similar to the Lennard–Jones (L–J) force is applied to avoid the particles from penetrating the boundary. The regular wave making is first used to validate the accuracy of the present GPU-based SPH method. The result indicates that the present method can achieve simulation results in good agreement with the reference data. Further, both 2D and 3D wave breaking examples are simulated by the GPU-based SPH method while the computational efficiency is discussed in depth. With the well-validated method, we numerically simulate various large-scale wave breaking problems and illustrate some underlying physical governing mechanisms.

Key Words: *Finite particle method (FPM), Riemann solver, Weakly compressible flows, High-order accuracy*

Weakly compressible SPH (WCSPH) method developed by Monaghan [1] has been widely applied for solving hydrodynamic problems. Although the conventional WCSPH method is a simple and frequently-used approach, it is generally affected by the poor accuracy and sometimes spurious oscillations which may lead to numerical instability.

In order to dampen the pressure oscillation without introducing excessive dissipation, a modified Riemann solver with a low-dissipation limiter was proposed by Zhang et al. [2] (i.e., Riemann-SPH). The present paper aims to integrate this low-dissipation Riemann solver into the finite particle method (FPM) proposed by Liu et al. [3] to produce a Riemann-FPM which is expect to obtain better accuracy together with low dissipation.

Figure 1 shows the comparison of the pressure profile along the diagonal direction obtained by the proposed Riemann-FPM and the Riemann-SPH. It is clear that the proposed Riemann-FPM is superior to Riemann-SPH in producing smooth and accurate pressure field..

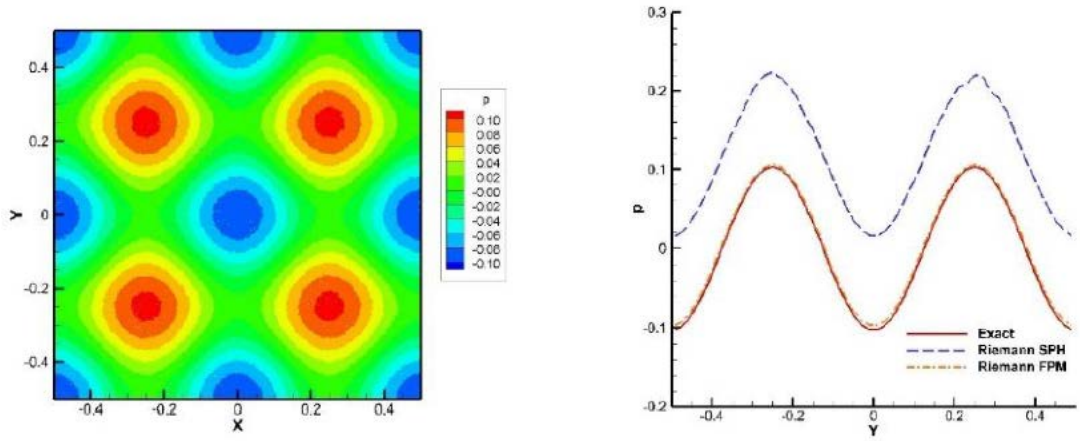

Fig. 1 Pressure profile obtained by the Riemann-FPM with dp=L/200.

Key Words: SPH, porous media, FSI, fluid channel

We present a weakly compressible smoothed particle hydrodynamics (SPH) model, which can be applied to model the fluid-structure interaction (FSI) problems of porous media with large deformations. Two types of SPH particles, namely solid and fluid particles, are used to discretize the corresponding phase of materials. The interaction forces between the phases are derived from the theory of mixture, which is in line with the view of continuum mechanics. To stabilize the numerical scheme, the so-called $\delta-$SPH method is employed in cooperation with the artificial stress technique. The numerical model is first verified by solving a static problem: an infinite long porous medium submerged in hydrostatic conditions [1]. Then, dynamic problems, like porous structures in a fluid channel, are also investigated. In this talk, we also present a stress-based failure model in cooperation with the proposed SPH model, which can successfully reproduce the loss of material induced by the sloughing of the fluid. The new SPH model presented in this talk has a great potential to be applied in studying biomedical problems, such as biofilms or tissues' detachment in the bio-fluid environment.

Key Words: *Discrete Element Method (DEM), Vertical Stirred Milling, Optimisation*

Over half of all products sold globally are powders, are formed from granular or powdered material, or include at least one size reduction step as part of the manufacturing process [1]. So many products in fact, that milling and comminution contributes around 2% of global energy use [2]. However, the vast majority of that energy is wasted as heat and noise, so a better understanding and improved efficiency of this sector will help contribute towards fighting the global climate emergency.

The research presented will centre around vertical stirred milling, a continuous wet milling technique which can produce fine particles with a better energy efficiency than other types of ball mill [3]. For this reason, it is used in multiple industries, including Fast-Moving Consuming Goods (FMCG), pharmaceuticals, cosmetics and food processing. While the technology has been around for nearly a century [4], there is still a disconnect of knowledge between industry meeting particle size specifications and increased process efficiency. To bridge this gap, the Discrete Element Method (DEM) has been used so far to create, validate and simulate the behaviour of a mill under different parameters, with the aim being to find an idealistic set of operating conditions which can later be re-validated through experimentation. In future work, the simulative aspects will be extended by introducing CFD-DEM coupling, with the ultimate objective being the creation of an optimised and validated DEM simulation that can mimic the coupled properties. In turn, this reduces the amount of computational expense required; a key requirement when applying these methods to industry, where processing speed and accuracy are essential.

Key Words: *Requirements Spatial Discretization Schemes, Meshfree Particle Methods, State-based Peridynamics*

Meshfree particle methods have been considered a big promise in numerical simulation for years. Due to their enormous flexibility, arbitrarily large deformations can be handled in a Lagrangian description of the underlying differential equation. This property especially facilitates the simulation of processes with very large deformations and free surfaces, such as in the context of additive manufacturing [1] or machining operations [2].

Due to the non-unique subdivision of the domain into regular geometries and the loss of information of the direct neighbors, new challenges arise. For meshfree particle methods to accurately approximate the solution of the differential equation, numerous conditions regarding consistency and stabilization must be met [1].

For this reason, all necessary conditions on meshfree particle discretization schemes are presented. Moreover, it is shown which criteria are not fulfilled by standard meshfree particle methods like Smoothed Particle Hydrodynamcis, the correspondence formulation of state-based Peridynamics [3], [4] or the Optimal Transportation Meshfree Method. Unlike the first two schemes, the last method is based on dividing the domain into two types of points. This creates additional challenges.

Based on the aforementioned list of requirements, a new formulation based on state-based Peridynamics is presented which fulfill the necessary conditions. Several examples demonstrate the improved behavior of the new approach.

In this study, a coupled numerical method based on Lattice Boltzmann Method (LBM) and Discrete Element Method (DEM) is used to simulate particles settling in a Bingham fluid. The multiple relaxation time (MRT) LBM is employed to solve Bingham fluids flows[1], while the DEM is used to model particles dynamics. The coupling framework is achieved by using an immersed moving boundary technique[2]. The LBM-DEM framework is validated by simulating Bingham fluids flow around a fixed and moving cylinder (or particle). It is demonstrated that the present method can provide the accurate and efficient numerical results. Moreover, the mechanical interaction and kinematic behavior of particles are also studied, and the drafting, kissing, and tumbling (DKT) behaviors of particles are observed in Bingham fluids. The results show that the yield stress of Bingham fluids makes the drafting, tumbling and separating movement of particles more difficult.

Particle entrainment and spattering are commonly-seen phenomena in powder-based laser additive manufacturing if laser's powder density is sufficiently high. They simultaneously evolve with the molten pool and the vapor jet, and have significant impacts on the final quality of the printed product. However, present modelling framework of massive particulate flows, unresolved CFD-DEM, demands the CFD grid size to be at least 3 times larger than the particle diameter so as to properly estimate the background fluid field. This handicaps the modelling of particle melting and deformation in Additive Manufacturing. Recently, we proposed a semi-resolved CFD-DEM that allows the mesh to be refined by employing a kernel function to reconstruct the background field [1]. In this work, we extend this semi-resolved modelling approach to Volume of Fluid method, couple recoil pressure, Marangoni Effect and other multi-physics models [2], and finally establish an Additive Manufacturing modelling framework based on semi-resolved VOF-DEM. With this model, phenomena like particle spattering and entrainment are simultaneously reproduced with molten pool evolution for the first time. Hence, it is believed that this model will be a powerful tool for future numerical investigations in various particle-fluid interactions in powder-based additive manufacturing

The dynamic failure process of concrete structures under the impact and blast loading can be often observed in field of military and civil engineering, which involves strong non-linear phenomena with high speed, high temperature, high pressure, high strain rate and large deformations. In this case, some typical damage and failure phenomena are difficult to be accurately reproduced by conventional methods. As a Lagrangian particle method, SPH has natural advantages in treating large material deformations in explosion and impact problems, especially in describing crack propagation of solid materials. In this work, the concrete constitutive model is added to the improved smoothed particle hydrodynamics (SPH) method. With the present novel SPH model, two validations examples are tested and analyzed. One is concrete slabs under impact loading of the steel projectile, where the entire penetration process is well modeled with different initial velocities of projectiles being considered. The other is the explosion in concrete. Two different burial depths are employed in this example and the concrete heave, throw, splash and other characteristics are well reproduced. The damage accumulation and progressive failure process are also captured by our simulation. By comparing present numerical results with the reference data, we demonstrate that the improved SPH is effective for modeling various impact and explosive problems involved with concrete structures. With the improved SPH method, the crack propagation and the damage evolution are analyzed and studied. Furthermore, it can be applicable to shaped charge jet problem and we model the whole process of shaped charge jet from detonation to penetration of target plates well while illustrating some important mechanisms, which can give guidance to the design of the shaped charge jet and protective armours.

[*]duchaofan@yzu.edu.cn

Key Words: *Cell-based smoothed finite element method, Rotating plates, Mindlin plate theory, High-order rigid-flexible coupled model*

Abstract: A cell-based smoothed finite element method (CS-FEM) is formulated for dynamic analysis of a plate attached to a rigid rotating hub. The first–order shear deformation theory which is known as Mindlin plate theory is used to model the plate. Considering the high-order terms of non-linear coupling deformation which means the in-plane longitudinal shortening terms caused by transverse deformation, the high-order rigid-flexible coupled (HOC) dynamic model is established via employing Lagrange's equations of the second kind. In the process of formulating the system stiffness matrix, the discrete shear gap (DSG) method is used to construct the strains to overcome the shear locking issue. This model can not only deal with thin plate problems but also thick plate problems. The effectiveness of the CS-FEM is first demonstrated in some static cases and then extended for dynamic analysis of a rotating rectangular plate undergoing large overall motion. The simulation results are compared with those obtained by using first-order approximation coupled (FOAC) dynamic model and zero-order approximation coupled (ZOAC) dynamic model, which shows the ZOAC dynamic model can only be applied to the case with low rotating speed, and the HOC dynamic model is more accurate and has wider scope of application. The results of CS-FEM are also compared with those other existing method including the finite element method (FEM) and the assumed modes method (AMM). It is found that the CS-FEM based on Mindlin plate theory provides more accurate and "softer" solution compared with FEM even if using coarse meshes.

Key Words: Gradient Smoothing, Multiscale Finite Element Method, Heterogeneous Coefficients

In this presentation, we study gradient smoothing methods with improved convergence behaviors for high-contrast problems such as the flow in heterogeneous porous media. We propose a gradient smoothing method in which a smoothed gradient field within each element is constructed by utilizing the gradient fields of the adjacent elements [1, 2]. The proposed gradient smoothing method is adaptive to the heterogeneity of the problem in the sense that gradient smoothing is applied inside each of homogeneous regions separately. In addition, we propose a multiscale variant [3] of the proposed gradient smoothing method, which results in an accurate numerical solution even if a computational grid coarser than the scale of the heterogeneity is utilized. While existing gradient smoothing methods have stiffness matrices with larger bandwidth than the standard finite element method in general, the proposed multiscale gradient smoothing method has the same bandwidth as the plain multiscale finite element method. Hence, the online computational cost of the proposed method is essentially the same as that of the plain one. Improved performance of the proposed methods is demonstrated through various numerical examples.

Nonlinear elastomers like rubber-like polymers have been widely used by virtue of their outstanding performance. The prediction of their fracture behaviour or failure is of great significance for engineering applications and academic research. In this regard, this study presents the Griffith-type phase-field formation [1, 2] at large deformation in the framework of adaptive edge-based smoothed finite element method (ES-FEM). Thanks to the high accuracy and mesh distortion insensitivity of ES-FEM [3-5], the advantages of the phase field approach in dealing with complex cracks are sufficiently released in terms of large deformation. However, albeit the combination of the two methods manifests high precision, faster convergence rate and better robustness than existing approaches, it was testified as computationally demanding. For this reason, a multi-level adaptive mesh scheme designed for the coupling of ES-FEM and PFM was presented. Unlike the adaptive grid in the context of FEM, adaptive ES-FEM requires to identify the connectivity of the edges and their supporting elements after each update of the mesh. Notwithstanding this strategy adds about 1%~2% extra computational overhead, it not only improves accuracy but also raises computational efficiency by roughly 20 times. In addition, we also outlined the specific numerical implementation of the proposed method, the effectiveness of which is verified by several representative numerical examples. Particularly, an experiment in which cracks deflected in rubber-like solid due to impinging on a weak interface was first reproduced by our approach.

Key Words: Smoothed Finite Element Method, Parallel Computing, Overset Mesh Method, 4-Node Tetrahedral Meshes, Superlinear Mesh Convergence Rate, Electrodeposition

Electrodeposition (ED) [1] is widely used as an anti-corrosion base-coating method for various metal products such as automobile carbodies. In the cationic ED coating, the coating objects (cathodes) are dipped in a paint pool with electrodes (anodes), and direct current is applied from the anodes to the cathodes. Therefore, the governing equation in the space of the ED simulation is a simple Laplace equation. By calculating the time histories of electric current density at any location on the carbody surface, the distribution of deposited film thickness at the end of the ED process can be predicted. In order to guarantee a certain thickness of coating film over the entire surface, ED simulation has become an indispensable technology in automobile manufacturing.

In contrast to the computational fluid dynamics (CFD) simulation of carbodies, an ED simulation requires a meshing on complex narrow spaces in the carbody, such as side-sill. Accurate prediction of the film thickness necessitates accurate calculation of the current that passes through many small holes on the carbody surface. Therefore, the number of meshes for ED simulation is tens of millions per carbody, which requires large-scale computation. Moreover, it is necessary to handle the moving boundary using the overset mesh method because the carbodies move in the paint pool of the actual manufacturing line.

In this study, we develop an in-house ED simulator based on the smoothed finite element method (S-FEM) [2]. The edge-based S-FEM using 4-node tetrahedral meshes (ES-FEM-T4) is adopted for the BVP solver as ES-FEM-T4 has the superlinear mesh convergence rate. The MPI/OpenMP hybrid parallelization method is introduced to our code for large-scale analyses. The MINRES method is adopted for the matrix solver as MINRES can solve positive indefinite matrix equations that appear when the MPC of the overset mesh method is satisfied by the Lagrange multiplier. Our benchmark tests reveal that our simulator using ES-FEM-T4 presents much more accurate results than FEM-T4 with the same CPU time.

Key Words: Smoothed Finite Element Method (S-FEM), Bi-directional Evolutionary Structural Optimization (BESO), Gradient Elasticity, GRADELA, Stress Criterion

In this work, a structural topology optimization scheme with size effect is investigated based on Aifantis's strain gradient elasticity theory. The domain is discretised with arbitrary polygonal elements to avoid the checkerboard pattern and the essential matrices are computed using the cell-based smoothed finite element method (CS-FEM). The stringent requirement of C^1 continuous element is circumvented by employing the Ru-Aifantis theorem [3]. The main idea of the CS-FEM is to divide the element into simplical sub-cells and then use a weight/smoothing function to obtain the smoothed gradients [1]. S-FEM has the following notable characteristics: (a) does not require an explicit form of the shape functions, (b) alleviates the need of isoparametric mapping. Recently, the variant S-FEMs, cell-based, edge-based and node-based S-FEM, have been successfully incorporated in the context of structural topology optimization within the solid isotropic material with penalization method (SIMP) [2]. They proposed the smoothing domain-wise density-based method with the power-law and thus the design variables were implemented on each smoothing domain. For structural topology optimization, von Mises stress is minimized by bi-directional evolutionary structural optimization (BESO) scheme based on stress criterion that the non-local stress is obtained by the split fourth-order constitutive law on each smoothing domain. A series of numerical examples shows the effectiveness of the proposed approach.

Key Words: *Smoothed Finite Element Method, Hyperelastic Material Model, Strain Energy, Numerical Differentiation. Complex-step Derivative Approximation.*

We present a robust and efficient numerical approximation of the internal force vectors and the element stiffness matrices of the smoothed finite element method (S-FEM) [1] for a hyperelastic material model. This method is based on the complex-step derivative approximation (CSDA), which can compute first-order derivatives with high accuracy.

In this method, CSDA is used to compute internal force vectors from the computation code of the strain energy using the smoothed deformation gradient tensor. The accuracy of this method is almost the same as that of the analytical implementation. Then, based on the above results, the element stiffness matrices are computed from the strain energy using second derivatives by implementing the complex-step approach [2]. Since this method does not require the derivation and coding of analytical solutions for internal force vectors and element stiffness matrices, the complexity of implementing S-FEM is significantly reduced.

To verify the efficiency of the proposed method, it was applied for the implementation of the edge-based/node-based selective smoothed finite element method (ES/NS-FEM) [3]. In the proposed scheme, the strain energy at each integration point was computed using the smoothed gradient tensor that was reconstructed with the deviatoric deformation gradient tensor based on ES-FEM and the volumetric part of the deformation gradient tensor based on NS-FEM. This investigation confirmed that the results of the deformation and the convergences of the S-FEM are almost the same as the analytical implementation results.

Moreover, the present scheme of ES/NS-FEM was applied to the dev/vol coupled material model, which was difficult with the conventional formulation [4]. The analysis confirmed a reduction in the volume locking of the dev/vol coupled material model and the quadratic convergence of S-FEM.

Finite Line Method for Solving Thermal Mechanical Problems

Xiao-Wei Gao[1]

[1] Dalian University of Technology, Dalian 116024, China
xwgao@dlut.edu.cn

Abstract. In this paper, a complete new collocation type numerical method, Finte Line Method (FLM), is proposed for solving general engineering problems governed by second or high order partial differential equations with proper boundary conditions. The method is based on the use of a cluster of lines crossing the collocation node under consideration and the Lagrange interpolation formulation is used to construct the shape functions over each line. When the number of the crossed lines exceeds what requires, the Least-Square technique is applied to all lines' equations to form an equation set to solve the first and high orders of partial derivatives of any physical variables with respect to the global coordinates. Then, the derived spatial partial derivatives are directly substituted into the governing partial differential equations and related boundary conditions to set up the system of equations with physical variables, temperatures and displacements, at all collocation nodes as unknowns. As an application, the proposed method is used to solve the heat conduction and mechanics problems and a numerical example is given to verify the correctness of the proposed method.

[3] Massachusetts Institute of Technology, Cambridge, MA 02139, USA

Key Words: *Granular Materials, Multiphase Flow, Material Point Method*

Mixtures of fluids and granular sediments play an important role in many industrial, geotechnical, and aerospace engineering problems, from riverbed erosion and slurry flow in pipelines (liquid–sediment mixtures) to dust kick-up below helicopter rotos (gas–sediment mixtures). These mixed flows often involve bulk motion of hundreds of billions of individual sediment particles and can contain both highly turbulent regions and static, non-flowing regions. This breadth of phenomena necessitates the use of continuum simulation methods, such as the material point method (MPM), which can accurately capture these large material deformations while also tracking the Lagrangian features of the flow (e.g., the granular surface and elastic stresses).

Recent works using two-phase MPM frameworks to simulate these mixtures have shown substantial promise [1–3]; however, these approaches are hindered by the numerical limitations of MPM when simulating pure fluids. In this presentation, we present an improved, two-phase continuum simulation framework that uses the finite volume method (FVM) to solve the fluid phase equations of motion and MPM to solve the solid phase equations of motion. This numerical method is shown to accurately predict solutions to standard poromechanics problems, improve accuracy in simulations of dynamic liquid–sediment flows, and provide a robust framework for simulating gas–sediment mixtures, including rocket exhaust impinging on Martian soil.

A Locking-Free Variational Multiscale Meshfree Formulation for Reissner-Mindlin Plate Problems

Tsung-Hui (Alex) Huang*, Yen-Ling Wei

Power Mechanical Engineering, National Tsing Hua University, Hsinchu, Taiwan.
thhuang@mx.nthu.edu.tw

Key Words: *Reproducing kernel particle method, Stabilized nodal integration, Variational multiscale method, Shear locking, Reissner–Mindlin plate*

The Reissner-Mindlin plate formulation in the thin-plate limit will encounter the well-known shear-locking phenomenon that must be overcome. The meshfree nodal integration can easily handle the locking issue, but it may suffer from zero and low energy instability. Although the conventional domain-subdivision-based or nodal gradient-based stabilization can avoid the low energy instability, the stabilization may cause the violation of the bending exactness (BE) in the Galerkin framework or fail to suppress the instability in the shear terms. In this research, a variational multiscale approach [1] is employed for the proposed meshfree Reissner-Mindlin plate formulation, where the solution is decoupled into coarse-scale and fine-scale under the variational equation. The coarse-scale solution utilizes the mesh-free reproducing kernel particle method (RKPM) with the stabilized conforming nodal integration (SCNI). The RK approximation in second-order monomial basis stratifies the Kirchhoff mode reproducing condition (KMRC), and SCNI guarantees the bending exactness in the Galerkin meshfree equation [2] without triggering zero-energy instability. The fine-scale solutions represent the residual of the coarse-scale equation, and the embedment of the fine-scale solutions in the coarse-scale system results in a residual-based stabilization, which eliminates the spurious oscillatory modes. The stabilization parameter is determined by dimensional analysis, and a smoothed divergence operator is applied in the fine-scale terms to ensure the satisfaction of locking free condition. RKPM naturally avoids computational challenges associated with low-quality meshes, allows efficient adaptive refinement, and provides flexible control of continuity and locality in numerical approximations [3]. The proposed framework, termed VMS-RKPM, is verified by different numerical examples, and it exhibits a better convergence rate than the conventional approach with comparable efficiency [4]. We recently developed a bending consistent nodal integration that bypasses the use of smoothing cells to enhance the efficiency, which will also be demonstrated in this study.

A Variationally Consistent Material Point Method for Large Deformation Problems

Cameron Rodriguez*, Tsung-Hui Huang

Power Mechanical Engineering, National Tsing Hua University, Hsinchu, Taiwan.
thhuang@mx.nthu.edu.tw

Key Words: *Material Point Method, Variationally Consistent Integration, Reproducing Kernel/Moving Least-Squares Approximation*

The material point method (MPM) [1] suffers from low accuracy and convergence rates compared to other meshfree numerical methods due to the under integration: the locations of material points are determined independently from the background grid and are thus suboptimal locations to perform numerical quadrature. Such an approach enables MPM to model large deformation but it also results in the loss of Galerkin exactness in the variational equation. In this research, we present a modified MPM formulation that recovers first order Galerkin exactness by employing an assumed strain variationally consistent integration method [2]. Using this approach, the gradient field of the test function space is constructed such that the numerical integration scheme is capable of numerically integrating the divergence equality, the integration constraint to achieve linear exactness. The Reproducing Kernel or Moving Least-Squares (RK/MLS) approximation [3] is introduced which overcomes the cross-cell instability because of the higher order continuity employed. The stabilization technique under the proposed integration framework is considered to remove the numerical oscillation. The proposed method is validated by solving a series of benchmark problems, and the results demonstrate that the new method can effectively improve the accuracy from the conventional MPM.

A viscosity enhanced peridynamic model for shock wave problems

Xiaodan Ren[1*] and Jinggao Zhu[1]

[1] Tongji University, 1239 Siping Road, Shanghai, 200092, China

Key Words: *Peridynamics, Shocks, Oscillatory instability, Zero-energy mode, Bulk viscosity*

The computational methods for shocks modeling demand two critical capabilities: 1) to model the dynamic fracture and fragments and 2) to capture the intermittent wave propagation. Peridynamics (PD) adopts the integral form of governing equation thus shows great advantages in modeling dynamic fracture and fragments. However, the propagation of intermittent wave within the PD based numerical system often encounters oscillatory instability. It can be attributed to the instability in time domain and the zero energy mode. To address these issues, the viscosity enhanced PD model is proposed for stabilization. The general framework is established with the introduction of artificial viscosity. Under such framework, the formulations of viscosity are developed based on the features of the spurious oscillations and improved with the balance between oscillation suppression and shock front width control. The case studies indicate that the proposed methods show good performance in shocks modeling and are well-suited for the bond-based as well as the state-based PD scheme, with which both the suppression of oscillation and control of shock front width are achieved.

Key Words: *Immersed Methods, Meshfree Methods, Reproducing Kernel Particle Method, RKPM, Transformed Interface Method, TIM, Heterogeneous Materials*

A vast array of engineering problems involving such things as composites and biological structures require the accurate and efficient simulation of heterogeneous materials. Typically, these simulations utilize the finite element method with a body-fitted mesh in which the discretizations of two different materials conform to their interface allowing for jumps in strain or stress as one passes from one material to the other. Constructing such meshes, however, can be quite time-consuming especially for complex, three-dimensional geometry, and thus, immersed methods [1] which can work with unfitted meshes are desirable. However, immersed methods which enforce compatibility using an interfacial constraint use contour integrals over the material interface, a potentially tedious procedure given the higher-order quadrature necessary and one which often yields an ill-conditioned system due to the near-zero internal energy in the overlapping region. Furthermore, immersed methods that use a volumetric constraint in the overlapping region to impose compatibility can produce spurious oscillations and large errors in strain and stress near the interface [2].

An immersed formulation using Nitsche's method to enforce the interfacial constraint is transformed by integration by parts into a formulation which uses only domain integrals and is proposed to avoid the use of tedious contour integrals and ill-conditioned systems of the standard interfacial constraint, on the one hand, and the spurious oscillations and errors near the interface of the volumetric constraint, on the other. The resulting formulation is termed the Transformed Interface Method (TIM). Being based on a set of scattered points and capable of higher levels of continuity, meshfree methods such as the reproducing kernel particle method (RKPM) are particularly well-suited to deal with the presence of the resulting second derivative terms as well as the body-unfitted nature of immersed methods. Numerical examples are given which show the advantages of the proposed formulation.

Key Words: *Inverse Problem, Underwater Acoustics, Reproducing Kernel Particle Method*

Underwater Acoustics positioning is an important area of research and has numerous applications. Due to the complex and variability of underwater acoustic environment, the acoustic waves may travel through extremely complex paths, which brings certain challenges to underwater acoustic positioning technology. In this research, we focus on the wave source identification in the cavitation tunnel located in National Taiwan Ocean University. According to the wave traveling distance, the wave characteristics is divided into short wave length and long wave length according to the room-size and frequency ratio. For the short-wave length, we first assume that under the condition of free field, the relationship between a point source and the resultant pressure history on a surface of a control volume surrounding the point source can be established simply by using the beam tracing method [1]. Then the surface can be considered as an equivalent source object, and any location outside the control volume can be treated as a downstream location. Similarly, in the cavitation tunnel, a carefully selected cross-section of the tunnel, which is separating the testing object and hydrophone array can also be seen as the equivalent source surface. To handle the effect of reflection, we proposed using the image source surface method (ISSM) to mimic the reflecting boundary in the cavitation tunnel. Then we use the hydrophone signals as measured data to back calculate pressure field of random upstream equivalent source surface using proposed method. The algorithm will use bisection iteration method to find the surface with the highest signal strength. For the long wave length, we solve the three-dimensional inverse Helmholtz problem [2]. The complex domain is discretized by the reproducing kernel particle method (RKPM). The RPKM method can use high order approximation and special enrichment functions to ensure the high accuracy of the solution. The numerical test shows that proper support of the kernel function should be selected for specific wave length to achieve optimum solution of the inverse problem. To test the applicability of our proposed algorithm, we first compare the result obtained from the numerical tank. The developed algorithm can successfully locate the wave source with long- and short-wave length. The developed code will be applied in the real experiment in the cavitation tunnel by the end of 2022.

Key Words: *Meshfree, fast convolution, Fourier transform, large-scale computation*

Meshfree methods have been developed over the past few decades to overcome the limitations of the finite element method, especially when solving problems that involve major topological changes such as large deformation, fracture, flow, etc. Reproducing kernel particle method (RKPM) is a pioneer meshfree method, which uses reproducing kernel approximations and the Galerkin weak formulation to discretize the field equations. The computational cost of RKPM is however expensive, especially in 3D. Most of the efficient implementations of RKPM require neighbour search and storage, and also performing quadrature for each pair of neighbour nodes to obtain the stiffness matrix. The RK shape functions themselves are also expensive to construct since they require computing the moment matrix for each node by looping over its neighbour, and then inversing the moment matrices which have the minimum size of 4 by 4 (in 3D) [1].

Peridynamics is a nonlocal extension of continuum mechanics where spatial derivatives are replaced with volume integrals, allowing for emergence and evolution of discontinuities in the field variable, making the theory suited for fracture and fragmentation. Similar to RKPM discretization, PD simulations are computationally expensive in 2D and 3D due to the pairwise interactions of neighbouring nodes and the quadrature over the neighbourhood of each node [2]. Recently a fast convolution-based method (FCBM) for peridynamics has been introduced where the convolutional structures of PD volume integrals are exploited to allow for computing integrals via fast Fourier transform, i.e., FFT-accelerated convolution summations [3,4]. FCBM avoids explicitly identifying neighbours and looping over them for quadrature by transferring the burden of computations to cheap multiplications in the Fourier space. While most Fourier methods require periodicity of the domain which limit the applicability of them, FCBM uses an embedded constraint (EC) approach to enforce the desired boundary conditions on arbitrary geometries. In a similar fashion, the convolutional structures in RKPM formulations can be exploited to elevate the method's performance up to several orders of magnitude.

In this work, we introduce the fast convolution-based RKPM (FC-RKPM), where the convolution sums (arising from direct nodal integration of the Galerkin weak forms) are efficiently computed using FFT, and inverse FFT operations with the complexity of $O(N\log_2 N)$, where N is the total number of nodes. No prior neighbour search and storage, and no construction and storing of the stiffness matrix is required. Our preliminary 3D results show efficiency gains as high as 3000, where computations requiring months to run on a single processor can now be carried out in a few minutes!

Investigation of Shear-Band Evolution with Concurrent Multiscale Simulation

Yu-Chen Su[1] and Zhen Chen[2*]

[1] Chung Yuan Christian University, Taoyuan 320, Taiwan, ycsu@cycu.edu.tw
[2] University of Missouri, Columbia, MO 65211, USA, chenzh@missouri.edu, Corresponding author

Key Words: *Material Point Method, Molecular Dynamics, Smoothed Molecular Dynamics, Multiscale Simulation, Shear-Band Evolution*

Developing the multiscale numerical approaches has become a more popular research issue over the last decade because these approaches can be used to simulate and evaluate the mechanical behaviors at extreme-small scales, such as the microscale or nanoscale, in a rather shorter time. In the past, a concurrent multiscale method, smoothed molecular dynamics (SMD), has been proposed to combine the molecular dynamics (MD) and material point method (MPM) in a single framework, namely, MD-SMD-MPM [1]. MD is a discrete particle method in which an appropriate potential function is utilized to calculate the interatomic forces and describe the motion of an atomic or molecular system. In contrast, the MPM is a continuum-based particle method that is formulated based on the weak form of the governing differential equations similar to the finite element method. With the use of pure MD and MPM, a series of simulations associated with copper slopes have recently been conducted to investigate the shear-band evolution at nano- and macroscale, respectively [2]. However, the distribution of the shear bands at nanoscale is discrete and the corresponding band width is between 2- and 3- particle sizes, which is different from macroscale simulation with the MPM. For further investigating the shear band evolution in concurrent simulation, a series of numerical results by using the MD-SMD-MPM will be presented in this presentation.

Key Words: *Meshfree, 3D printing, deposition, thermo-mechanical, nodal integration*

A stable and efficient nodally-integrated reproducing kernel particle method (RKPM) [1,2] is introduced in this work for effective modeling of the deposition types of three-dimensional printing that involve thermo-viscous and viscoplastic flow. Coupled mechanical and thermal effects are considered in this work. First, it is shown that nodal integration of the coupled equations results in severe spurious oscillations in the solution, worse than pure mechanical problems. A naturally stabilized and variational consistent nodal integration is then proposed for the coupled equations to stabilize the solution and provide *n*th order convergence in the two-field problem [3,4]. Generalized thermo-mechanical theories of the hyperbolic type are also leveraged for a uniform explicit critical time step, with results essentially the same as the classical theory. Benchmark problems are solved to demonstrate the effectiveness of the proposed method in obtaining stable and accurate RKPM results under both thermo-viscous and viscoplastic flow. Simulations of three-dimensional printing are presented, including fused deposition modeling, and printing of concrete.

Key Words: *Finite element method, Material point method, Fiber reinforced composites, Mesoscopic model; Impact problem; Shock phenomenon*

The fiber reinforced composites exhibit outstanding features under impact loading conditions. It is important to understand how different constituents and composite microstructures affect the meso-to-macro level mechanical performance. The finite element method (FEM) has difficulties in mesoscale modeling and failure evolution problems due to the complex microstructures of the yarn and matrix. The material point method (MPM) overcomes the aforementioned limitation and has successfully simulated the plate impact problem with glass-fiber reinforced polymer composites (GRP) [1]. However, we observe that the rising time of the stress wave on the GRP free surface is inconsistent with that of the experimental data [2], which indicates that the MPM cannot accurately describe the shock phenomenon.

In this presentation, a particle-informed FEM that can accurately describe the rising time of stress wave, as consistent with the experimental data, is proposed to better simulate the shock response of the GRP composite systems. A two-dimensional computational model of GRP is established based on the MPM mesoscopic model. The numerical simulation is performed by using the particle-informed FEM, and compared with the MPM and experimental data, which demonstrates that the particle-informed FEM can accurately describe the shock phenomenon as compared with the MPM. Additionally, the corresponding mesh convergence effect of the particle-informed FEM is also discussed.

Key Words: *Implicit Material Point Method, Phase Field, Elastoplastic Fracture, Finite Deformation*

Abstract

A phase-field implicit material point method with the convected particle domain interpolation (PF-ICPDI) is developed to model the finite deformation elastoplastic fracture behavior of geomaterials, especially in considering the brittle-ductile failure transition process. In this method, a smooth two-yield-surface plasticity constitutive model is adopted to evaluate the complex elastoplastic deformation behavior of geomaterials. To simulate the brittle-ductile failure transition process, a phase-field fracture model derived from the microforce balance law is used to couple with the cap plasticity model by introducing an effective phase-field stress. Furthermore, the implicit material point method combining with the convected particle domain interpolation technique is utilized to avoid severe mesh distortion and improve the computational accuracy in treating the quasi-static large deformation elastoplastic fracture problem. The staggered incremental iterative scheme is implemented for the solution of the coupled discrete governing equations. Numerical simulations demonstrate that the proposed PF-ICPDI method can effectively and accurately capture complex fracture behaviors of elastoplastic geomaterials. Temporal Stability of Collocation, Petrov-Galerkin and Other Non-symmetric Method in Elastodynamics and an Energy Conserving Time Integration

Jiarui Wang[1*] **and Michael Hillman**[2]

[1] Department of Civil and Environmental Engineering, The Pennsylvania State University, University Park, PA 16802, USA, E-mail address: jxw5912@psu.edu.

[2] Department of Civil and Environmental Engineering, The Pennsylvania State University, University Park, PA 16802, USA, E-mail address: mhillman@psu.edu.

Key Words: Collocation, Petrov-Galerkin, Temporal stability, Elastodynamics, Non-symmetric, Energy conservation

Non-symmetric matrices may arise in the discretization of elastodynamics when a Petrov-Galerkin, collocation method, or finite-volume method is employed. While these methods have been widely applied, it will be shown that the use of these non-symmetric matrices is inconsistent with the conservation of energy in the elastodynamic problems. First, the consistency between the continuous forms of the momentum equation and energy equation is examined. It is shown that the conservation of linear momentum is equivalent to conservation of energy provided the solution is sufficiently smooth. The semi-discrete counterparts are then examined, where it is shown they are also equivalent, but only conditionally: the mass and stiffness matrices must be symmetric. As a result, employing a non-symmetric method elastodynamics may artificially generate or dissipate energy. The fully discrete forms with Newmark time integration are then examined where it is shown that unconditionally unstable algorithms may arise. An energy-conserving time integration algorithm is then proposed which provides stability non-symmetric systems. The reproducing kernel (RK) collocation and finite-volume methods are employed in numerical examples as the typical non-symmetric methods to demonstrate the effectiveness of proposed time integration methodology.

A highly efficient and accurate Lagrangian-Eulerian stabilized collocation method (LESCM) for the fluid-structure interaction problems with free surface

Lihua Wang[1*], Zhihao Qian[1] Chuanzeng Zhang [2]

[1] *School of Aerospace Engineering and Applied Mechanics, Tongji University, Shanghai 200092, PR China, lhwang@tongji.edu.cn*

[2] *Department of Civil Engineering, University of Siegen, 57076 Siegen, Germany*

Abstract: A novel numerical method for the fluid-structure interaction problems with free surface is proposed in this work. The method is based on the hybrid Lagrangian-Eulerian description. The problem domain covering the fluid is discretized into the Lagrangian particles which carry the fluid information, and the problem domain covering the entire movement space is discretized into the uniformly distributed Eulerian background nodes. The coupling governing equations of the fluid, structure and interface are solve by the meshfree stabilized collocation method employing the reproducing kernel (RK) approximation on the Eulerian nodes. The solution is very efficient since the Eulerian nodes are set to be the initial positions in each time and it's no need to reconstruct the shape function. The information mappings between the Lagrangian particles and the Eulerian nodes are also conducted by the RK approximation which can keep the mass and momentum conservation of the solution. The cell-cut algorithm is introduced to couple the fluid and the structures which can solve the fluid pressure and the fluid-structure interactional force simultaneously and avoid the complicated iterations of the traditional interaction algorithms. Several numerical examples including the collapse of water column with a rigid barrier, water entry of a half-buoyant circular cylinder and a rigid box rotating and sinking in water are simulated, which demonstrate the high accuracy, high efficiency and good stability of the proposed method. This method can be extensively applied to the engineering applications with fluid-structure interactions.

Magnetic vortex has attracted much attention due to its potential application in magnetic logic and memory devices. Understanding the dynamic response of magnetic vortex subjected to elastic waves is crucial for its application in the future devices. In the present study, a dynamic phase field model based on the LLG equation, Maxwell equation and elastodynamic equation is proposed to predict the evolution of magnetic vortex under elastic wave. Due to nonlinearity and multi field coupling, the phase field equations cannot be solved by normal finite element method. Based on the multi-field coupled variation method, a nonlinear finite element method is employed to solve the governing equations of the phase field model. The phase field model based on finite element is able to simulate the evolution of the topological structures with complex geometrical shapes and arbitrary boundary conditions under elastic waves. In order to confine the magnetization amplitude near saturation magnetization, Lagrange multiplier method is adopted in the phase field model. The phase field simulations show that the high frequency force applied to the left side of the film produces an elastic wave of short wavelength in the film. The elastic wave can induce the reversal of vortices. The results in the present work suggest that elastic wave can be used to remotely control the topologically nontrivial vortex in ferromagnetic thin films, which may hold promise for applications in magnetic devices.

Key Words: *Local Radial Basis Function, Collocation, Rayleigh-Taylor Instability, Gravity Effect*

Rayleigh-Taylor instability is an instability phenomenon at the interface where a denser fluid is placed on the top of a lighter fluid in a gravitational field, such as in astrophysics the crab Nebula formed by an exploding supernova, and in nuclear engineering inertial confinement fusion controlled by Rayleigh-Taylor mixtures. In this paper, the local radial basis function (LRBF) collocation method is used to solve Rayleigh-Taylor instability problem. We use collocation method to avoid a time-consuming process to generate mesh. Meanwhile, different topological methods are adopted for the local collocation points to avoid problems similar to the full matrix and ill-condition of the global interpolation matrix. As a result, the positions of rising bubbles and falling spikes obtained from the calculation are compared with those achieved from literature, and a good agreement is obtained. In addition, we also analyzed the position changes of rising bubbles and falling spikes under different gravity effects. With the increase of gravity, the rate of rising bubble slows down while the rate of falling spikes basically remains unchanged, which provides a basis for future research on Rayleigh-Taylor instability in extreme environments.

Abstract: This paper introduces the recent advances on physics-informed-based collocation methods (PICM) and their various engineering applications [1-4]. The basic concepts of the physics-informed-based collocation methods are first introduced, such as the global and localized collocation schemes, physics-informed kernel functions. Introducing any underlying physical laws as prior information, a group of physics informed kernels could be derived to provide the efficient and accurate numerical solutions of PDEs in the kernel-based collocation solvers. The PICMs can be classified into two categories, namely, global physics-informed collocation methods and localized physics-informed collocation methods. Several numerical examples demonstrate the efficiency and accuracy of the proposed physics-informed-based collocation solver.

Keywords: Global collocation methods; Localized collocation methods; physics-informed kernel functions; meshless

Key Words: *polyamide, hydrogen bonding, strain rate dependence, crystallinity, constitutive equation, finite element method*

Polyamide (hereafter, PA) is a semi-crystalline polymer in which repeating units of amide groups (-NHCO-) is contained in a molecular chain. PA shows excellent mechanical properties by intermolecular hydrogen bond between hydrogen atom and oxygen atom of amide groups at neighboring molecular chains. The hydrogen bond densities and existence of aromatic ring in the molecular chain affect the rigidity of the molecular chain. In addition, the nonlinear mechanical behavior of PA is characterized by the debonding and rebonding of intermolecular hydrogen bond [1]. Predicting the mechanical properties of PAs having different molecular structures is very important to the research and development of new materials such as bio-based PA.

In this study, the effects of the tensile rate, density of amide groups and crystallinity were investigated by uniaxial tensile tests of commercial PA, PA11, PA610, amorphous/semi-crystalline PA6, and amorphous/semi-crystalline PA-MXD10. In addition, the surface of the test pieces during the tensile test were photographed, and the local strain generated in the test pieces during the tensile test was evaluated by the Digital Image Correlation (DIC) method. The mechanical response and the strain distribution significantly affected by the molecular-structure and crystallinity of PA. The initial stiffness and strength of PA increases with the density of the hydrogen bond and crystallinity. In amorphous PAs, the rapid drop of stress was observed after reaching the maximum stress whereas the stress gradually decreases in the crystalline PAs. The prominent strain concentration was observed at the necked region in the PA showing rapid stress drop. The numerical predictions of the mechanical response and strain distribution characterized by the molecular chain structure and crystallinity are important for the material development of PA.

To represent the experimentally observed mechanical characteristics of PA, the constitutive equation based on the debonding and rebonding of intermolecular chain [2] was applied for PA, and the neck propagation process under uniaxial tensile deformation was demonstrated by the numerical simulation based on the large-deformation rate-form finite element method. The simulation results reproduced the mechanical responses and development of strain distributions of several kinds of PA.

Key Words: Adaptive Mesh Refinement, Local Multigrid Methods, Nonlinear Solids Mechanics, Field Transfer, Error Control

We propose an adaptive mesh refinement (AMR) algorithm dedicated to the simulation of nonlinear quasi-static solid mechanics problems with phenomena localized at the structural scale [1]. The proposed method allows us to follow in time the evolution of studied phenomena in a *fully-automatic* (thanks to an *a posteriori* error estimator [2]), *precise* (respecting user-prescribed accuracies) and *efficient* (in terms of memory space and computational time) way.

We adopt the multilevel Local Defect Correction (LDC) refinement method [3] for its great potentialities for solving elliptic problems [4]. We propose an algorithmic extension of the LDC method to nonlinear quasi-static problems and provide key aspects associated to its practical implementation. We highlight its efficiency in the nonlinear context and show its natural ability to generate a hierarchy of meshes of limited sizes that dynamically follow the evolution over time of studied phenomena.

We address generic AMR-related questions associated to dynamic mesh adaptation, such as fields transfer between time steps as well as the discretization error control over time. We propose a straightforward and efficient equilibration strategy lying on the introduction of the initial non equilibrated residual as a source term of the problem. We also develop a reliable remeshing algorithm aiming to limit the number of mesh regeneration over time while guaranteeing the fulfillment of prescribed errors.

Several numerical experiments, in $2D$ and $3D$, with different types of material behavior as well as variable loadings are proposed to validate the efficiency of the developed algorithm.

Key Words: Imperfect Interfaces, Plasticity, Stochastics

Gluing has become in recent years an essential technique for the assembly of structures. These techniques are even essential in aeronautical or marine engineering. Although many models are available in the literature, much work remains to obtain reliable and accurate one.
A recently developed technique in this framework uses asymptotic expansions to generate models that take into account the small thickness of adhesive joints but also finite strains or damage. Non-linear effects are often prevalent for certain adhesives used in engineering. In this talk, we will extend this technique to associated and non-associated elasto-plasticity. It will be shown that the limit problem is very close to a Coulomb friction type model.
Another very important element is the control of uncertainties due to, for example, bonding defects, thickness irregularities, the presence of micro-cracks, etc. For this purpose, we propose to work in the framework of stochastic PDEs (Ito integral). Some theoretical and numerical results will be presented during the talk.

We present an efficient data assimilation framework for nonlinear dynamical systems that uses multi-fidelity statistical estimates based on a projection-based hyper-reduced order model (ROM) that is trained on-the-fly. This framework is particularly applicable to conservation laws in aero- dynamics that yield expensive forward models. The formulation comprises the following technical components: (i) an ensemble Kalman filter to tractably handle high-dimensional, strongly-nonlinear dynamical models; (ii) multi-fidelity forecast models, where ROM-based coarse fidelities are con- structed on-the-fly; and (iii) hyperreduction for the ROM, based on proper orthogonal decomposi- tion and the empirical quadrature procedure, constructed using the ensemble of full order model trajectories. We show that the multi-fidelity statistical estimates based on efficient, on-the-fly construction of the ROM enables the rapid and reliable state estimation for practical nonlinear dynamical systems. We demonstrate the effectiveness of our framework to estimate the state of a separated flow around an airfoil by (i) showing that the ROM-based multi-fidelity method is more accurate than the single-fidelity method for comparable computational cost and (ii) showing that multi-fidelity statistics enable the use of a less accurate surrogate when compared against ROM-only filters at negligible cost.

Key Words: Reduced-order model, weakly invasive, LATIN-PGD, non-linear, SAMCEF

Reduced-order models (ROM) are powerful engineering tools that allow reducing drastically computational time for complex problems in order to build "virtual charts" [1]. Among other ROM technics, the LATIN-PGD provides a reduced-order basis without any a priori knowledge of the problem nor snapshots and is particularly suitable for non-linear simulations [2,3]. However, the development of ROM-based methods in the industry is currently slowed down by the difficulty of introducing them into commercial finite element software, mainly due to the strong intrusiveness of the associated algorithms. This work introduces a weakly-invasive reformulation of the LATIN-PGD method [4], in the form of generalized quantities, which is intended to be directly integrated into the finite element analysis software. The main idea remains to reuse all facilities already included in an industrial solver (all non-linearities, element types, capabilities, ...) by only changing the non-linear solver algorithm. As part of this work, this approach is carried out in the non-linear finite element analysis software SAMCEF developed by Siemens. The feasibility of the method is highlighted with some particular problems: elastic-visco-plastic material, contact, parametrized aspects.

Constructing Reduced Order Model for Two Phase Flow using Dynamic Mode Decomposition

Tomoyuki Hosaka[1*], Masamichi Nakamura[1], Taisuke Sugii[1] and Eiji Ishii[1]

[1] Research & Development Group, Center for Technology Innovation – Electrification, Hitachi, Ltd., 7-1-1, Omika, Hitachi, Ibaraki 319-1202, Japan

Key Words: *Dynamic Mode Decomposition, Multiphysics Problems, Reduced Order Model*

In developing products to achieve higher efficiency, the computational fluid dynamics (CFD) is being used. In addition to cutting costs by reducing the number of prototypes, there is a growing need for technology that reduces design time by using automatic optimization and other methods. However, since the computational cost of CFD is very high, it is difficult to apply to automatic optimization, and there is a strong need to reduce the analysis time. As a trend in speeding up CFD, constructing reduced order models (ROM) have attracted much attention in recent years. Dynamic mode decomposition (DMD)[1] is one of key techniques for identifying low-dimensional dynamic system from spatio-temporal data in numerical and experimental fluid mechanics, and has received much attention because it can be used to construct ROMs.

Although DMD has been applied to various problems, its applications to the two-phase flow analysis are limited. As previous study, Krolick and Owkes[2] presented a technique to extract the primary instability from an atomizing jet's core. In order to apply DMD to more general two phase flows, in this study, we investigated the stability of ROMs obtained by different definitions of the gas-liquid interface: the raw VOF field and a signed distance function.

The current study presents a technique to extract wave form of sloshing tank problem. The simulation was conducted using a volume of fluid (VOF) method and the experimental data by Goudarzi and Sabbagh-Yazdi[3] was used to verify the simulation result. The ROM was constructed for the flow field using the randomized DMD[4], and there is an instability issue that occurs when DMD is applied to the VOF field. The reason for this comes from the discontinuity of the VOF fields both in space and time. The current study revealed that the ROM constructed by the hyperbolic tangent function of the signed distance function gives more stable result than other definitions of the gas-liquid interface.

Empirical Quadrature Procedure with Constraint Reduction for Reduced Order Modeling of Large Scale Problems

Adrian Humphry[1*], and Masayuki Yano[2]

University of Toronto Institute for Aerospace Studies, 4925 Dufferin St, Toronto, ON M3H5T6, Canada,
[1]adrian.humphry@mail.utoronto.ca [2]masa.yano@utoronto.ca

Key Words: Model reduction, hyperreduction, constraint reduction, aerodynamics

Projection-based model reduction of parametrized/unsteady nonlinear partial differential equations (PDEs) requires hyperreduction to accelerate the evaluation of the reduced residual. Our approach to hyperreduction is based on the empirical quadrature procedure (EQP)[1], which solves a constrained optimization problem to identify a reduced (i.e., sparse) quadrature rule tailored for a given reduced basis and the parametrized/unsteady problem that satisfies "residual matching conditions" at a set of parameter/time training points. The selection of the training points, or more generally constraints, is crucial, and we wish to meet two competing requirements: a large number of training points to ensure that the residual is well approximated over the entire parameter/time domain; a small number of training points to reduce the training cost. These competing requirements pose challenges especially for large-scale and high-dimensional problems.

To handle these challenges, we present a rigorous and efficient approach to hyperreduction, with an emphasis on large-scale and high-dimensional problems. Our formulation exploits the fact that, in many parametrized systems, the constraints belong to a manifold, are similar, and hence are amenable to substantial reduction. We develop a constraint reduction algorithm that uses QR factorization to determine a set of orthogonalized constraints, along with judiciously selected truth values and tolerances, such that our original constraints are well represented. The factorization is used to rank the "importance" of each constraint, then an iterative process selects a minimal set of constraints, while ensuring that the resulting solution satisfies all original constraints. We exploit the powerful constraint reduction capabilities of this method to develop an algorithm for efficiently sampling a large or high-dimensional parameter space. This approach employs a greedy algorithm to rapidly determine a minimal set of training points such that the resulting reduced quadrature rule is accurate over the entire parameter domain.

We demonstrate the formulation using a family of large-scale and high-dimensional aerodynamics problems, including the following: parametrized Reynolds-averaged Navier-Stokes (RANS) flow over an ONERA wing; multi-fidelity ensemble Kalman filter for separated Navier-Stokes flow past NACA0012; and high-dimensional parametric uncertainty quantification of the RANS Spalart-Allmaras turbulence model. For these large-scale problems (up to 40,000 constraints and 10^6 quadrature points), we observe significant improvements in the training time when the constraint reduction methods are employed.

Model Reduction for Aerodynamics: High-Dimensional Problems and Shape Optimization

Benjamin Gibson[1], **Adrian Humphry**[1], **and Masayuki Yano**[1]

[1] University of Toronto Institute for Aerospace Studies
4925 Dufferin St, Toronto, ON M3H 5T6, Canada, masa.yano@utoronto.ca

Key Words: model reduction, error estimation, adaptivity, optimization, aerodynamics

We consider model reduction of shape-parametrized aerodynamics problems governed by the Euler and Reynolds-averaged Navier-Stokes (RANS) equations. Our goal is to provide rapid and reliable predictions of quantities of interest, such as lift and drag, with an emphasis on high-dimensional problems arising from geometry parametrizations in design optimization and uncertainty quantification. The key ingredients are the adaptive high-order discontinuous Galerkin (DG) finite element method, which provides efficient solutions of convection-dominated problems; reduced basis (RB) spaces, which provide rapidly convergent approximations of the parametric manifolds; the dual-weighted residual (DWR) method, which provides effective error estimates for quantities of interest in both the DG and RB approximations; and the empirical quadrature procedure (EQP), which provides efficient hyperreduction. We consider the application of the shape-parametrized model in two distinct context.

The first is the construction of a shape-parametrized hyperreduced model and its application to probabilistic analysis under geometric uncertainties. A weak greedy algorithm simultaneously adapts the DG spaces, RB spaces, and EQP to meet the user-specified output error tolerance over the entire parameter space. The algorithm adaptively enriches the training parameter set to effective train the reduced model in high-dimensional parameter spaces. In the online stage, the DG-RB-EQP method reduces the computational time by several orders of magnitude. In the offline stage, the adaptive training algorithm provides efficient training while controling the discretization errors associated with the DG, RB, and hyperreduction approximations.

The second is in the context of aerodynamics shape optimization. We combine the above ingredients with a trust-region method to construct a sequence of reduced models on-the-fly to accelerate the optimization process. The key additional ingredients are the trust region informed by the DWR error estimate, and the tailored EQP hyperreduction which ensures that the reduced model satisfies required consistency conditions for the convergence of the trust-region method. We demonstrate on-the-fly acceleration of shape optimization procedure using an inverse-design problem and a drag-minimization problem.

Key Words: Reduced Order Modeling, Domain Decomposition, Rocket Combustion

Combustion dynamics is characterized by the coupling between heat release, hydrodynamics, and acoustics. In combustion engines, this complex coupling can lead to combustion instabilities that can cause devastating engine failures. Even with advances in modern computational capabilities, high-fidelity (e.g., Large Eddy) simulations of full-scale engines remain out of reach. In this work, we develop a framework to enable efficient prediction of combustion dynamics in rocket engines using component-level training on reduced domains, and integrating these components as a network of Reduced Order Models (ROMs). The full rocket engine is decomposed into different components, each of which adapts different modeling strategies. Model reduction methods using model-form preserving least-squares projections with variable transformation (MP-LSVT) [1] are adapted to obtain efficient and accurate ROMs to represent complex combustion dynamics near rocket injectors. These ROMs are effectively trained based on offline LES simulations with a reduced number (e.g., < 3) of injectors, a small fraction of the full-scale engine, which usually contains hundreds of injectors. External excitation is introduced in the offline LES simulations to incorporate essential dynamics for ROM training. The trained ROMs are then coupled to form a network. Computational fluid dynamic (CFD) models are used in components, dominated by acoustically propagating waves (manifolds, injector posts, and nozzle) and coupled to the aforementioned network of ROMs which model the near-injector dynamics [2]. We demonstrate the framework to predict combustion instability characteristics in a multi-injector rocket engine.

Key Words: *adaptive bases, model reduction, parametric PDEs, nearest neighbors*

Projection-based model order reduction (PMOR) techniques rely on the precomputation of an approximation subspace that, despite having a dimension much smaller than that of its underlying high-dimensional model (HDM), exhibits the ability to capture its dominant features. It is common to construct this approximation subspace by collecting many solution snapshots from the HDM and compressing a matrix of these snapshots using the singular value decomposition (SVD). However, for highly nonlinear problems that are convection-dominated or characterized by mutiple distinct scales or regimes (or more generally, any problem with a high Kolmogorov n-width), a single global reduced-order basis (ROB) often needs to be prohibitively large to deliver sufficient accuracy. One existing method [1] addresses this issue by partitioning the state space into regions with a clustering algorithm and pre-computing multiple smaller ROBs, one for each region of the partitioned state space. Then at each time-step of the simulation, the ROB constructed for the region of state space occupied by the current state vector is used to advance the simulation. This leads to a piecewise affine approximation manifold where each local ROB is constructed by compressing snapshots in the neighborhood of the current state vector, with these neighborhoods constructed a priori by a clustering algorithm.

The PMOR method proposed here similarly makes use of the concept of state-space locality, using at each time-step a ROB constructed from snapshots in the neighborhood of the current state vector. However, the proposed method discards the a priori partitioning of the state space into a discrete number of neighborhoods via clustering and the pre-computation of ROBs via data compression. Instead, at each time-step, it constructs on-the-fly a ROB using a small number of nearest snapshots to the current state vector without any data compression. Efficient distance formulas are derived to enable the real-time construction of such nearest-neighbor ROBs which by design, are adaptive. Using this approach, the offline processing of PMOR is simplified and made more computationally efficient, the dimension of the local projection-based reduced-order model needed to achieve a certain level of accuracy is made smaller than otherwise possible, and therefore the overall computational efficiency of PMOR is significantly improved. Under reasonable conditions, the proposed PMOR approach is capable of achieving a perfect accuracy for "reproduction" problems using exceedingly small basis sizes. Its potential for parametric, highly nonlinear, convection-dominated flow problems is demonstrated on several parametric, large-scale, CFD applications pertaining to aerodynamics, using the least-squares Petrov-Galerkin (LSPG) method [2] for PMOR.

Nonlinear Projection-Based Model Order Reduction in the Presence of Adaptive Mesh Refinement

Clayton Little[1*], Charbel Farhat[2]

[1] Stanford University; 450 Jane Stanford Way, Stanford, CA 94305; crl11@stanford.edu
[2] Stanford University; 450 Jane Stanford Way, Stanford, CA 94305; cfarhat@stanford.edu

Key Words: *adaptive mesh refinement, CFD, model reduction, hyperreduction*

For many problems in computational mechanics, Adaptive Mesh Refinement (AMR) is desirable as it enhances accuracy for a given computational cost and reduces this cost for a specified accuracy. While it is fairly practiced in the context of high-dimensional, mesh-based computational models, it is in its infancy in that of low-dimensional, generalized-coordinate-based computational models such as Projection-based Reduced-Order Models (PROMs) and Hyperreduced PROMs (HPROMs). This is primarily due to the fact that when AMR is applied at the high-dimensional level, different solution snapshots may be computed on different meshes, which raises two different but related issues: the solution snapshots may have different dimensions, which complicates their collection and compression into a Reduced-Order Basis (ROB); and even if they happen to have the same dimension due to a fortuitous balance between mesh refinement in some regions of the computational domain and mesh coarsening in other regions, they may suffer from some inconsistency due to the fact that their same-index entries may not evaluate the solution at the same spatial location. Recent work in the literature [1] addresses, to some extent, both aforementioned issues by interpreting all mesh-based computations underlying the data-driven POD procedure as inner products and computing them in the continuous solution space rather than the semi-discrete counterpart. Here, this approach is extended to hyperreduction, which is indispensable for parametric, Projection-based Model Order Reduction (PMOR) when it is not possible or computationally tractable to pre-compute offline the reduced-order operators and quantities, and the computational complexity of their online computation does not scale only with the size of the PROM. Specifically, the context is set to that of the Energy-Conserving Sampling and Weighting (ECSW) hyperreduction method presented in [2] for second-order dynamical systems semi-discretized by finite element methods, and recently extended in [3] to first-order hyperbolic problems discretized by finite volume methods. To achieve computational tractability in the presence of AMR, the concept of local ROBs in the state-space [4] is adopted. This concept is equipped with that of local "supermeshes", where the construction of each local supermesh is dictated by the subset of the collected solution snapshots underlying the construction of a local ROB; and the reduction of such a supermesh is performed and trained using the underlying local ROB and ECSW. All presented ideas and their significance are illustrated and highlighted with the solution of three-dimensional, nonlinear, convection-dominated turbulent flow problems.

Key Words: Parametric PDEs, reduced models, piecewise polynomials, reduced basis spaces

We consider model reduction methods for parametric/random partial differential equations. The usual approach to model reduction is to construct a linear space V_n of (hopefully low) dimension n which accurately approximates the parameter-to-solution map, and then use it to build an efficient forward solver. However, the construction of a suitable linear space is not always feasible. It is well-known that numerical methods based on nonlinear approximation outperform linear methods in many contexts. In a so-called library approximation, the idea is then to replace the linear space V_n by a collection of linear or affine spaces $V_1, V_2, \ldots, V_N$ of dimension $m < n$.

In this presentation, we first review standard linear methods for model reduction before introducing nonlinear reduced models with a focus on library approximation. We then present different strategies which can be used to generate such nonlinear reduced models, namely libraries based on piecewise (Taylor) polynomials and on local reduced basis spaces. We provide some theoretical results and illustrate the performances of the methods through several numerical experiments.

Operator inference to construct low-dimensional models for incompressible flows

Peter Benner[1], Pawan Goyal[1*], Jan Heiland[1] and Igor Pontes Duff[1]

[1] Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg, Germany,
{benner, goyalp, heiland, pontes}@mpi-magdeburg.mpg.de

Key Words: Data-driven modeling, operator inference, reduced-order models, incompressible flows

Dynamical modeling of a process is essential to study its dynamical behavior and to perform engineering studies such as control and optimization. With the ease of accessibility of data, learning models directly from the data have recently drawn much attention. It is also desirable to construct compact low-dimensional models describing complex non-linear dynamics, leading to perform simulations and engineering studies on modest computer hardware. To that aim, the construction of low-order models is well reflected in the recent successes of data-driven approaches such as dynamic mode decomposition and operator inference. However, for a process, typically, some known physical constraints (e.g., mass conversation, energy conversation) are not incorporated in learning models using the approaches above.

In this talk, we discuss the use of the operator inference approach to learning structured low-dimensional models for incompressible flow from data. To that end, we utilize the intrinsic structure of the Navier-Stokes equations for incompressible flows and show that learning dynamics of the velocity and pressure can be decoupled, thus leading to an efficient operator inference approach for learning the underlying dynamics of incompressible flows. Finally, we show the operator inference performance in learning low-order models using some benchmark problems and compare it with an intrusive method and other data-driven approaches.

Key Words: Model reduction, autoencoder, neural ordinary differential equations

This work proposes an extension of neural ordinary differential equations (NODEs) by introducing an additional set of ODE input parameters to NODEs. This extension allows NODEs to learn multiple dynamics specified by the input parameter instances. Our extension is inspired by the concept of parameterized ordinary differential equations, which are widely investigated in computational science and engineering contexts, where characteristics of the governing equations vary over the input parameters. We apply the proposed parameterized NODEs (PNODEs) for learning latent dynamics of complex dynamical processes that arise in computational physics, which is an essential component for enabling rapid numerical simulations for time-critical physics applications. For this, we propose an encoder-decoder-type framework, which models latent dynamics as PNODEs. We demonstrate the effectiveness of PNODEs with important benchmark problems from computational physics.

Piecewise polynomial approximation manifold for the model reduction of nonlinear convection-dominated problems

Joshua Barnett[1*] and Charbel Farhat[2]

[1] Stanford University, Stanford, CA, jb0@stanford.edu
[2] Stanford University, Stanford, CA, cfarhat@stanford.edu

Key Words: *CFD, hyperreduction, projection-based model order reduction, quadratic approximation manifold*

Projection-based model order reduction (PMOR) provides a parsimonious description of otherwise a very high dimensional parametric model (HDM), by constructing global shape functions as opposed to local ones – often used in the context of finite element methods. The key difference in the case of PMOR is that the global shape functions are computed based on prior knowledge of the problem to be solved, obtained through exercising the parametric HDM. The low-dimensional description of a computational model afforded by PMOR, equipped with hyperreduction in the case of an arbitrarily nonlinear model significantly accelerates the time-to-solution of the problem of interest. For example, in [1], the authors demonstrate the ability of PMOR to reduce the wall-clock time required by a turbulent flow computation past a complex geometry from 100 *hours* on over 3500 CPU cores for the HDM, to only 3 *minutes* on 32 cores for its hyperreduced, projection-based reduced order model (HPROM) counterpart. Unfortunately, for highly nonlinear problems and in particular for convection-dominated problems, the performance of traditional PMOR techniques is greatly limited by the Kolmogorov barrier which underscores the need for many basis vectors for an affine approximation to achieve reasonable accuracy. To meet this challenge, a variety of nonlinear rather than affine approximations have been proposed, from locally affine approximations [2] that have demonstrated their potential for 3D challenging applications [1], to more general nonlinear approximation manifolds generated by neural networks [2] that seem to be limited to simple 1D and 2D applications – due to the extensive training and hyper-parameter tuning they require, which questions their practicality.

Here, an alternative, piecewise quadratic approximation manifold is proposed for mitigating the Kolmogorov barrier. It is trained in a two-step approach that builds on the data-driven approach underlying the traditional construction of PROMs; is application-independent; is linearization-free and therefore is more robust for highly nonlinear problems. Most importantly, if for a nonlinear, convection-dominated flow problem a PMOR method equipped with the traditional affine approximation delivers a certain level of accuracy using a PROM of dimension n, the proposed piecewise approximation manifold produces a piecewise quadratic PROM that delivers a similar level of accuracy using however a dimension that is smaller than $\sqrt{n}$. The proposed piecewise approximation manifold is implemented in the least-squares Petrov-Galerkin (LSPG) method for PMOR and equipped with the ECSW method for hyper reduction [1]. Its superior accuracy for a fixed low dimension n and its superior performance for a fixed level of accuracy are demonstrated for several realistic, convection-dominated, turbulent flow problems.

Key Words: Embedded Boundary Method, Nonlinear Model Order Reduction, Hyperreduction

The state of the art of nonlinear, projection-based model order reduction (PMOR) has significantly advanced in recent years for many applications, including computational fluid dynamics (CFD) analysis. For example, the least-squares Petrov-Galerkin (LSPG) PMOR method first presented in [1] was recently demonstrated in [2] for a challenging high-speed, turbulent, viscous flow problem past a complex fighter aircraft geometry. However, the state of the art of PMOR for CFD has been restricted to date to body-fitted meshes. The reason is that in general, embedded boundary models (EBMs) are not compatible with traditional PMOR frameworks due to their dynamic partitioning of the computational fluid domain into real and fictitious subdomains. Hence, complex flow problems that necessitate the use of an EBM for CFD–such as problems involving large shape changes, deformations, or topological changes–cannot be accelerated today by PMOR. Notable work pertaining to the initial development of a PMOR approach for EBMs includes the alternative right reduced-order basis (ROB) developed in [3], which accounts for the real/fictitious dynamic partitioning of the computational fluid domain. Here, this approach is generalized to more advanced EBMs than the standard ghost fluid method, which was the focus of the work in [3]. More importantly, it is equipped with hyperreduction–another challenging task to perform when the domain is dynamically partitioned into real and fictitious subdomains–to enable wall-clock time reduction. The result is a comprehensive framework for constructing nonlinear, projection-based reduced-order embedded boundary models for CFD and hyperreducing them using a variant of the energy-conserving sampling and weighting (ECSW) [4] method tailored for this purpose. This framework is demonstrated on a series of large-scale, convection-dominated CFD applications that necessitate the use of an EBM. It delivers significant wall-clock time speedup factors while maintaining accuracy.

There are inherent limitations to linear dimensionality reduction methods like the proper orthogonal decomposition (POD). To overcome these limitations, there has been recent interest in finding a nonlinear extension that retains many important properties of POD such as (1) the stability of the POD coefficients with respect to the data, or (2) the regularity in the POD modes. In this talk, we will discuss a generalization of POD to the nonlinear setting, in the form of a neural network called the reduced deep network (RDN) introduced in [1]. We present theoretical and numerical results showing that this extension yields a stable approximation to various datasets that proved challenging for POD in the past. We will focus on datasets taken from numerical solutions to nonlinear partial differential equations describing wave phenomena.

We provide the state of the art of Reduced Order Methods (ROM) for parametric Partial Differential Equations (PDEs), and we focus on some perspectives in their current trends and developments, with a special interest in parametric problems arising in offline-online Computational Fluid Dynamics (CFD). Efficient parametrisations (random inputs, geometry, physics) are very important to be able to properly address an offline-online decoupling of the computational procedures and to allow competitive computational performances. Current ROM developments in CFD include: a better use of stable high fidelity methods, considering also spectral element method and finite volume discretisations, to enhance the quality of the reduced model too, and allowing to incorporate some turbulent patterns and increasing the Reynolds number; more efficient sampling techniques to reduce the number of the basis functions, retained as snapshots, as well as the dimension of online systems; the improvements of the certification of accuracy based on residual based error bounds and of the stability factors, as well as the guarantee of the stability of the approximation with proper space enrichments. For nonlinear systems, also the investigation on bifurcations of parametric solutions are crucial and they may be obtained thanks to a reduced eigenvalue analysis of the linearised operator. All the previous aspects are very important in CFD problems to focus in real time on complex parametric industrial, environmental and biomedical flow problems, or even in a control flow setting with data assimilation or uncertainty quantification. Model flow problems will focus on few benchmarks, as well as on simple fluid-structure interaction problems and shape optimisation applied to industrial problems.

Reduced Order Modeling for modular anisotropic Structures based on Proper Orthogonal Decomposition and Mesh Tying

Stephan Ritzert[1*], Domen Macek[1], Jaan Simon[1] and Stefanie Reese[1]

[1] RWTH Aachen University , Mies-van-der-Rohe-Str.1, D-52074 Aachen, Germany ,
stephan.ritzert@ifam.rwth-aachen.de, https://www.ifam.rwth-aachen.de/cms/ mwefc/IFAM/

Key Words: Proper Orthogonal Decomposition, Mesh Tying, Anisotropy, Interpolation

A model order reduction technique in combination with mesh tying is used to efficiently simulate a large number of different structures that are assembled from a set of substructures. The stiffness matrices of the substructures are computed separately and assembled into a global stiffness matrix with tied contact formulation. The computational time can be further decreased by reducing the degrees of freedom of each substructure with a projection-based model order reduction technique. The precomputations to obtain the mode matrices are computationally cheap because they can be carried out on each substructure separately. For the development and optimization of new construction strategies for fiber reinforced concrete, a large number of different combinations of the modules have to be tested. The nonlinear anisotropic material behavior, like the primary directions of orthotropic materials [1], leads to parameter-dependent mode matrices. The precomputations can only be done for a relatively small number of parameters. For all other parameters, the mode matrices have to be adapted with interpolation methods to obtain an accurate solution [2].

ROM Closures and Stabilizations for Under-Resolved Turbulent Flows

Traian Iliescu [1*]

[1] Department of Mathematics, Virginia Tech, Blacksburg, VA 24061, USA
iliescu@vt.edu, https://sites.google.com/view/iliescu/

Key Words: Reduced Order Models, Closures, Stabilizations, Data-Driven Modeling, Turbulent Flows

In this talk, I will survey reduced order model (ROM) closures and stabilizations [1] for under-resolved turbulent flows. Over the past decade, several closure and stabilization strategies have been developed to tackle the ROM inaccuracy in the convection-dominated, under-resolved regime, i.e., when the number of degrees of freedom is too small to capture the complex underlying dynamics. I will present regularized ROMs, which are stabilizations that employ spatial filtering to alleviate the spurious numerical oscillations generally produced by standard ROMs in the convection-dominated, under-resolved regime. I will also survey three classes of ROM closures, i.e., correction terms that increase the ROM accuracy: (i) functional closures, which are based on physical insight; (ii) structural closures, which are developed by using mathematical arguments; and (iii) data-driven closures, which leverage available data. Throughout my talk, I will highlight the impact made by data on classical numerical methods over the past decade. I will also emphasize the role played by physical constraints in data-driven modeling of ROM closures and stabilizations.

A Computational Approach To The Effective Viscosity Of Non-Newtonian Fiber Suspensions

Benedikt Sterr[1], Daniel Wicht[1], Matti Schneider[1], Thomas Böhlke[1]

[1] Institute of Engineering Mechanics, Karlsruhe Institute of Technology (KIT), Kaiserstraße 10, 76131 Karlsruhe, Germany; {benedikt.sterr, daniel.wicht, matti.schneider, thomas.boehlke}@kit.edu

Key Words: Fiber Reinforced Polymer, Fiber Suspension, FFT-based Computational Homogenization, non-Newtonian Fluid, Effective Viscosity

Due to their high specific stiffness and high degree of design freedom, fiber reinforced polymer components have been employed over a wide range of industries to facilitate technological progress. Manufacturing of fiber reinforced polymer components often involves fiber suspensions, for example the widely used injection and compression molding. Thus, an accurate understanding of the viscous properties of fiber suspensions is important for appropriate industrial application. Taking microstructural parameters into account, Fast Fourier Transform (FFT) based simulations enable high fidelity homogenization of mechanical properties of fiber suspensions [1].

Previous work [1] was restricted to FFT-based viscous homogenization under the assumption of a Newtonian polymer matrix. However, polymer melts usually show non-Newtonian behavior. Here we extend the computational methodology to shear thinning rheology by employing the Cross-WLF [2, 3] material model.

Based on a Newton method, we derive an efficient implementation of the cross fluid material model. We investigate the influence of microstructural parameters on the effective viscosity of fiber suspensions with a non-Newtonian matrix. We compare our results to effective viscosities of fiber suspensions with a Newtonian matrix and mean-field estimates. Finally, we identify sensitivities with respect to microstructural parameters.

Key Words: *Fractional Step method, Square Root transformation, Oldroyd-B*

This report presents an efficient stabilized finite element scheme for simulating viscoelastic flows at high Weissenberg numbers. The velocity and pressure variables in the momentum conservation equations are uncoupled using an incremental fractional step method based on the second order backward differentiation formula (BDF2). The pressure gradient projection (PGP) stabilization technique and the discrete elastic-viscous-split-stress (DEVSS) formulation are introduced into the scheme, in explicit versions, to circumvent the LBB constraints. For the constitutive equation, a square root transformation is firstly applied to retain the positive definiteness of the polymer conformation tensor, and then the streamline upwind/Petrov-Galerkin (SUPG) method and the second order Runge-Kutta scheme are employed for spatial and time discretizations. Three benchmark problems are tested and numerical results have revealed the accuracy and convergence of the scheme. What is more, since the presented scheme enables the use of equal low-order interpolations for all variables and requires no iterative process, it is computationally efficient and easy to be implemented.

An adaptive rotated entropy stable scheme for the ideal MHD equation

Supei Zheng, Mengqing Zhai, Jianhu Feng and Xiaohan Cheng

School of Science, Chang'an University, Xi'an 710064, China, E-mail:zsp2008@chd.edu.cn

Key Words: Magnetohydrodynamics equation; Entropy stable scheme; Rotated angle; Adaptive moving grid; Runge-Kutta method.

The numerical solution of the magnetohydrodynamics(MHD) equation is of great significance in the fields of plasma physics, astrophysics research, and flow control. A rotated entropy stable scheme based on the moving grid is constructed for solving the ideal MHD equation. This method combines the Roe-type rotated entropy stable scheme based on the adaptive rotated angle and the adaptive moving grid algorithm, where the entropy stable scheme is used to discretize the MHD equation in space, and the grid evolution equation is constructed by the variational method and then is solved iteratively by Gauss-Seidel method for the adaptive grid. Furthermore, the method uses the conservative interpolation formula for the value transfer between on the new nodes and the old ones. And the rotated angle is defined by the velocity gradient function. The third-order strong stable Runge-Kutta method is used in time step. Numerical experiments show that the algorithm can effectively capture the structure of the solution (especially shock waves and rarefaction waves), and has high resolution, good versatility, and strong robustness.

Efficient and Decoupled Schemes with Unconditional Energy Stability for the Block Copolymer Model in Copolymer/Homopolymer Mixtures

Qi Li[1]*

[1] Chang'an University, Xi'an, Shaanxi 710064, P.R. China, liqihao@chd.edu.cn

Key Words: Block copolymer model, SAV approach, Step-by-step approach, Energy stability

In this talk, the numerical approximations of the Cahn-Hilliard type and conserved Allen-Cahn type block copolymer (BCP) model describing the phase separation of the copolymer and homopolymer mixtures are considered. We develop a series of efficient, unconditionally energy stable, non-iterative schemes based on the SAV, 3S-SAV, and new Lagrange multiplier approaches. The proposed numerical schemes lead to decoupled linear equations with constant coefficients at each time step, and their unconditional energy stabilities are proved rigorously. Numerical examples are provided to validate the accuracy and energy stability of the proposed schemes, and ample simulations are presented to show a variety of morphologies of pattern formations of the copolymer and homopolymer mixtures.

The finite element numerical investigation of gas entrapment phenomenon in non-isothermal polymer filling process

Puyang Gao

School of Science, Chang'an University, Xi'an 710064, China
gaopuyang@chd.edu.cn

Abstract: In this paper, the intricate gas entrapment phenomenon in the non-isothermal polymer filling process is investigated via a combined finite element and discontinuous Galerkin numerical algorithm. The evolving melt interface is captured via level set method and the eXtended Pom-Pom (XPP) constitutive model is employed to describe the viscoelastic fluid. The governing equations of flow field are solved via a coupled continuous and discontinuous Galerkin method. The implicit discontinuous Galerkin method is utilized for the solution of the XPP constitutive equation, level set and its re-initialization equations. The good agreement of experimental and simulation results illustrates the validity of this combined computational algorithm. The influence of injection velocity and the gate size on the gas entrapment phenomenon are both studied in the irregular cavity with complex insert. We have found that the entrapped gas is easy to appear for the case of higher injection velocity and smaller gate size. The distribution of temperature field in different cases are also shown.

Key Words: *gas entrapment, finite element; discontinuous Galerkin; XPP constitutive model, level set method*

Key Words: High Wi Number, Dual Splitting Scheme, High-Order Discontinuous Galerkin, Square-Root-Conformation

In this work, we present a high-order discontinuous Galerkin method (DGM) for simulating Oldroyd-B viscoelastic fluids at high Weissenberg (Wi) numbers. The dual splitting scheme is performed to decouple the velocity and pressure in the momentum and mass equations, and circumvent the limitation of the LB-B condition. The square-root-conformation representation (SRCR) method is applied in the constitutive equation to preserve the positive definiteness of the conformation tensor and improve the computational stability at high Wi numbers, and then the local Lax-Friedrichs flux and second-order Runge-Kutta scheme are employed for spatial and time discretization. Several typical benchmarks are considered to verify that the combinations of the dual splitting scheme, DGM and SRCR effectively improve the accuracy and stability compared with traditional methods for solving the Oldroyd-B viscoelastic flow problems at high Wi numbers.

3D Transient Response of Layered Soils with Local Inhomogeneities

Julian Freisinger[1]* **and Gerhard Müller**[1]

[1] Technical University of Munich, Arcisstrasse 21 80333 Munich
julian.freisinger@tum.de, gerhard.mueller@tum.de

Key Words: Soil Dynamics, Soil-Structure-Interaction (SSI), Integral-Transform-Method (ITM), Finite-Element-Method (FEM), Substructure technique, Elastic wave propagation

The three-dimensional dynamic interaction of surface foundations with structures buried in the ground or local geological inhomogeneities can have a significant impact on the structural responses and the wave propagation patterns in the ground. In particular, when amplification of ground motions occurs due to diffraction and scattering, it is essential to integrate these inclusions into prediction models and thus consider the Structure-Soil-Structure-Interaction (SSSI).

In this contribution an efficient 2.5D coupled Integral Transform Method (ITM) – Finite Element Method (FEM) approach [1] is used to compute the complex, dynamic stiffness at the surface of a layered soil including a longitudinally invariant structure or inhomogeneity. Herein, the analytical ITM solutions of the dynamic wave equation allow to account for the infinite extension of the soil by satisfying the radiation condition. The FEM enables to model complex, spatially limited structures and a part of the surrounding soil within a cylindrical outer boundary, on which both methods are coupled. The foundation on the ground surface is modelled using 3D finite elements and is coupled to the soil substructure enforcing the compatibility conditions at the common interface [2, 3].
By solving the overall system of equations in the frequency domain for an external load with unit amplitude over the entire frequency range, the transfer functions for the foundation compliances are calculated, weighted by the frequency spectrum of the transient load, and finally transformed to the time domain by an inverse Fourier transform.

The effect of soil stratification as well as embedment depth, size and stiffness of the inclusion on the transient foundation behaviour is investigated and interpreted by drawing correlations to the frequency spectra of the foundation compliances and power input at the soil-foundation interface. In addition, time-dependent displacement distributions on and within the soil are presented to illustrate the effects of the SSSI on wave propagation characteristics such as predominant wave types, propagation directivity, as well as interference and wave impeding effects due to the inclusion. For this purpose, a postprocessing procedure is used in which the interaction forces at the soil-foundation interface are applied as an external load to the soil substructure.

Accuracy Analysis of Second-order-type Linear Multistep Time Integration Methods for Structural Dynamics

Jie Zhang*

MOE Key Lab of Disaster Forecast and Control in Engineering, School of Mechanics and Construction Engineering, Jinan University, Guangzhou, 510632, China
Email: jiezhang@jnu.edu.cn

Key Words: *Accuracy analysis, linear multistep methods, time integration, structural dynamics*

Abstract: The linear multistep (LMS) methods family had been a basic solving procedure for the ordinary differential equations, and also be a significant member of the time integration schemes for structural dynamics. They can be utilized solely for the equations of motion, such as the central difference method, the BDF2 method, the Houbolt method, etc; and can also be the sub-step methods of the composite schemes, such as the Park method, the Bathe methods family, etc. In addition, the accuracy analysis framework of the LMS methods had been extended to many single-step methods based on the spectral equivalence, such the Newmark-β method, the Wilson-θ method, the HHT-α method, the three-parameters optimal scheme, the GSSSS method, etc. The present study focuses on the second-order-type LMS methods which solve the second-order differential equations of motion directly. A generalized LMS methods family is considered, and a rigorous accuracy analysis is performed for desirable numerical properties. The accuracy conditions based on consistency, stability, convergence analyses are derived. Moreover, the error constant concept of the second-order-type LMS methods is developed. It has played an important role in the first-order-type LMS methods for algorithm optimization.

Key Words: Energetic Boundary Element Method, Time-Domain Wave Propagation, Infinite Media

Full-Waveform Inversion (FWI) is a challenging data-fitting procedure based on full-wavefield modeling to estimate the elastic parameters in the underground, in order to deduce a very detailed geophysical model. This can be achieved by minimizing the energy between the modeled and the field data using a gradient optimization approach. Key ingredients of the FWI are an efficient forward-modeling engine and a local differential approach, in which the gradient and the Hessian operators are efficiently estimated. In this light, the design of a suitable, efficient an accurate numerical method to solve the elastic forward problem is essential to develop a FWI strategy for an independent inversion of isotropic elastic material parameters. Even if different directions exist, the use of a Boundary Integral Equation (BIE) technique, whose discretization is known as the Boundary Element Method (BEM), is an appealing choice because it allows to handle problems defined on the exterior of bounded domains as easily as those defined in the interior, without the introduction of an artificial boundary to truncate the computational domain. Furthermore, this technique requires the discretization only of the domain boundaries, leading to a drastic reduction of the total number of degrees of freedom of the problem. Recently, a direct space-time Galerkin BEM for the discretization of time-domain BIEs related to 2D scalar and vector wave propagation problems has been introduced in [1] and [2]. This technique is based on a natural energy identity satisfied by the solution of the corresponding differential problem, which leads to a space-time weak formulation of the BIEs with precise continuity and coerciveness properties. Consequently, the integral problem can be discretized by unconditionally stable schemes with well-behaved stability constants even for large times. In this work, starting from optimal results obtained for 3D scalar wave propagation [3], we extend the energetic BEM to 3D realistic elastodynamic problems, showing the capabilities of the method of modelling a full wavefield rather than specific wave types.

Key Words: *Brownian dynamics, collision, linker-DNA*

Eukaryotic chromatin chain with chromosomes is a physico-chemically stable material inside cell nucleus. Chromatin structure can be changed slowly or drastically through various physico-chemical interactions between nucleosomes, among which repulsion plays a key role in regulating material properties, genetic transcriptions, and gene expression. However, this type of physically driven changes is not fully understood, particularly in human cells. On the other hand, recent experiments in vivo reveals a dynamic liquid-like state of the polymer in a human cell [1]. This dynamic behavior has been observed in 100 milli second [2]. It suggests that the fluidity of the polymer and density effects of crowded molecules should be taken into account. And elastic response of linker-DNA is numerically estimated as non-linear. Therefore, it remains a crucial problem that Brownian dynamics simulation of the prototype Rouse model has a limitation of the short time step of 1ps to 1ns with the assumption of constant external force. Besides it is difficult to handle with the overstretching transition of a semiflexible polymer.

In this study, we aim to construct a simulation model of a chromatin fiber by improving Brownian dynamics with a time step longer than picoseconds, and by implementing the density effect of nucleosomal collisions. In our model, we proposed two plausible collision algorithms. One is to apply a wall solution to the Brownian process. As evaluation of the one, we confirmed diffusion property of nucleosomes which is similar to some estimated data. The other is to extrapolate the Brownian process from in-silico experiments of two-body collision. We treated nucleosomes as Brownian particles with Lenard-Jones interaction and spring interaction, and simulated the dynamics of these collisions in nanoseconds. Then, we constructed a probability function of a pair of nucleosomes based on the generalized collision process. As a result, we found that nucleosome displacements have characteristic distribution and we compared it with the wall solution algorithm. The results indicate that the Brownian collision process should be modified by our generalized extrapolated function.

Key Words: Modified formal variational formulation, Conservation laws, Noether's theorem, Variational integrator

In the modelling and simulation of physical phenomena, numerical analysis of differential equations that represents the phenomena of objects can be evaluated based on stability, accuracy, and speed. In recent years, however, in addition to stability, structural conservation, i.e., whether the numerical method can reproduce the essential properties of the phenomenon, has been greatly emphasized. For variational systems, the symplectic structure is among one of the most important features, beside symmetries and conservation laws, which are connected by the celebrated Noether's theorem. One well-known efficient structure-preserving numerical methods for variational systems are variational integrators [1].

Unfortunately, many physical systems can not be naturally derived from variational calculus. The formal Lagrangian formulation was found useful for deriving conservation laws of some special non-variational systems [2] and for constructing their variational integrators [3]. This was extended to the modified formal variational formulation [4], which is applicable to arbitrary differential equations, that, on the one hand, allows us to derive conservation laws through Noether's theorem, and, on the other hand, provides necessary foundations for constructing variational integrators for arbitrary differential equations. In this talk, we will mainly be focused on applications of this novel method to the Burgers' equation.

Filtering Spurious Eigenmodes in Electromagnetic Cavities Discretized by Energy-Orthogonal Twenty-Nodes Hexahedral Finite Elements

Francisco J. Brito

Universidad de La Laguna, fjbrito@ull.edu.es

Key Words: *Energy-Orthogonal Formulation, Electromagnetic Cavities, Spurious Eigenmodes*

An electromagnetic cavity as discussed in this contribution will be a source-free region enclosed by a perfect conductor and filled with a linear dielectric in which modes of free oscillation can exist at an infinite number of discrete frequencies. These standing-wave fields and natural frequencies are solutions of the eigenproblem associated with the double-curl operator. If the electric field is the variable solved then the magnetic field will be called the induced field, and vice versa. As is well known, if the operator double-curl is discretized with nodal finite elements then eigenspectrum computed will be severely polluted with spurious eigenmodes, the spurious eigenvalues having the same order of magnitude as the physical eigenvalues and not easily distinguished from them [1].

A standing-wave field can be represented by the superposition of plane harmonic waves travelling in several directions. For these fundamental wave solutions, by a dispersion analysis, the behavior of the energy density of the induced field is researched in unbounded domains discretized by regular meshes of twenty-nodes hexahedral finite elements formulated in energy-orthogonal form [2]. In this formulation the element stiffness matrix is split into basic and higher order components, which are respectively related to the mean and deviatoric components of the element induced field. This decomposition is applied to the element energy of the induced field and holds for the finite element assemblage. The first physical branch of the dispersion equations is selected for the analysis. The main results are summarized. Given the mesh, in the limit of long wavelength, although the energy density does not vanish, its higher order component does vanish. Similarly, given the wavelength, as the solution converges on account of mesh refinement, the energy density is increasingly dominated by its basic component. Nevertheless, the higher order energy density vanishes as a cancellation of the component associated with the vertex nodes and the one associated with the mid-side nodes, which do not vanish but are equal and opposite in sign. A sign characteristic is also satisfied by the vertex and mid-side components of the basic energy density. The convergence values of these energy components do not depend on the direction of wave propagation, direction of polarization, and mesh parameters. The relationship between the density of the mesh, the higher order energy density, and the energy error is researched for high precision discretization.

For cavities discretized by twenty-nodes hexahedral finite elements is proposed to accept only those eigenmodes for which the basic energy component of the induced field prevails over the higher order energy component. Additionally, the behavior of the vertex and mid-side energy components must be in accordance with the fundamental behavior deduced for these energy components by the dispersion analysis carried out for plane harmonic waves. The numerical research reveals that applying these energy constraints the spurious eigenmodes can be efficiently identified.

Key Words: Coupling, Mixed-dimensional, Dimensional reduction, 3D-2D, 2D-3D, Panasenko, Hybrid model, Time-dependent, Elastic waves, Elastodynamics, Finite element.

Many engineering applications require the numerical solution of a large scale three dimensional (3D) or two-dimensional (2D) problem, which consists of a large number of degrees-of-freedom (DOF). Mixed-dimensional modeling suggests the reduction of a part of the domain in which the solution is expected to exhibit a lower-dimensional behavior to a domain of lower dimension, forming a hybrid multi-dimensional model with a significantly lower number of DOF. If designed properly, the hybrid model allows for reduced computational effort with small mixed-dimensional modeling error. Fields of application where mixed-dimensional modeling is of special interest include, among others, hydrological and geophysical flow models, blood-flow analysis, and elastic structures.

The coupling of 3D and 2D finite element (FE) models to form a single hybrid 3D-2D model is considered for linear elastodynamic problems. The research focuses on the way the 3D-2D coupling is performed, and on the coupling error generated. The Panasenko technique is used to couple the 3D and 2D models. This method has been used previously for mixed-dimensional coupling in steady-state problems [1], as well as for 2D-1D coupling of acoustic waves [2]. Here it is being used for the first time for the 3D-2D coupling of time-dependent elastic problems. The hybrid formulation is shown to be well-posed, and it is shown that the Panasenko method is extremely simple to implement in the framework of FE analysis, yet the resulting coupling yields a rather small error level, provided the 3D-2D interface is sensibly placed.

Key Words: Reaction-Diffusion, Matrix Exponential, IIF Method, Nonlinear solver, Parallelization

Stiff Reaction-Diffusion (R-D) equations are used to model various bio-chemical phenomena such as pattern formation and enzymatic reactions as well as motion of self-propelled particles [1].The stiffness of the problem necessitates the selection of very small time steps during numerical simulation of the equations if time-explicit integrators are used. The exponential integrator based methods such as implicit integration factor (IIF) [1] remove this constraint. Semi-implicit IIF has been used to model stiff R-D equations in several cases since it gives unconditional linear stability for second order accurate scheme [1]. This method, however, faces mainly two difficulties - computational efficiency of calculation of matrix exponential and time-complexity for nonlinear equations for large sized systems.

In this work, we address both the problems by proposing a novel method for calculation of matrix exponential and an algorithm for parallelizing the nonlinear solver. We calculate an approximation to the matrix exponential which reduces the computational time as well as memory usage during the computation of the exponential. For the nonlinear part we use GPU parallelization to improve the computational speed for 2D and 3D problems.

We simplify calculation of the matrix exponential by taking leverage of certain properties of the structure of the matrix exponential for 1-Dimensional Dirichlet problems. The matrix exponential of a large system is approximated using a smaller sized matrix without incurring significant errors. This leads to optimization of the memory usage of the matrix exponential as well as improvements in computational time compared to Padé approximation and scaling factor method used in MATLAB® *expm()* function.

The problem of time complexity of nonlinear solver is identified for R-D systems with the nonlinear reaction terms. The semi-implicit approach models the reaction term implicitly. This results in a nonlinear system which is decoupled from the evaluation of the linear diffusion term. We implement a parallelization algorithm to solve the nonlinear system. The presentation will first focus on the results of the matrix exponential approximation in comparison with MATLAB® *expm()* function. Secondly, we shall discuss the parallelization algorithm and its implementation for higher dimensional cases.

Mixed Time Integrator for Finite Element Analysis of Wave Propergation in Nearly Incompressible Elasticity

Takahiro Yamada

Graduate School of Environment and Information Sciences, Yokohama National University,
79-7 Tokiwadai, Hodogaya-ku, Yokohama, Japan,tyamada@ynu.ac.jp

Key Words: Finite Element Method, Wave Propagation, Nearly Incompressible Elasticity, Mixed Time Integrator

In finite element procedures for dynamic problems of solid structures, explicit time integrators with relatively small phase error are suitable for calculating wave propagation phenomena[1]. However, they are conditionally stable and time increments should be determined from the propagation velocity of the elastic wave. When they are applied to nearly incompressible media such as rubber-like materials and biomaterials, very small time increments are required because of high velocities of P-wave representing volumetric deformations[2]. Therefore implicit time integrators with unconditional stability are usually adopted in such problems. In this work, a novel time integrator that posseses numerical properties of explicit time integrators in S-wave propegation is proposed[4]. To alleviates limitation of time increments, the present scheme is obtained by extending the Rattel method[3], which is proposed for constrained Hamiltonian systems.
In the proposed procedure, nearly incompressibility is considered using a u-p mixed finite element method with displacement and pressure as unknowns. An algorithmic relationship of volumetric strain with displacement and velocity is introduced to the Rattle method, in which constrained conditions must be treated implicitly. Further we derive an algorithm for solving linear equations with only pressure degrees of freedom, which is similar to the semi-implicit integrator by Kadapa[2]. The obtained method can be interpreted as a mixed time integration with an implicit solver for P-wave propagation and an explicit solver for S-wave propagation. Numerical experiments confirm that the numerical stability is determined by the Courant number of the S-wave. The mathematical analysis of the stability of the proposed method is also discussed.

Key Words: *Blast wave, CEL analysis, jet impingement, structural integrity assessment*

A high energy line break(HELB) with operating conditions over 200 °F (93.3 ℃) or 275 psig (18.96 bar) involves physical phenomena such as pipe whip, jet impingement and blast wave that cause dynamic loads on structures, systems and components(SSCs) of nuclear power plants [1]. With regard to the HELB as a design basis event, a well-known design procedure [2] has been widely adopted. However, USNRC [3] recommended additional evaluation of amplificated blast wave through colliding with nearby SSCs and further conservative evaluation and realistic consideration of jet impingement. If HELB occurs, blast wave is first generated due to pressure difference between the compressed fluid in the line system and the air within a few milliseconds. Subsequently, jet impingement induced by the release of the fluid applies an irregular load on the SSCs. Since previous studies [4, 5] have been mainly conducted on independent phenomena, comprehensive researches to reflect these phenomena are needed for safe design.

The present study is to address blast wave and jet impingement evaluation under a typical HELB condition of 1,400MWe power plant. At first, dynamic load of blast wave was determined using computational fluid dynamics analysis, trinitrotoluene(TNT) equivalent approach and theoretical correlation. Coupled Eulerian-Lagrangian(CEL) analyses were also conducted to investigate structural effect of the load by applying a TNT explosive model. Then, dynamic characteristic model such as mode shape and effective mass ratio of the two component was made and power spectral densities(PSDs) were determined by using pressure-time histories from previous jet impingement assessment [5]. Based on the CEL analysis results, combined effect of blast wave and jet impingement were evaluated by performing random vibration analyses with PSD. Finally, structural integrity assessments of main components were carried out by comparing analysis results with allowable criteria for concrete and metallic materials.

[2] Hohai University, No.8, Focheng West Road, Nanjing 211100, cbdu@hhu.edu.cn

Key Words: *field effect, seismic wave propagation, overburden layer, fault fracture zone, topography*

Local site condition is an important factor affecting ground motion response , and it has a great influence on seismic wave field propagation and ground motion energy. Typical local site conditions, such as topography, layered site and fault fracture zone site, have always been a hot research topic. In this paper, the elastic wave equation is solved by using scaled boundary finite element method. The asymptotic transmission boundary is used to simulate the radiation of wave at the boundary towards half infinity. The ground motion response characteristics of these types of site models are studied, and the propagation characteristics of seismic wave field and amplitude characteristics of ground motion are calculated under the incident conditions of Rayleigh wave and SH wave. The effects of the order of interpolation function of the element, element size and integral method on the calculation results are discussed, and the results are compared with those of ABAQUS. The results show that the soft soli overburden layer site has amplification effect on the ground motion. The wave field conversion and coherence interaction on the interface of layered soil layer of the site lead to the amplification effect of the ground motion. The fault fracture zone in the fault fracture zone site has the effect of amplification and isolation on ground motion. When the seismic wave propagates to the fault fracture zone, it will reflect and refraction between the low-speed fault zone and the surrounding rock high-speed zone, and the wave field conversion and coherence will form the trapped wave. The local convex topography can amplify the seismic wave to some extent, but the seismic response of the local concave is small.

Optimal Local Truncation Error Method for Solution of PDEs on Irregular Domains and Interfaces with Optimal Accuracy and Unfitted Cartesian Meshes.

Alexander Idesman

Texas Tech University, Box 41021, Lubbock, TX, USA, E-mail: alexander.idesman@ttu.edu

Key Words: *Numerical Method, PDEs, Optimal Accuracy, Unfitted Cartesian Meshes*

A new numerical approach called the optimal local truncation error method (OLTEM) is suggested for the solution of partial differential equations (e.g., see [1,2]). Similar to the finite difference method, the structure and the width of stencil equations are assumed in advance. Discrete equations include regular uniform stencils for internal points and non-uniform stencils for the points close to the boundary. The unknown coefficients of the discrete system are calculated by the minimization of the order of the local truncation error. The main advantages of OLTEM are an optimal high accuracy of discrete equations and the simplicity of the formation of a discrete (semi-discrete) system for irregular domains and interfaces (composite materials). For the regular uniform stencils without interfaces, the stencil coefficients can be found analytically. For non-uniform cut stencils, the stencil coefficients are numerically calculated by the solution of a small system of linear algebraic equations (20-100 algebraic equations). In contrast to finite elements, a trivial unfitted Cartesian mesh (no need in complicated mesh generators) is used with OLTEM. Changing the width of the stencil equations, different high-order numerical techniques can be developed. OLTEM does not include unknowns on irregular boundaries and interfaces. The known interface and boundary conditions at small number of selected points are added to the stencils as the right-hand side. Therefore, the width of 'boundary' and 'interface' stencils is smaller and equal to that for regular stencils. Currently OLTEM is applied to the solution of the wave, heat, Helmholtz, Poisson and elasticity equations. The theoretical and numerical results show that for the width of the stencil equations similar to that for linear finite elements, OLTEM yields the 4^{th} order of accuracy for the considered scalar PDEs on irregular domains (it is much more accurate compared with linear and high-order finite elements at the same number of degrees of freedom). E.g., 3-D numerical examples on irregular domains show that at accuracy of 5%, OLTEM reduces the number of degrees of freedom by a factor of greater than 1000 compared to that for linear finite elements with similar stencils. **At the computational costs of quadratic finite elements, OLTEM yields the 10^{th} order of accuracy for the time-independent elasticity equations and the 11^{th} order of accuracy for the Poisson equation with complex irregular interfaces.** This leads to a huge reduction in computation time for OLTEM at a given accuracy.

Key Words: *Adjoint method, Shape identification, Gradient, Inverse problem.*

This work deals with the inverse problem of *accurately* identifying the shape, size and location of scatterers in a 2D-membrane by measuring the signals of waves scattered from them. The proposed method is based on two stages. In the first stage we use the Arrival Time Imaging method [1] to significantly reduce the search area – there is no renewal in this stage. In the second and innovative stage, we load the membrane to generate waves which are being measured by a small number of sensors located at chosen points. Based on these measurements, an iterative process is performed to find the closed curve that represents the boundary of the scatterer. The process of translating the measured signals to a closed curve is an iterative process which minimizes a cost functional that represents the difference between the measured signals and the wave signals obtained in the presence of a candidate scatterer. The gradient of this functional, which represents its sensitivity to the scatterer geometry, is calculated efficiently using the adjoint method. Similar to what was done in [2], we discretize the unknown scatterer boundary from the outset, thereby allowing a simple and intuitive derivation of the adjoint formula for the gradient. The unknown curve is defined by a parametric representation that is completely general and does not make any preliminary assumptions about the scatterer geometry. A series of numerical example have been done, and showed that excellent identification is obtained even in the presence of noise, with a small number of sensors, and with no need for regularization. Additional different phenomena will be discussed during the lecture.

Direct Method-based Gear Shakedown Analysis Considering Kinematic Hardening

Lizhe Wang[1], Min Chen[1*] and Fuyuan Liu[1]

[1] School of Advanced Technology, Xi'an Jiaotong-Liverpool University, Suzhou, 210053, China

Key Words: *Gears, Shakedown Theorem, Tetrahedron Element Discretization*

In some working conditions, gears are subject to heavy-cyclic loads, such as wind turbines [1], and their failure modes are commonly caused by plasticity deformation accumulation. However, prior to the plasticity-induced failure, the shakedown states occurs when the increase of plastic strain ceases and the whole structure exhibits elastic response. Thus, the fatigue damages can be avoided by analyzing the shakedown loads of the gears in the plastic period.

Shakedown theory was first introduced in the 1930s, and Melan introduced the lower bound theorem that can be described: If the external cyclic loads vary within a scope, named *Load Domain L*, and a time independent self-equilibrium residual stress field $\overline{\boldsymbol{\rho}}$ of the structure body Ω and a load factor $\alpha > 1$ exists, shakedown happens in Ω under the defined *Load Domain L* when the superposition of $\overline{\boldsymbol{\rho}}$ and elastic stress arising from the external load. α is named as the shakedown factor, which determines the limit load of the shakedown state. Shakedown analysis has been widely utilized in fields of manned spacecraft, hull and pressure vessel. With respect to gears, Kapoor et al. [2] analyzed the shakedown limit of spur gears based on the upper and lower bound shakedown methods. He et al. [1] utilized the incremental method to evaluate the shakedown state of the two-dimensional turbine gear contact model considering the effects of residual stress and strain-hardening. However, it has the limitation of high computation costs and unsuitability in conditions that the loads' variation laws with time are unknown. In addition, due to the inadaptability of hexahedral element-based discretization on geometrically irregular gears, little research has focused on the shakedown limit of gears in a three-dimensional scale.

This abstract addresses these issues by proposing a shakedown theorem-based direct method for predicting the loading capacities of a typical industrial gear based on tetrahedral element-based discretization. For reducing the computation cost, the reduced Gaussian integration point scheme is applied to the elements to increase the efficiency of the computational algorithm. The rationality and precision of the proposed method are validated through a classical numerical model. The shakedown limit loads of the gear model under the perfect elastic-plastic and kinematic hardening material properties are compared, which demonstrates that the hardening material has a positive contribution to the loading capacity of the gear. It can be mainly explained by the witnessed redistribution of the residual stress field. The results demonstrate that the proposed direct method provides an effective means for predicting the limit loading capacity of gears under cyclic loading.

Hybrid High-Order methods for Electromagnetics

Simon Lemaire[1]*

[1] Inria, Univ. Lille, France, simon.lemaire@inria.fr

Key Words: Polyhedral meshes, Hybrid High-Order method, Electromagnetics

Introduced in [2], the Hybrid High-Order (HHO) method provides a novel framework for the discretization of models based on PDEs. Its construction hinges on (hybrid) polynomial unknowns attached to both the cells and the faces of the mesh. HHO methods have several assets: (i) they are applicable on general polyhedral meshes, (ii) they allow for an arbitrarily large approximation order, and (iii) they are amenable to static condensation, thus allowing for a reduced computational burden.

The design of HHO methods for electromagnetics models is still in its infancy. As a matter of fact, there are (at least) three obstacles that make their devising highly challenging.

- The reconstruction of a local higher-degree potential (as standard in the HHO context) for the **curl** operator is nontrivial.
- The **grad**-**curl** orthogonality is lost at the discrete level.
- The well-posedness of the methods relies on (hybrid) discrete Weber inequalities [3], which are nontrivial to derive due to the fact that the HHO setting is non-compatible. The statement of the discrete Weber inequalities both strongly depends on the topology of the continuous problem, and on the choice of the discrete framework (discrete spaces and operators). Related discrete Maxwell compactness results are also nontrivial to prove.

This contribution will review the recent developments in the HHO approximation of (three-dimensional) electromagnetics problems [1]. This is a joint work with F. Chave and D. A. Di Pietro.

Key Words: Fourth-order PDEs, hybrid high-order method, stability, error analysis, computational performance, curved domains

We devise and analyze two hybrid high-order (HHO) methods for the numerical approximation of the Fourth-order PDEs problem. The methods support polyhedral meshes, rely on the primal formulation of the problem, and deliver $O(h^{k+1})$ H^2-error estimates when using polynomials of order $k \geq 0$ to approximate the normal derivative on the mesh (inter)faces. Both HHO methods hinge on a stabilization in the spirit of Lehrenfeld–Schöberl for second-order PDEs. The cell unknowns are polynomials of order $(k+2)$ that can be eliminated locally by means of static condensation. The face unknowns approximating the trace of the solution on the mesh (inter)faces are polynomials of order $(k+1)$ in the first HHO method which is valid in dimension two and uses an original stabilization involving the canonical hybrid finite element, and they are of order $(k+2)$ for the second HHO method which is valid in arbitrary dimension and uses only L^2-orthogonal projections in the stabilization. A comparative discussion with the weak Galerkin methods from the literature is provided, highlighting the close connections and the improvements proposed herein. Additionally, we show how the two HHO methods can be combined with a Nitsche-like boundary-penalty technique to weakly enforce the boundary conditions even on the curved domains. An originality in the devised Nitsche's technique is to avoid any penalty parameter that must be large enough. The numerical results showcase the efficiency of the proposed methods, and indicate that the HHO methods can generally outperform discontinuous Galerkin methods and even be competitive with C^0-interior penalty methods on triangular meshes.

Key Words: Elliptic hemivariational inequality, Virtual element method, Contact mechanics

An abstract framework of the virtual element method is established for solving general elliptic hemivariational inequalities with or without constraint, and a unified a priori error analysis is given for both cases. Then, virtual element methods of arbitrary order are applied to solve three elliptic hemivariational inequalities arising in contact mechanics, and optimal order error estimates are shown with the linear virtual element solutions. Numerical simulation results are reported on several contact problems; in particular, the numerical convergence orders of the lowest order virtual element solutions are shown to be in good agreement with the theoretical predictions.

Key Words: virtual element method, generalized membrane shell, polygonal mesh, cone shell, cylindrical shell

Virtual element method(VEM), a new numerical method with high regularity and flexible mesh, is being applied widely to Poisson problem, Stokes problem, linear elasticity problem, plate bending problem, biharmonic problem, Cahn-Hilliard problems, Steklov eigenvalue problem, some contact problems and so on. For two-dimensional shell models, this method has not been used. In this talk, we provide the VEM scheme for steady generalized membrane shell model for the first time. Concretely, conforming virtual element function space and degrees of freedom of the shape functions are proposed. A projection from the virtual element space to the polynomial space for this model is established. Then, the stability, convergence and error estimate of the discrete scheme are proven. Finally, we execute numerical examples involving a portion of a cone shell and cylindrical shell to verify the convergence and stability of the numerical scheme.

[3] Tokyo Institute of Technology, 2-12-1 Ookayama, Meguro-ku, Tokyo, 152-8550, Japan, xiao.f.aa@m.titech.ac.jp

Key Words: Finite Volume Method, Reconstruction, Total Variation Diminishing, Limiter Function, Boundary Variation Diminishing

The TVD (Total Variation Diminishing) scheme[1] is one of the high-order and numerically stable schemes for the finite volume method. The basic idea of this scheme is to suppress numerical oscillations by using the limiter function which satisfies the TVD condition. Although a variety of limiter functions have been proposed, it is hard to determine the optimal limiter for difference problems.

In addition, BVD (Boundary Variation Diminishing) schemes[2, 3] have been recently developed. This scheme effectively reduces the numerical dissipation error by following the BVD principle, which minimizes the jump of the left- and right-value of a reconstructed cell boundary value.

This study presents a new TVD framework based on the BVD principle. In the second order TVD region, the present scheme determines a suitable value of the TVD limiter function in the context of the BVD principle.

We compared numerical results using the present scheme with conventional TVD schemes in some benchmark tests for compressible flows. The present scheme is less dissipative near discontinuous solutions and capture small vortex structures caused by the Kelvin-Helmholtz instability. The new scheme also improves to avoid strange solutions due to the so-called squaring effect of some limiters. It is revealed that the combination of TVD and BVD frameworks has higher fidelity than the conventional TVD schemes.

Abstract: For compressible flow simulations involving both turbulence and shockwaves, the competing requirements render it challenging to develop high-order numerical methods capable of capturing the discontinuities sharply and resolving the turbulence with high spectral resolution. In particular, when deployed with the advanced large-eddy simulation (LES) approach, for which the governing equations are solved with coarse mesh, the solution is extraordinarily sensitive to the numerical dissipation resulting in large uncertainties for cross-code comparisons. In this talk, the family of high-order targeted essentially non-oscillatory (TENO) schemes are reviewed for general hyperbolic conservation laws with an emphasis on the high-speed turbulent flows. As a novel variant of the popular weighted ENO (WENO) scheme, the TENO scheme retains the sharp shock-capturing capability of WENO and is suitable for resolving turbulence with controllable low numerical dissipation. The key success of TENO relies on a strong scale-separation procedure and the tailored novel ENO-like stencil selection strategy. In addition, the built-in candidate stencils with incremental width facilitate the construction of arbitrarily high-order (both odd- and even- order) schemes featuring superior robustness. In this talk, the first-ever extension of TENO schemes to unstructured meshes with arbitrarily high-order reconstructions and mesh-element types will be presented. The tailored stencil arrangement and the new TENO weighting strategy for unstructured meshes will be elaborated. Detailed comparisons between WENO and TENO schemes with both structured and unstructured meshes will be discussed. Examples of the applications of TENO schemes to challenging compressible fluids with broadband length scales will be presented.

Solution property preserving method for compressible turbulence simulation

Zhen-Hua Jiang[1*], Wei Yang[2]

[1] Beihang University, Beijing, China, jiangzhenhua@buaa.edu.cn
[2] HIWING General Aviation Equipment Co., Ltd., Beijing, China

Key Words: *compressible turbulence, solution property preserving, BVD, MOOD*

The accurate simulation of complex flow including shock wave is a frontier and difficult problem in the field of computational fluid dynamics. Under the framework of finite difference and finite volume, researchers have developed a large number of classical shock capture methods. Although modern discontinuity-capturing methods have been able to solve the problem of shock capture, the methods still need to be further developed and improved for some complex flow phenomena including compressible turbulence simulation.

The solution property preserving method has been developed to simulate compressible turbulence, in particular, with strongly compressible characteristics. By combining the advantages of high-accuracy low dissipation scheme and high-resolution shock-capturing scheme, the method has obtained high-accuracy solution in smooth region and has suppressed numerical oscillation in discontinuous region. The method is implemented in the finite volume (FV) framework. Under the FV framework, based on the MOOD (multi-dimensional optimal order detection) concept, the hybrid computation of low dissipation reconstruction and solution property preserving reconstruction is realized, so as to give full play to the low dissipation characteristics of the central scheme and the shock capture ability of multi-step BVD (boundary variation dimensioning) scheme to the greatest extent.

Numerical experiments show that the developed method has good numerical characteristics such as low dissipation and positivity preservation, and can be applied to high accuracy simulation of compressible turbulence with and without wall bounded.

Key Words: multiphase flows, viscoelastic flows, non-Newtonian fluids, relative energy, weak-strong uniqueness

We consider a viscoelastic phase separation model that describes phase-separation behaviour of a dynamically asymmetric mixture, which is composed of fast and slow components, see [1, 2].

In dynamically asymmetric mixtures the phase separation generally leads to the transient formation of network-like structures of a slow-component-rich phase and its volume shrinking. Consequently, in order to model such a rich dynamical behaviour the resulting viscoelastic phase separation model consists of the Cahn-Hilliard-type equation for two-phase flows and the Peterlin-Navier-Stokes equations for viscoelastic fluids. We will present our recent results on the global existence of weak solutions (also for degenerate mobility function) and the weak-strong uniqueness principle [3, 4, 5]. Numerical simulations are realized by an energy dissipative finite element method. Applying the relative energy we obtain the convergence of finite element solutions to a weak solution [6]. Numerical experiments will illustrate rich dynamical behaviour arising in the viscoelastic phase separation.

Key Words: Suspension rheology, tensorial models, shear jamming, log-conformation tensor, finite element method, tensorial transport equations

The rheology of highly concentrated suspensions of solid particles dispersed in a viscous fluid features a number of surprising phenomena [1]. By varying the rate of deformation we can observe shear thinning, continuous or discontinuous shear thickening and, at very high concentrations, even the phenomenon of shear jamming. While the understanding of the microscopic origin of these phenomena has reached a significant depth [2, 3], the definition of suitable continuum-level models able to capture the rheology of dense suspensions is still the subject of active research efforts [4].

Building on a recently proposed tensorial model for shear-jamming suspensions [5], we develop constitutive relations that allow to include further effects such as shear thickening and yielding. In particular, the inclusion of rate-dependent phenomena requires the addition of evolution equations for tensorial measures of strain, akin to the conformation tensors used in viscoelastic fluid models. The presence of such evolution equations and the nonlinearities that arise in coupling them to the flow equation require appropriate computational strategies to guarantee the reliability of the numerical results [6].

Different features of the proposed continuum model are analyzed and illustrated with numerical solutions in paradigmatic examples of complex flows, in which the geometric features of the domain and the possible presence of free surfaces make it necessary to have available a fully tensorial model. In parallel, we discuss the numerical strategies employed to treat such heterogeneous flows.

Key Words: *Numerical solution, droplet collision, viscoelastic fluids, Front-tracking*

We have numerically investigated the binary collision of viscoelastic drops by using a Front-tracking/Marker-And-Cell methodology. The numerical scheme is validated with shear-thinning fluids under surface tension effects. After, we have solved the droplet-droplet dynamics for viscoelastic constitutive models of Oldroyd-B and Phan-Thien-Tanner (PTT). In order to describe our main finding, maps of outcomes as functions of the dimensionless numbers that govern the problem are provided.

The simulations describe the bouncing, coalescence, and separation outcomes varying the Weber number as well as Weissenberg number. Our findings suggest that surface tension and elasticity act to maintain the integrity of the merged drop and avoid separation.

Second-order finite difference approximations of the upper-convected time derivative

Hirofumi Notsu[1*], Débora O. Medeiros[2] and Cassio M. Oishi[3]

[1] Kanazawa University, Kanazawa 920-1192, Japan, notsu@se.kanazawa-u.ac.jp
[2] Universidade de São Paulo, SP 05508-220, Brazil, deboramedeiros@usp.br
[3] Universidade Estadual Paulista Júlio de Mesquita Filho, SP 19060-900, Brazil, cassio.oishi@unesp.br

Key Words: Generalized Lie derivative, Lagrangian scheme, Finite difference method

For $d \in \{1,2,3\}$, the velocity $u : \Omega \times (0,T) \to \mathbb{R}^d$ and a tensor $\zeta : \Omega \times (0,T) \to \mathbb{R}^{d\times d}_{\mathrm{sym}}$ to represent the non-Newtonian contribution, we focus on the so-called upper-convected time derivative or Oldroyd derivative $\overset{\triangledown}{\zeta}$ defined by $\overset{\triangledown}{\zeta} := \partial\zeta/\partial t + (u\cdot\nabla)\zeta - (\nabla u)\zeta - \zeta(\nabla u)^\top$, which usually appears in the constitutive equation of popular viscoelastic models, cf., e.g., [1]. It is worthy to note that the idea of the generalized Lie derivative can reformulate the upper-convected time derivative, cf., e.g., [2]. In this talk, based on [3], we firstly present a two-step second-order approximation in time for $\overset{\triangledown}{\zeta}$. Secondly, we propose new finite difference approximations for the upper-convected time derivative. The theoretical analysis of the truncation errors of the finite difference approximations considers the linear and quadratic interpolation operators with a Lagrangian framework. Thirdly, we present numerical results illustrating the theoretical results for a model equation for $d = 1$ and 2. Finally, we also apply the finite difference approximations of second-order in time for solving a two-dimensional Oldroyd-B constitutive equation subjected to a prescribed velocity field at different Weissenberg numbers.

Key Words: *FEM, Shell and beam, Inertia relief, Geometrically nonlinear, Superelement*

In the New Energy and Industrial Technology Development Organization (NEDO) project "Toward Ideal Aircraft-Structure Design with Carbon Fiber Reinforced Thermoplastics", structural analysis code has been developed based on the finite element method. This code is referred to as *NLFEASTR*, and used for aircraft design simulations using carbon-fiber-reinforced plastics and thermoplastics (CFRP and CFRPT). The code uses structural elements including shell elements such as MITC4 [1] and MITC3 [2] and beam elements, and can perform static analyses, eigenvalue analyses for natural frequency and buckling load, and transient analyses. In addition, it has the following capabilities.

- An inertia relief function to perform static analysis for unconstrained structures subjected to a constant external load
- A geometrically nonlinear analysis function to consider large deformations and rotations of a structure
- A superelement technique to reduce the size of the finite element model
- A shear panel element for buckling tolerance design analysis

In the presentation, an outline of the developed code *NLFEASTR* will be given, and numerical results that verify its functions will be provided.

High-Fidelity Wall-Modeled LES around Full Aircraft Configuration near Stall Condition

Hiroyuki Asada[1*], **Soshi Kawai**[2]

[1] Tohoku University, Sendai, Miyagi, Japan, h.asada@tohoku.ac.jp
[2] Tohoku University, Sendai, Miyagi, Japan, kawai@tohoku.ac.jp

Key Words: CFD, wall-modeled LES, full aircraft configuration, hierarchical Cartesian, KEEP scheme

This study presents the wall-modeled LES of complex flows around full aircraft configuration at stall condition using hierarchical Cartesian meshes. The key numerical methods in the presented wall-modeled LES are the wall-modeling on non-conforming wall boundaries [1], the non-dissipative kinetic energy and entropy preserving (KEEP) scheme [2], and the conservative low-pass filter on the hierarchical Cartesian mesh[3], proposed in our group. The aircraft configuration is the JAXA standard model (JSM) which involves high-lift devices. The presented wall-modeled LES successfully predicts lift coefficient, pressure distribution, and flow separation (Fig. 1). Additionally, compared to the conventional upwind scheme, the advantages of the non-dissipative nature of the KEEP scheme are demonstrated (Fig. 2).

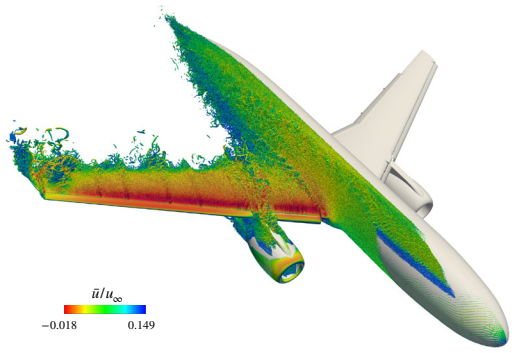

Figure 1: Instantaneous iso-surfaces of Q criterion.

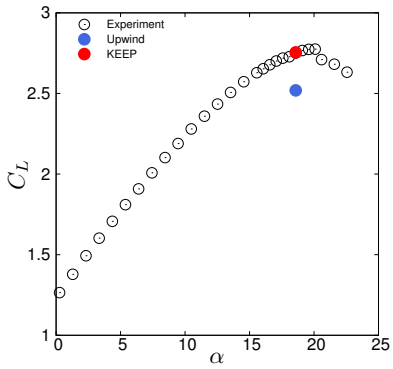

Figure 2: Lift coefficient C_L.

Key Words: CFD, High-Fidelity Aerodynamic Evaluation, Operating Engine, Airframe

This study integrated and analyzed an operating engine with an airframe. The engine simulates 22 rotors and a passage on NASA Rotor 67; the airframe consists of a fuselage, a wing, a nacelle, and a pylon based on NASA Common Research Model. In the past developments, engines were designed alone; they modeled the intake flow distribution affected by the airframe. For the high bypass ratio engines expected to be developed in the future, it is desirable to estimate the engine's performance in a form faithful to the practical engine without modeling because past knowledge is insufficient. This study would enable us to assess the high-fidelity aerodynamic loads on the main wing and accomplish an ideal structural design. The engine and fuselage are discretized separately and analyzed in an integrated manner using the overset mesh method, and the flow at the engine inlet is estimated without modeling. An unstructured mesh method, suitable for designing complex 3D geometries of engines and airframes, is adopted to ensure robustness to their changes. Since the analysis was successfully running, we would examine the mesh dependency and verify the validity of the results by comparing them with experimental data.

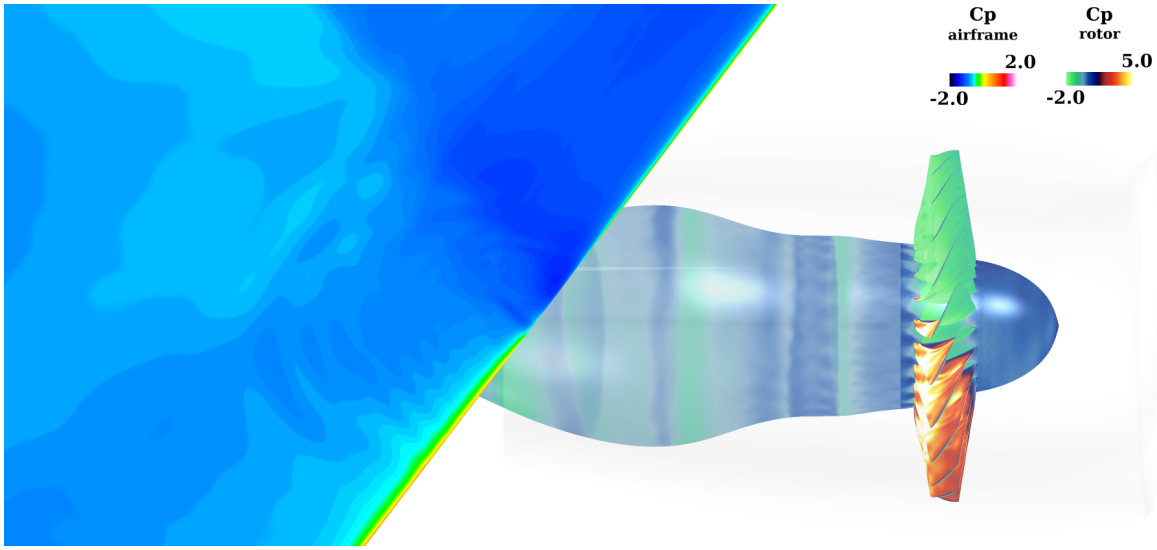

Figure 1: C_p distributions on the rotor, the passage, and the wing upper surface at rotating four-pitch (4/22). We look down on the computational object from above; the nacelle and the pylon are depicted in translucent view.

Key Words: Aircraft Design, Fluid-Structure Interaction, Optimization, CFRP

Digital design of aircraft has been one of the most challenging topics in engineering fields, which requires highly multidisciplinary simulation tools and has yet to be fully realized in industries [1]. This study has developed a multiscale design framework of aircraft wings with carbon fiber reinforced plastics (CFRPs), wherein a multiobjective design exploration of wing geometries has been performed using a genetic algorithm [2]. Figure 1 represents a preliminary optimization results for different carbon fibers, i.e., T800S (black) and T1100G (red), where two objective functions are adopted: minimization of the drag and structural weight under the constraint of a specified lift coefficient ($C_L = 0.5$). The plot shows a reasonable result that the stiffer fiber leads to a lighter weight.

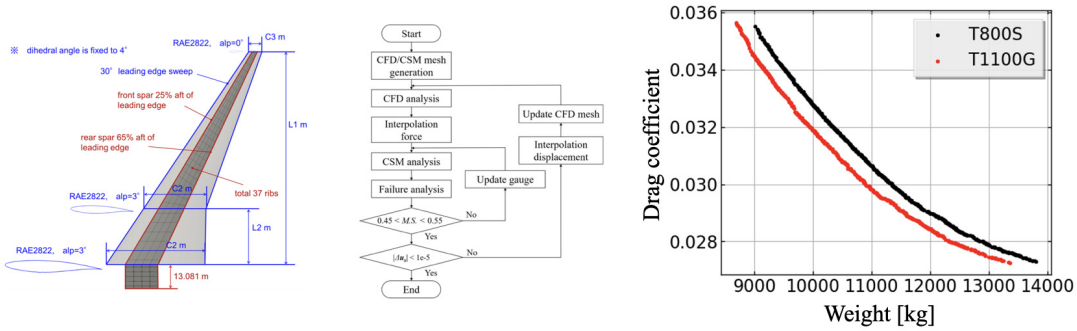

Figure 1: Multi-objective design exploration of CFRP wings

New calculation scheme for compressible Euler equation

Takashi Nakazawa[1*] and Taku Nonomura[2]

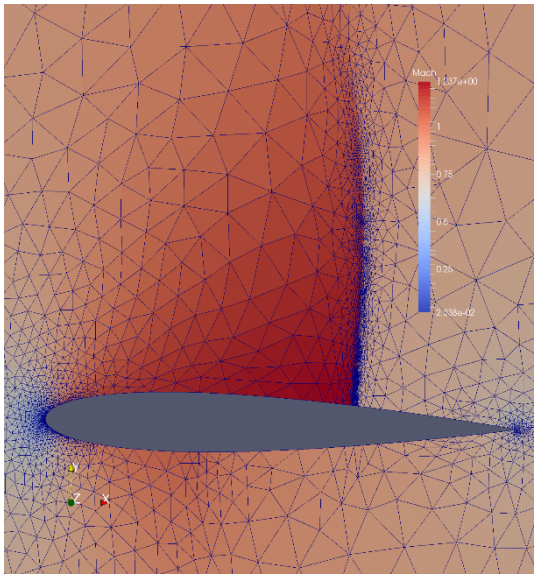
[1] Osaka University, Machikaneyama, Toyonaka, Osaka, Japan,
nakazawa@sigmath.es.osaka-u.ac.jp
[2] Tohoku University, Aobayama Aza Aoba, Sendai, Miyagi, Japan,
nonomura@tohoku.ac.jp

Key Words: *Compressible Euler equation, Finite element method, NACA0012*

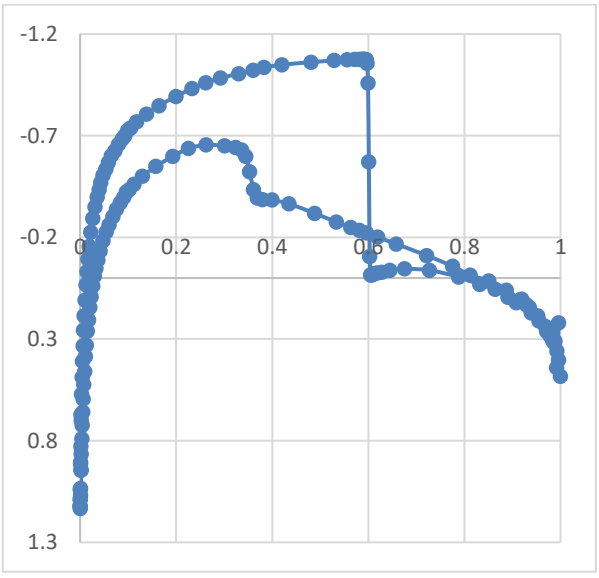
F. De Vuyst (HAL Id : cel-00842234, ver. 1) suggests a new mathematical model for compressible Euler equation as follows;

$$\frac{Da_\rho}{Dt} + \nabla \cdot \boldsymbol{u} = 0, a_\rho = \log(\rho),$$
$$\frac{1}{T}\frac{D\boldsymbol{u}}{Dt} + \nabla a_p = 0,$$
$$\frac{Da_p}{Dt} + \gamma \nabla \cdot \boldsymbol{u} = 0, a_p = \log(p).$$

In general, compressible fluid is calculated by using finite volume method (FVM) or discontinuous Gelerkin method (DGM), to gurantee high numerical calculation accuracy. However, these discritizing sheme is needed high calculation cost. The above mathematical model is able to be used standard Gelerkin method with lower calculation cost than FVM and DGM. In this presentation, NACA0012 is adopted as a first trial domain, and calculation results are very similar to previous results.



(a) Mach number and FEM mesh.



(b) Pressure distribution on NACA0012.

Figure 1. Numerical simulation results.

A nonlinear elimination preconditioned inexact Newton method for blood flow problems in human artery with stenosis

Li Luo[1*] **and Xiao-Chuan Cai**[2]

[1] Faculty of Science and Technology, University of Macau, Macau, China, liluo@um.edu.mo
(www.fst.um.edu.mo/personal/liluo/)
[2] Faculty of Science and Technology, University of Macau, Macau, China, xccai@um.edu.mo

Key Words: Blood flow problem, inexact Newton method, nonlinear preconditioning, parallel computing

Simulation of blood flows in the human artery has become a powerful tool for understanding the hemodynamics. The blood flow is often smooth in a healthy artery, but may become locally chaotic in a diseased artery with stenosis, and as a result, a traditional solver may take many iterations to converge or does not converge at all. To overcome the problem, we develop a class of nonlinear preconditioning algorithms in which the variables associated with the stenosis are iteratively eliminated and then a global Newton method is applied to the smooth part of the system. More specifically, we model the blood flow in a patient-specific artery based on the unsteady incompressible Navier-Stokes equations with resistive boundary conditions discretized by a fully implicit finite element method. The resulting nonlinear system at each time step is solved by using an inexact Newton method with a domain decomposition based Jacobian solver. To improve the convergence and robustness of the Newton method for arteries with stenosis, we develop an adaptive nonlinear elimination preconditioner which performs subspace correction to remove the local high nonlinearities. Numerical experiments for several cerebral arteries are presented to demonstrate the superiority of the proposed algorithm over the classical method with respect to a variety of physical and numerical parameters. We also report the parallel scalability of the proposed algorithm on a supercomputer with thousands of processor cores.

Classification of in Vivo Mice Magnetic Resonance Imaging for Early Detection of Liver Fibrosis by Machine Learning Technique

Yi-Zhen Su[1*], Feng-Nan Hwang[2] and Dennis Hwang[3]

[1] National Central University, No. 300, Zhongda Rd., Zhongli District, Taoyuan City 320317, Taiwan, nick760110@gmail.com
[2] National Central University, No. 300, Zhongda Rd., Zhongli District, Taoyuan City 320317, Taiwan
[3] Academia Sinica, 128 Academia Road, Section 2, Nankang, Taipei 115201, Taiwan

Key Words: MRI segmented, Noninvasive, Liver fibrosis, Support Vector Machine (SVM)

In recent years, chronic liver disease has been a severe disease that affects health, and in the early stage of liver fibrosis, there are possible ways to restore health through treatment and diet. At present, noninvasive diagnosis methods such as blood tests and abdominal ultrasound are not easy to detect the early stage of liver fibrosis. In this work, we proposed using a machine-learning (ML) technique to predict the stages of liver fibrosis, classified as healthy, mild, or severe, through mice in vivo experiments. Specifically, we employed a support vector machine as the classifier. Two types of features, namely the simply connected domain scores and estimated porosity related to liver fibrosis from mice's magnetic resonance (MR) imaging, are used to train the classifier. The basic idea of these two feature extractions is originated from the geometric and topological properties of liver imaging. After parameter tunning, the classification accuracy of our proposed method for the testing result outperformed a baseline, convolution neural network method (CNN), 95.5% versus 87.8%. We demonstrated that the ML method, in conjunction with suitable features extracted from MR images, can be served as a diagnostic tool for the stage of liver fibrosis.

Computational Fluid Dynamics in Intracranial Atherosclerotic Disease: The Clinical Implications

Xinyi Leng, Assistant Professor, Department of Medicine and Therapeutics,
The Chinese University of Hong Kong, Hong Kong SAR

Background and objectives: Intracranial atherosclerotic disease (ICAD) is an important cause of stroke, particularly in East Asian populations. Those with an ischemic stroke attributed to ICAD (i.e., symptomatic ICAD) face a considerable risk of stroke relapse despite contemporarily best medical treatment. We aimed to investigate the clinical relevance of cerebral hemodynamics in symptomatic ICAD, assessed via a computational fluid dynamics (CFD) model.

Methods: In a series of studies, we used a CFD model constructed based on computed tomography angiography images to simulate blood flow across the symptomatic ICAD lesion, in patients with an ischemic stroke or transient ischemic attack attributed to ICAD with 50-99% luminal stenosis. Translesional pressure ratio (PR) and translesional wall shear stress ratio (WSSR) were obtained in the CFD model to quantify the relative changes of these two hemodynamic metrics across a symptomatic ICAD lesion, when a low PR (relatively large pressure gradient across the lesion) and high WSSR (significantly elevated wall shear stress upon the lesion) indicate a hemodynamically more severe ICAD lesion.

Results: We found that symptomatic ICAD patients with a low PR and a high WSSR had a significantly higher risk of recurrent ischemic stroke in the same territory than those with normal PR and WSSR, despite best medical treatment, with hypoperfusion and/or artery-to-artery embolism as the probable mechanisms of most of the recurrent strokes. We have also identified a significant association between wall shear stress measures across symptomatic ICAD lesion and progression/regression of luminal stenosis in the lesion in medically treated patients. Moreover, we have associated low PR and high WSSR with more severe covert cerebral small vessel disease burden in the ipsilateral hemisphere, in those with symptomatic ICAD in the anterior circulation.

Conclusions: Cerebral hemodynamics plays an important role in governing lesion evolution and the mechanisms and risk of stroke in ICAD, which may also underlie the development/progression of cerebral small vessel disease. There could be wide applications of CFD models in investigating the clinical implications of cerebral hemodynamics in ICAD and other cerebrovascular diseases.

High Resolution Patient-specific Blood Flow Simulations with High Performance Computing

Rongliang Chen[1*], Zaiheng Cheng[1], Zhengzheng Yan[1], Shanlin Qin[1], Zeng Lin[1], and Xiao-Chuan Cai[2]

[1] Shenzhen Institutes of Advanced Technology Chinese Academy of Sciences, Shenzhen (518055), China, rl.chen@siat.ac.cn
University of Macau, Macau, China, xccai@um.edu.mo

Key Words: *Blood Flow Simulations, Parallel Computing, Domain Decomposition Method*

Patient-specific blood flow simulations have the potential to provide quantitative predictive tools for virtual surgery, treatment planning, and risk stratification. To accurately resolve the blood flows based on the patient-specific geometry and parameters is still a big challenge because of the complex geometry and the turbulence, and it is also important to obtain the results in a short amount of computing time so that the simulation can be used in surgery planning. In this talk, we will discuss some scalable parallel methods for the simulation of blood flow in compliant arteries on large scale supercomputers. The blood flow is modelled by 3D unsteady incompressible Navier-Stokes equations with a lumped parameter boundary condition, which are discretized with a stabilized finite element based on unstructured meshes in space and a fully implicit method in time. The large scale discretized nonlinear systems are solved by a parallel Newton-Krylov method preconditioned by linear and nonlinear domain decomposition preconditioners. Some patient-specific cases with clinical measured data are used to verify the accuracy of the simulation results and show the performance of the algorithms. Numerical results show that the proposed methods work well for realistic geometry and parameters on a supercomputer with thousands of processor cores. A patient-specific analysis, with a resolution higher than 4D MRI can be obtained in less than one hour.

Key Words: Effective Stiffness, 3D Graph, Finite Element, FEA, Porous, Heterogenous

Applications with anisotropic structures require a precise description of their mechanical properties. While recurring shapes are accessible for detailed investigations by homogenization methodologies, naturally grown, heterogenous structures like the human bone tissue with no identifiable unit cell need a different approach for material characterization. Rietbergen et al. demonstrated the computation of such information by direct numerical simulation [1].

In this Publication, we propose the modeling of porous, heterogenous and anisotropic structures, by their transformation into an equivalent 3D graph. The graph is retrieved by thinning the plates and struts of the structures into lines of a discrete width of one voxel. In a subsequent step, the irregular lines are converted into straight lines, defined by the position of their adjacent nodes.

By directly discretizing the graph with 1D elements like beams or trusses, a mesh of finite elements is created. The total mesh gets decomposed by intersection with control volumes of a user defined size and shape. The effective stiffness matrices of the control volumes are derived by numerical evaluation of their finite element structure according to Schmid [2].

In principle, the computational effort of the proposed methodology depends on the algorithms to transform the image into a 3D graph, the density of the anisotropic structure and the type of 1D finite elements, used to discretize the graph. Additionally, the order of the macroscopic elements representing the control volumes for which the effective stiffnesses are calculated has an impact on the performance of our method.

We will show, that our methodology, due to the 1D FEA approach, requires lower computational effort compared to the methodology proposed in [1], while preserving an accurate mechanical representation.

A Matrix–Free Approach for Smoothed Aggregation Algebraic Multigrid

Graham Harper[1]*

[1] Center for Computing Research, Sandia National Laboratories, Albuquerque, NM, USA,
gbharpe@sandia.gov

Key Words: Multigrid, Algebraic Multigrid, Matrix-Free, GPU

In the past decades, the advancement of software and algorithms has allowed multigrid (MG) algorithms to take advantage of the computational benefits provided by graphics processing units (GPUs) in more advanced machines. These MG solvers are often referred to as geometric MG (GMG) or algebraic MG (AMG) based on whether transfers between grids are constructed using geometric or algebraic properties of the problem being solved. The main difficulties of working with GPUs are latency of memory transfers and lower memory storage abilities, meaning many traditional algorithms require changes in order to utilize the acceleration provided by GPUs to the fullest extent. Recently, GMG frameworks have been introduced for matrix–free (MF) finite element methods (FEMs) [1], where the matrix resulting from the FEM discretization is never stored explicitly, but instructions for application of the matrix as an operator are stored instead and utilized in the MG hierarchy. This approach greatly reduces the memory footprint of the algorithm and takes advantage of GPUs better than traditional solvers for FEMs. However, due to the nature of many AMG algorithms querying individual values of a matrix to construct grid transfers, MF AMG solvers are not commonly explored.

We present a matrix–free approach for smoothed–aggregation (SA) based AMG [2] for FEMs. Our approach constructs the FEM operator for the matrix via sum factorization and constructs the AMG coarsening operators by querying the matrix operator through its application against carefully chosen inputs without explicitly storing the fine matrix in memory, leading to performance benefits for the algorithm on GPUs. We discuss the algorithm and then present its implementation in the MueLu MG library, and we present results including scaling studies, comparisons with existing SA–AMG approaches within MueLu, and comparisons with MF approaches in other scientific software libraries. Finally, we discuss the impact of this work within the context of MFMG solvers for FEMs and directions for future work.

A scalable and robust *p*-multigrid preconditioner with a vertex-star relaxation for high-order FEM

Pablo D. Brubeck[1*], Patrick E. Farrell[2]

[1] Mathematical Institute, University of Oxford, Oxford UK, brubeckmarti@maths.ox.ac.uk,
[2] Mathematical Institute, University of Oxford, Oxford UK, patrick.farrell@maths.ox.ac.uk

Key Words: Preconditioning, High-order, Tensor product, Additive Schwarz, Sparse Cholesky

Pavarino [1] proved that the additive Schwarz method with vertex patches and a low-order coarse space gives a *p*-robust solver for symmetric and coercive problems. However, for very high polynomial degree it is not feasible to assemble or factorize the matrices for each patch. In this work we introduce a direct solver for separable patch problems that scales to very high polynomial degree on tensor product cells. The solver constructs a tensor product basis that diagonalizes the blocks in the stiffness matrix for the internal degrees of freedom of each individual cell. As a result, the non-zero structure of the cell matrices is that of the graph connecting internal degrees of freedom to their projection onto the facets. In the new basis, the patch problem is as sparse as a low-order finite difference discretization, while having a sparser Cholesky factorization. We can thus afford to assemble and factorize the matrices for the vertex-patch problems, even for very high polynomial degree. In the non-separable case, the method can be applied as a preconditioner by approximating the problem with a separable surrogate. We apply this approach to high-order discretizations of incompressible neo-Hookean hyperelasticity.

Analysis of multigrid methods for systems of PDEs using structured matrices

Matthias Bolten[1*]

[1] Bergische Universität Wuppertal, Gaußstraße 20, 42119 Wuppertal, Germany,
bolten@math.uni-wuppertal.de

Key Words: Multigrid methods, systems of PDEs, structured matrices

Systems of partial differential equations are of interest in many applications in engineering, e.g., the elasticity equations or the Stokes equations. For large-scale simulations multigrid methods are often the method of choice, as they provide an efficient way of solving the associated linear systems. In the case of geometric multigrid methods the analysis is usually carried out using Fourier analysis. This does not allow for an asymptotic multilevel analysis and becomes relatively complicated for systems.

Instead, we use structured matrices, i.e., Toeplitz matrices or circulant matrices, and traditional multilevel theory to analyze the properties of the multigrid methods. While this approach is similar to Fourier analysis, an estimate of the convergence rate is also possible for the multilevel case. For scalar problems, including those arising from the discretization of PDEs, this technique has been studied intensively. Recently, we started transfering these results to the systems case that results in block-Toeplitz matrices or block-circulant matrices [1]. Besides studying higher-order discretizations of scalar PDEs, systems of PDEs also fit in this framework.

The usage of structured matrices allows for a rigorous treatment of different discretizations (finite differences, finite elements, finite volumes) and the analyses carry over to non-constant coefficients and more complex triangulations. Further, the multilevel hierarchy arises naturally and the multiplication with structured matrices and multgrid methods for them can be implemented on modern computer architectures in a very efficient manner.

In the talk the analysis technique, the derived sufficient conditions for optimal convergence and numerical results will be presented. Further, the application to problems in mechanics will be discussed.

Block smoothers within geometric multigrid methods for the solution of the Stokes equations

Lisa Claus[1*]

[1] Lawrence Berkeley National Laboratory, One Cyclotron Road, Berkeley, CA 94720, lclaus@lbl.gov

Key Words: numerical mathematics, geometric multigrid methods, Stokes equations, block smoother, local Fourier analysis, finite difference discretization

Multigrid (MG) methods are efficient methods to solve systems of partial differential equations (PDEs). They are used to speed up linear system solves in a wide variety of applications. The efficiency of multigrid methods is due to the combination of suitable smoothers with a coarse grid correction. As one of the two key ingredients, smoothers have a significant impact on the performance of multigrid solvers. Most of the literature on smoothers in multigrid methods is concerned with scalar PDEs, only. Systems are considered less often. This talk is concentrated on the development and analysis of new smoothers within geometric multigrid methods for the solution of the Stokes equations discretized on staggered grids. We compare the commonly used Vanka smoother with a non-overlapping variant of the Vanka smoother, the so-called triad-wise smoother. While the latter is computationally cheaper, the convergence depends much more on the implementation than that of the overlapping method. We develop new non-overlapping smoothers, the so-called fourfold triad-wise smoothers, and show their efficiency within multigrid methods to solve the Stokes equations. Local Fourier analysis and a general comparison including the computational cost and the convergence properties of the overlapping and non-overlapping methods will be presented.

Key Words: Contact and fracture problems, multiphysics Problems, non-standard discretization, non-linear problems

Multilevel methods are well established for the solution of sparse linear systems. For constrained and non-linear systems, however, multilevel methods need to be adapted in order to ensure multilevel efficiency as well as global convergence. In this talk, we will provide an overview on multilevel approaches for constrained and non-linear systems and will provide several examples for problem dependent multilevel decompositions.

As examples, we will present multilevel solution strategies for constrained and non-linear systems, as they arise in the simulation of, e.g., contact problems or coupled non-linear problems in mechanics. We will start our discussion with the designing multilevel decompositions for contact problems in linear elasticity, i.e., convex minimization problems with inequality constraints, and will investigate how these multilevel decompositions do depend on the respective discretization. Starting from classical primal discretizations, we will consider the case of mixed finite elements in the context of least square finite element methods and eventually non-fitting discretization techniques. We will show how efficient multilevel methods for these different discretizations can be developed and which particularities have to be taken into account. We then will comment shortly on the case of non-linear problems, which here will be phase-field problems for fracture propagation. We will derive efficient multilevel decompositions for this problem class and will discuss the design of multilevel decompositions for non-linear problems. For all cases we will discuss the convergence properties of the resulting non-linear or non-smooth multilevel methods. Our findings will be illustrated by different numerical examples.

[4] Sandia National Laboratories, Livermore, CA 94551 USA, rstumin@sandia.gov

Key Words: Multigrid Methods, Geometric Multigrid, Algebraic Multigrid

In this talk we discuss the development of a framework for multigrid solvers targeted at semi-structured meshes. In terms of exascale computing, memory, and setup time, there are significant potential advantages to multigrid on structured meshes over unstructured meshes. Unfortunately, many applications are not conducive to the use of structured meshes. Thus we focus on semi-structured meshes which provide flexibility to address complex computational domains while still allowing most multigrid calculations to be accomplished using efficient structured grid ideas and kernels. These semi-structured meshes center around the concept of block structured or region structured grids, and are created from the union of of a number of fully structured meshes that are each prescribed on subdomains and that conform at region interfaces. The idea behind these meshes can be further relaxed to allow for some unstructured mesh regions when needed.

We present a formal mathematical framework for describing the semi-structured solver. This formalism allows us to precisely define the associated regional multigrid method and to show its relationship to a more traditional multigrid solver. Additionally, the mathematical framework clarifies the associated software design and implementation. Numerical experiments highlight the relationship of the new solver with classical multigrid. We also demonstrate the generality and potential performance gains associated with this type of semi-structured multigrid as well as showcase its application to meshes with structured/unstructured mesh interfaces.

Key Words: Physics-Based Block Preconditioning, Algebraic Multigrid, Sparse Approximate Inverse

Algebraic multigrid (AMG) methods have shown to be highly efficient and scalable preconditioners for mortar methods ranging from contact to meshtying problems [1]. An interesting application in this field is the mixed-dimensional coupling of slender beam structures embedded into three-dimensional solid bodies [2]. Such beam/solid interactions can be found in several engineering scenarios (e.g. fiber-reinforced composite materials or reinforced concrete). Imposing the coupling constraints via a penalty method as proposed in [2] leads to an ill-conditioned and highly non-diagonal dominant matrix. Solving such problems in an efficient and scalable manner with iterative solvers is difficult and makes an appropriate preconditioning essential. Using AMG in this context is yet again challenging as there are several open questions regarding AMG for beams and the coarsening of the mixed-dimensional coupling terms.

This talk will discuss a physics-based block preconditioning approach based on AMG. The outer block iteration is taken care of with an inexact LU-decomposition. A crucial part of the calculation is the approximation of the inverse appearing in the Schur complement. Using a sparse approximate inverse [3] based on an appropriate sparsity pattern helps to retain a low iteration number and parallel scalability. Multilevel ideas will be used to approximate the block inverses appearing in the system. There, the computation of the near nullspace of the beam part is highlighted, which effectively projects the errors onto a coarser grid. We will assess the performance of the proposed block preconditioner using examples of the interaction of solids with torsion-free Kirchhoff-Love beam finite elements.

Key Words: Domain Decomposition, Fast and Robust Overlapping Schwarz (FROSch), High Performance Computing, Many-Core, Trilinos Software Library

A new approach to three-level overlapping Schwarz domain decomposition methods of GDSW (Generalized Dryja-Smith-Widlund) type for linear elasticity is presented. This approach was recently implemented in the Fast and Robust Overlapping Schwarz (FROSch) framework [1, 2], which is part of the Trilinos software library [3]. In this approach, no explicit geometric information is needed in the recursive application of the preconditioner.

Parallel results for a three-dimensional linear elasticity problem obtained on the Theta supercomputer (ALCF, Argonne, USA) using up to 220 000 cores are discussed and compared to results previously obtained on the SuperMUC-NG supercomputer (LRZ, Garching, Germany).

Notably, it can be observed that a hierarchical communication operation in FROSch related to the coarse operator starts to dominate the computing time on Theta for 100 000 MPI ranks or more. The same operation, however, scales well and stays within the order of a second in all experiments performed on SuperMUC-NG. Using hybrid MPI/OpenMP parallelization, better performance is achieved on Theta.

Key Words: *Interstitial pneumonia, Bronchiectasis, Graph theory, Tree-matching*

The target of this research is efficient assessment for interstitial pneumonia. Interstitial pneumonia shows several imaging findings on computed tomography, among which traction bronchiectasis/bronchiolectasis is useful to predict disease progression. This imaging finding is represented by irregular bronchial and bronchiolar dilatation, which are caused by retractile pulmonary fibrosis affecting the surrounding tissues. When a physician assesses a patient, whether the patient's condition is getting better or getting worse, they must compare CT images from different dates, perhaps in different disease stages. They must know how much a patient's bronchi are dilated, in which bronchus, or in which part of the lungs. Furthermore, they must compare other geometrical characteristics among different stages. A conventional method is to compare two CT datasets visually in side-by-side manner. However, workload for this procedure is extremely high. Moreover, the tree-structures from same patient in different disease stages are often not exactly same due to disease progression and other factors. Therefore, our objective is to construct a robust automatic mapping algorithm for the airway trees from a same patient in different disease stages. Then we assign geometrical information such as the cross-sectional area, curvature, and torsion to the respective edges, which can be easily used for assessment by physicians.
This work was supported by JST CREST Grant Number: JPMJCR15D1, Japan.

Key Words: *Molecular Design, Quantum Chemistry, Artificial Intelligence, Deep Learning, Surrogate Model*

Efficient methods for searching the chemical space of molecular compounds are needed to automate and accelerate the design of new functional molecules such as pharmaceuticals. Given the high cost in both resources and time for experimental efforts, computational approaches play a key role in guiding the selection of promising molecules for further investigation. Here, we construct a workflow to accelerate design by combining approximate quantum chemical methods [i.e., density-functional tight-binding (DFTB)], a graph convolutional neural network (GCNN) surrogate model for chemical property prediction, and a masked language model (MLM) for molecule generation. Property data from the DFTB calculations are used to train the surrogate model; the surrogate model is used to score candidates generated by the MLM. The surrogate reduces computation time by orders of magnitude compared to the DFTB calculations, enabling an increased search of chemical space. Furthermore, the MLM generates a diverse set of chemical modifications based on pre-training from a large compound library. We utilize the workflow to search for near-infrared photoactive molecules by minimizing the predicted HOMO-LUMO gap as the target property. Our results show that the workflow can generate optimized molecules outside of the original training set, which suggests that iterations of the workflow could be useful for searching vast chemical spaces in a wide range of design problems.

Bayesian Model Selection of Partial Differential Equations for Pattern Formation

Natsuhiko Yoshinaga[1,2*] and Satoru Tokuda[2,3]

[1] Tohoku University, Sendai 980-8577, Japan, yoshinaga@tohoku.ac.jp

Key Words: *Pattern Formation, Partial Differential Equations, Bayesian Inference, Model Selection*

Partial differential equations (PDE) have been widely used to reproduce patterns in nature. To understand the mechanism of pattern formation, nonlinear PDEs have been employed for fluid convection[2], microphase separation of block copolymers[3], and crystals[4]. These PDEs may also be applied to pattern formation in biological systems[5]. Although a number of PDE models have been proposed, they rely on pre-request knowledge of physical laws and symmetries, and it requires significant efforts to develop a model reproducing the desired pattern. The challenge is quantitative and interpretable modelling of a complex phenomenon, which demands both developing a model and parameter estimation. The identification of a model equation is a recent key topic of machine learning and data science. Several methods have been proposed to derive PDEs from time-series data[6]. In this study, we propose the method to select a PDE model and its parameters to reproduce a given snapshot of a pattern, and from that, to get a physical insight of the target pattern[1]. We apply our method to nontrivial patterns, such as dodecagonal quasi-crystal, double gyroid, and Frank-Kasper structure, and we could successfully reproduce these patterns from the estimated PDE models.

We consider a pattern that is expressed by the scalar density field. We explorer a model to reproduce a target pattern at the steady state of an unknown model described by nonlinear PDEs. We consider a family of the models based on a phase-field crystal (PFC) model in which each model has different length scales. For a given target pattern, we estimate the appropriate number of length scales by estimating the best model, and also estimate the parameters in the model. The estimation is performed by the Bayesian model selection in which we compute the posterior distribution of parameters and marginal likelihood using the replica-exchange Monte Carlo (REMC) sampling. Our method is based on statistical inference, and therefore, it works for a noisy target and a target without ground truth.

Bump Attractors and Waves in Networks of Integrate-and-Fire Neurons

Daniele Avitabile[1*], **Joshua Davis**[2], **Kyle Wedgwood**[3]

[1] Department of Mathematics, Vrije Universiteit Amsterdam, The Netherlands e-mail: d.avitabile@vu.nl

Bump attractors are localised patterns observed in in vivo experiments of neurobiological networks. They are important for the brain's navigational system and specific memory tasks [1, 2]. A bump attractor is characterised by a core in which neurons fire frequently, while those away from the core do not fire. We uncover a relationship between bump attractors and travelling waves in a classical network of excitable, leaky integrate-and-fire neurons [3]. This relationship bears strong similarities to the one between complex spatiotemporal patterns and waves at the onset of pipe turbulence [4, 5]. We define and study analytical properties of the voltage mapping, an operator transforming a solution's firing set into its spatiotemporal profile. This operator allows us to construct localised travelling waves with an arbitrary number of spikes at the core, and to study their linear stability. A homogeneous "laminar" state exists in the network, and it is linearly stable for all values of the principal control parameter. We show that one can construct waves with a seemingly arbitrary number of spikes at the core; the higher the number of spikes, the slower the wave, and the more its profile resembles a stationary bump. As in the fluid-dynamical analogy, such waves coexist with the homogeneous state, are unstable, and the solution branches to which they belong are disconnected from the laminar state. We provide evidence that the dynamics of the bump attractor displays echoes of the unstable waves

Key Words: Arteriovenous Fistula, Hemodialysis, Disturbed flow, Regurgitation, Wall shear stress

Patient-specific computations are emerging extensively to assist hemodialysis patients in better assessing and planning surgical anastomosis. Over the last decades, end-stage renal disease (ESRD) has emerged as a severe clinical problem, leading to high morbidity rates. ESRD conditions are associated with impaired kidney function, for which hemodialysis procedures are strongly advised [1]. Such procedures require a well-functioning vascular access between the artery and the vein, known as an arteriovenous fistula (AVF). The hemodynamics characteristics within the AVFs depend greatly on patient-specific morphologies and flow conditions, which vary significantly between individuals.

This presentation analyzes blood flow dynamics for various three-dimensional AVFs for hemodialysis patients using CT scanning and phase-contrast MRI medical imaging data. Blood is modeled as a Newtonian fluid governed by unsteady, incompressible Navier–Stokes equations for computation. These governing equations have been solved numerically using stabilized finite element method [2], and details of the computational methods are described in [3]. In this study, we classified the considered AVFs as: *Splitting*, *Merging*, and *Almost one-way* cases, based on the regurgitation flow from the distal artery. We have computed several complex flow dynamics, pressure drops, and wall shear stresses. We have observed that the maximum inflows are confined to the distal vein near the anastomotic sites, for cases with regurgitation flow. In these cases, the pressure drop associated with disturbances in the main flow of the distal vein is also high. This regurgitation flow appears to be strongly associated with significant energy loss.

Finite element analysis for a generalized Robin boundary value problem in a smooth domain

Takahito Kashiwabara[1*]

[1] The University of Tokyo, 3-8-1 Komaba, Meguro, 153-8914 Tokyo, tkashiwa@ms.u-tokyo.ac.jp

Key Words: Generalized Robin Boundary Condition, Finite Element Method, Domain Perturbation

A generalized Robin boundary condition (GRBC) is one of the models appearing in coupled bulk-surface PDEs [2]. For example, [1] derived a reduced-order model for the fluid-structure interaction problem for blood flow in an arterial vessel by reducing the PDE describing the motion of a thin solid region—thus 3D—to the one defined on a fluid-solid interface which is 2D. The resulting equations, in a mathematically simplified form, have a feature represented by the GRBC.

In our previous work [3] we derived a weak formulation for the GRBC problem and established well-posedness as well as regularity properties on the level of PDE, assuming that the domain is smooth enough. We also provided some finite element analysis; however there we assumed that the domain is polygonal so that it can admit triangular meshes fitting its boundary exactly.

In the present study we treat a standard piecewise linear finite element method applied to the GRBC problem in a general domain with a curved boundary. Since a smooth domain is approximated by polygonal ones, we need to evaluate domain perturbation errors. We show that optimal error estimates are still available in this situation, which is the main result.

The novelty of this result is that the errors are evaluated in approximate domains in a more direct manner—thus may be useful for a practical purpose—than the ones used in [2, 4] where they compared approximate solutions with an exact one in the original smooth domain by introducing an abstract transformation which is not easy to compute in general.

Key Words: Hierarchical model reduction, Proper orthogonal decomposition, Domain Decomposition

Hierarchical Model (HiMod) reduction proved to be an efficient and reliable tool to deal with directional phenomena [2, 1]. So far, the main field of application for such a model reduction procedure has been the modeling of the blood flow in arteries. The theoretical formalization of HiMod reduction in [3] inherently excludes geometric settings characterized by branches, such as bifurcation regions in hemodynamics. This limit prompted us to propose a specific strategy to overcome such an issue. The idea we pursue is based on the splitting of the domain into subdomains, in order to isolate the bifurcation from the rest. Then, to contain the whole computational cost, we solve the reference problem in the bifurcation by combining finite elements with a standard Proper Orthogonal Decomposition (POD), while resorting to a HiMod approximation along the branches. Finally, the different approximations are linked together through a domain decomposition procedure.

In this presentation, we adopt a standard scalar advection-diffusion-reaction model as reference problem to track the transport of a substance of interest in the blood (for instance, the contrast medium in a CT angiography). After detailing the proposed procedure, we will focus on the numerical assessment in order to highlight the efficiency and the accuracy of the methodology.

skaji@imi.kyushu-u.ac.jp, https://www.skaji.org

Key Words: *Imaging, Radiology, Homology, Lung CT*

Modern medical imaging techniques have enabled access to the interior of the human body in the form of not only 2D images but also 3D volumes. It is, however, not easy to utilise the 3D information, and analysis is often limited to a slice-by-slice investigation. We need a set of features for volumetric data to take full advantage of the 3D measurements.
On the one hand, radiomic features have been proposed to capture textural characteristics of a volume. They are computed from small patches of a volume and encode only local properties.
On the other hand, persistent homology provides computational machinery to extract the global structure of a volume. Although persistent homology is a promising tool that would complement the conventional radiomics, it is not yet widely used in medical image analysis, partly due to the lack of convenient software and the unusual form of its output as a multiset in the plane.
In this talk, we present our software, Cubical Ripser [1,2], for efficiently computing persistent homology of volumetric data.
We demonstrate its clinical relevance on abnormality quantification and detection in lung CT [3].

Key Words: multi-scale model, one-dimensional arterial network, lumped-parameter models

Cardiovascular blood circulatory system serves as an important role in maintaining the normal operation of human life. Therefore, the pathological study and treatment of cardiovascular diseases attract researchers' interests. Mathematical models of the circulatory system which describe hemodynamic and vascular abnormalities have been recognized to be of great significance for this study and treatment.

In this work, blood circulation is numerically simulated by a multi-scale model which is constructed by coupling one-dimensional (1D) arterial network with lumped-parameter (0D) models[2]. 1D model, based on partial differential equations, aims to describe the detailed evolution of the cross-sectional area (A) and blood flow (Q) for each interested arterial segment, and that of mean pressure P consequently. 0D model, based on ordinary differential equations, describes the vascular subsystem corresponding to each peripheral artery. The combined 1D-0D multi-scale model can simulate hemodynamic and wave propagation characteristics of vascular system simultaneously in the time- and spatial-field. It is further assumed that the arterial tree is characterized by multi-branched arteries. At the bifurcations, flow conditions would be suitably matched with the conservation of mass flux and continuity of total pressure[1].

In computation, the boundary condition at the entrance of the arterial tree follows the action of heart. 1D and 0D models are solved by the two-step Lax-Wdndroff scheme and fourth-order Runge-Kutta method, respectively. The coupling of two models is numerically implemented at the spatial interfaces of two systems in a time-matching manner, and the derived equations are solved by using a Newton-Raphson method. Simulations of blood vessels with boundary conditions, and arterial networks with various bifurcations are presented in this study. It is shown how blood flows in the human arterial system including the circle of Willis. Furthermore, it has the potential to distinguish or predict the cerebrovascular states, such as occluded vessels, by investigating the effects of the blood flow patterns on cerebral outflows of time-dependent changes.

Multiscale design and topology optimization of architected implants for bone replacement

Damiano Pasini

McGill University, 817 Sherbrooke Street West, Montreal, damiano.pasini@mcgill.ca

Key Words: *Topology optimization, Mechanical biocompatibility, Bone replacement implants, 3D printing,*

Architected materials can be designed to bring about clinical advantages over existing materials currently used in orthopaedics. In this talk, I will present a platform technology to develop 3D printed bone replacement implants with tailored lattice architecture of superior biomechanical performance. I will focus on key aspects pertaining to the multiscale modelling of manufacturing induced defects and topology optimization of representative implants, such as knee and cervical fusion cage. Emphasis will be placed on how to boost their mechanical biocompatibility to reduce bone resorption and achieve long-term functional performance.

Sensitivity analysis of a partial hepatectomy hemodynamics model

L. Sala[1]*, N. Golse[2], A. Joosten[2], E. Vibert[2] and I. Vignon-Clementel[1]

[1] INRIA Saclay Ile-de-France, 91120 Palaiseau, France

Key Words: computational hemodynamics, sensitivity analysis, partial hepatectomy, polynomial chaos expansion

Partial hepatectomy is the partial removal of the liver that is usually executed as a treatment option in liver cancer or for living donor transplantation. Exploiting the electric analogy to fluid flow, our team has developed a lumped parameter model to study the effect of partial hepatectomy on hemodynamics changes in the liver and the entire circulation [1]. This hemodynamics model evaluates - in a non-invasive way - the risk of postoperative portal hypertension, which may lead to post-hepatectomy liver failure, the leading cause of postoperative death.
This work studies *(i)* a propagation of variabilities from model input to output to investigate the main statistical moments of the outputs and the model reliability, and *(ii)* a sensitivity analysis (SA) study to identify the most significant parameters with respect to the main clinical output of interest. From a modeling viewpoint, these results allowed us to simplify the model by fixing model inputs that have negligible effect on the selected output. From a clinical viewpoint, this analysis provides a first step towards a better understanding of which patient-specific measurements are pivotal in the clinical routine to improve the quality of the numerical predictions. From a numerical viewpoint, we combined a selection algorithm due to physiological constraints with the polynomial chaos expansion (PCE) method [3]. In order to obtain only physiological outcomes we considered valid only the outcomes that comply with clinical indications. This selection induced some difficulties in the SA, due to the fact that the selected sample space was no more respecting the required hypothesis to apply the classic Saltelli algorithm [2]. To overcome this issue and to avoid a full MonteCarlo study, which would explode the number of simulations needed, we employ the PCE method on the physiological subspace, thus obtaining at a controlled computational cost the sensitivity indices. Finally, we completed a convergence study of this new SA exploratory method to verify the accuracy of such technique in the context of a partial hepatectomy hemodynamics model.

Synthetic Q-Space Learning for Diffusion MRI Parameter Inference

Yoshitaka Masutani

Hiroshima City University Graduate School of Information Sciences
3-4-1 Ozuka-Higashi, Asa-Minami-ku, Hiroshima-shi, HIROSHIMA, 731-3194, Japan
masutani@hiroshima-cu.ac.jp

Key Words: *Diffusion MRI, Parametric Signal Models, Synthetic Q-Space learning*

Diffusion MRI (dMRI) can characterize and quantify the local properties of microstructures of the living organism such as the brain white matter [1]. The analysis is based on the parameters of various signal models of dMRI, such as diffusion tensor imaging (DTI), diffusion kurtosis imaging (DKI), neurite orientation dispersion diffusion imaging (NODDI), free-water imaging (FWI) and so on. One of the important features in those models is that anatomical structures are considered in the model. For example, parameters such as axon diameter and neurite orientation dispersion are included in the signal models. Consequently, the models become more complex and need more computational costs in parameter inference by conventional fitting methods.

Recent reports showed that machine learning approaches [2] are promising for inferring the parameters instead of fitting. Especially, training with synthetic data based on signal model equation and noise simulation, named synthetic Q-space learning (synQSL), showed great advantages and interesting characteristics [3]. In the synQSL scheme, the model parameters are randomly generated as gold standard in the practical range of the parameters first. Then, dMRI signal values are simulated by using signal model equation, and are contaminated by noise. A large quantity of pairs of gold standard parameters and simulated dMRI signals are prepared for training of a regressor used for parameter inference. The regressors can be chosen from the family of machine learning-based regressors, such as multi-layer perceptron (MLP), random forest and so on. The major advantages of synQSL are robustness and fast computation. It is known that the robustness depends on the training noise level, and noise level match between training data and test data yields optimal robustness.

In this talk, the basics of dMRI parameter inference by using synQSL are introduced with examples of parameter inference in models of DTI, DKI, NODDI and FWI. Also, the characteristics and current issues of the approach are discussed.

Uncertainty Related to the Use of Doppler Flow Waveforms as Inflow Boundary Conditions in Coronary Arteries Blood Flow Simulations

Maurizio Lodi Rizzini[1], Alessandro Candreva[1,2], Diego Gallo[1], Emanuele Gallinoro[3] Claudio Chiastra[1], Carlos Collet[3], Bernard De Bruyne[3] and Umberto Morbiducci[1]

[3] Cardiovascular Center Aalst, OLV-Clinic, Moorselbaan 164 Aalst, Belgium

Key Words: *computational hemodynamics, uncertainties, coronary arteries, wall shear stress*

Introduction: coronary arteries, supplying blood to myocardium are among the most clinically relevant arteries and the role that local hemodynamics play in atherosclerosis initiation and progression is well established [1]. In recent years the combination of computational fluid dynamics (CFD) and medical imaging has allowed to precisely profile wall shear stress (WSS) features in realistic coronary artery models with spatial and temporal accuracy that cannot be obtained with standard clinical measurement [2]. However, the clinical use of CFD simulations is still hampered by those assumptions/idealizations which each model-based strategy necessarily introduces, and which represent a source of uncertainty. One main source of uncertainty in modelling coronary hemodynamics is represented by the inflow boundary conditions (BCs), because of the paucity of information available. In this context the aim of this study was to investigate the budget of uncertainty on WSS profiles associated with blood velocity waveforms in coronary arteries as given by intravascular Doppler flow measurements when the latter are used as inflow BCs.

Methods: the geometry of 7 left anterior descending (LAD) and 7 right coronary arteries (RCA) were reconstructed from angiographic projections using a commercial software (QAngio XA bifurcation, Medis Medical imaging). Then geometries were discretized, and the governing equations of unsteady-state fluid motion were numerically solved by means of the finite volume-based commercial code Fluent (Ansys Inc.) by imposing two different inflow BCs: (1) patient-specific velocity waveforms from intravascular Doppler flow measurements and (2) generalized velocity waveforms obtained averaging patient-specific Doppler flow waveforms, scaled to the same cycle-average flow rate obtained from the patient-specific Doppler flow waveforms. The impact of inflow BC strategy was evaluated in terms of WSS profile accounting for WSS magnitude (time averaged WSS, TAWSS), pulsatility (oscillatory shear index, OSI), and topological features (topological shear variation index, TSVI) [3]. The impact on WSS-based descriptors was evaluated in terms of surface averaged values, percentage of surface area exposed to low TAWSS and high OSI and TSVI, and colocalization of surface area by means of similarity index (SI).

Results and conclusions: the main differences emerged between WSS obtained adopting the two different inflow BC strategies can be summarized as follows: (1) significant differences were observed in terms of surface averaged values for TAWSS ($p=0.002$), OSI ($p<0.001$), and TSVI ($p<0.001$); (2) a strong, significant linear correlation was observed for TAWSS ($r=0.98$, $p<0.001$), OSI ($r=0.94$, $p<0.001$), and TSVI ($r=0.80$, $p<0.001$); (3) no significant differences emerged on percentage surface area exposed to low TAWSS, and high OSI and TSVI; (4) colocalization was very high for TAWSS (SI=0.98[0.97-0.99]), and moderate for OSI (SI=0.66[0.50-0.81]) and TSVI (SI=0.60[0.48-0.71]). The findings of this study suggest that adopting patient-specific rather than generalized Doppler flow data as inflow BC in coronary hemodynamics simulations might influence more WSS directionality and topological features than WSS magnitude.

Well-posedness of One-dimensional Models of Blood Flow in Arteries

Norikazu Saito[1*] and Yutaro Himeki[2]

[1] The University of Tokyo, Komaba 3-8-1, Meguro, Tokyo 153-8914, Japan,
norikazu@g.ecc.u-tokyo.ac.jp
[2] The University of Tokyo, Komaba 3-8-1, Meguro, Tokyo 153-8914, Japan,
himeki@g.ecc.u-tokyo.ac.jp

Key Words: One-dimensional model, Reduced model, Well-posedness

One-dimensional (1D) models of blood flow are useful reduced models of the cardiovascular system and they are frequently applied in numerical simulations of blood flow in arteries. See [2] for example. Though models are highly simplified with respect to the local dynamics, they bring us reliable results at a low computational cost. To perform numerical simulation, it is required to derive the well-posed formulations with appropriate boundary and compatibility conditions. The aim of this study is to provide a mathematical study for the 1D model that will give an essential contribution to numerical simulations.

We consider the Navier–Stokes equations for an incompressible fluid flow in a simple compliant tube that is a model of the artery. An asymptotic analysis gives a nonlinear nonsymmetric hyperbolic system of partial differential equations, which we call the 1D system, for the area of a cross-section A and the mass flux Q across the section. We pose a constructive assumption on the pressure. That is, the pressure is assumed to be represented in terms of A. The 1D system contains a momentum-flux correction coefficient $\alpha \geq 1$. The case $\alpha > 1$ is physiologically interestsing, but mathematical study are often resctricted to the case $\alpha = 1$.

For the mathematical well-posedness of the 1D system, we usually refer to [1], where the unique existence of a time-global smooth solution is proved. However, the work [1] studied only the case $\alpha = 1$. The purpose of the present paper is to establish the well-posedness of the 1D system. In particular, we prove that under some suitable compatibility conditions there exists a $T > 0$ and a unique solution $(A,Q) \in C^0([0,T];H^2(\mathbb{R},\mathbb{R}^2)) \cap C^1([0,T];H^1(\mathbb{R},\mathbb{R}^2))$ of the 1D system with any $\alpha \geq 1$. Therein, $H^s(\mathbb{R},\mathbb{R}^2)$ stands for the Sobolev space in the L^2 sense. To accomplish the purpose, we apply an abstract theory of Kato [3].

A Further Extended Range of Stable Flux Reconstruction Schemes in One Dimension, Triangles, and Polygons

Will Trojak[1*], **and Peter Vincent**[1]

[1] Department of Aeronautics, Imperial College London, South Kensington, London SW7 9AG,
wtrojak@imperial.ac.uk

Key Words: High-order, flux reconstruction, summation-by-parts

We present new approaches for developing stable flux reconstruction (FR) [2] schemes in multiple dimensions, building on the previous work of Vincent et al. [4]. Starting in one-dimension, we explore the use of summation-by-parts (SBP) techniques [3], formulating methods to identify new multi-parameter correction functions. We then extend the approach to higher dimensions and tackle the more complex task of applying symmetry constraints for these elements. A new range of stable schemes will be presented for triangles, a subset of which are those of Castonguay et al. [1]. Finally, we will go on to present the new class of methods for both quadrilateral, and, for the first time, hexagonal elements.

Key Words: *Slope Limiter, Magnetohydrodynamics, MUSCL, Finite Volume Method*

Introduction: Magnetohydrodynamics (MHD), which takes into account the interaction between magnetic fields and plasmas, is used in a wide range of research fields such as astrophysics, space engineering, and nuclear fusion. In MHD simulations using the finite volume method, the monotonic upstream-centered scheme for conservation laws (MUSCL) is a very popular method for higher-order accuracy. In the conventional MUSCL, stable computation is achieved by adding a slope limiter to the region where overshoot/undershoot is likely to occur. However, this procedure may result in limiting the slopes more than necessary. To address this problem, we proposed "*a posteriori* limiter" (hereafter referred to as "Post Limiter") in gas dynamics simulations [1], which was a modification of the conventional MUSCL calculation procedure: By accepting slight overshoot/undershoot near discontinuities, this method has been confirmed to be effective in improving both resolution and convergence, and suppressing undesired oscillations in smooth regions. In this study, we extend the Post Limiter to MHD simulations involving more types of discontinuities (e.g., rotational discontinuity, fast/slow shock wave) than gas dynamics, and show its performance by one- and two- dimensional MHD tests.
Proposed Method: The Post Limiter does not limit the slope for weak shocks (pre-shock Mach number less than 1.36), even if the un-limited values do not satisfy the discrete maximum principle (see Ref. [1] for details). In the original Post Limiter, the pressure ratio was used to evaluate the shock strength. In gas dynamics, this evaluation method is appropriate since the pressure ratio corresponds to the pre-shock Mach number. In MHD, however, there is no corresponding relation between the pressure ratio and the Mach number of the pre-shock. Thus, in this study, the evaluation method of the Post Limiter is modified to consider the tangential component of the magnetic field.
Numerical Results: In many smooth regions, the Post Limiter achieves higher resolution than conventional calculation procedures. Although overshoot/undershoot occurs near the discontinuities, no further adverse effects are observed. For some tests, we have confirmed that Post Limiter suppresses oscillations and is closer to the reference than the 5-order monotonicity preserving (MP5) scheme, an expensive higher-order scheme (MP5 requires about 1.95 times more computation time than the conventional MUSCL for one-dimensional tests).
Conclusion: Numerical tests have shown the performance of the Post Limiter in MHD simulations. The proposed method provides resolution improvement by accepting overshoot/undershoot, and in one-dimensional tests, the resolution is about four times higher than the conventional MUSCL in many regions. In addition, the Post Limiter can be implemented for conventional MUSCL with only a few modifications to the computational code. Therefore, considering a marginal increase in computation time (about 1.25 times for one-dimensional tests), the Post Limiter is more effective than the use of a finer computational mesh. In the final paper, we will discuss in more detail the conditions necessary to extend Post Limiter to MHD simulations.

Extending High-Order Spectral Difference Method with Constrained Transport to Resistive Compressible Magnetohydrodynamic Simulations on Unstructured Grids

Kuangxu Chen* **and Chunlei Liang**

Clarkson University, 13699, kuchen@clarkson.edu

Key Words: *Spectral Difference, High-Order, Computational Magnetohydrodynamics, Unstructured Grids*

High-Order Spectral Difference method with Constrained Transport (SDCT) is proposed in [1] to solve compressible magnetohydrodynamic (MHD) equations. This approach can maintain the divergence-free constraint to the accuracy of machine-precision error throughout the simulations. And the additional computational cost is less than 1/8 compared with that without constrained transport. However, it can only be applied to ideal MHD equations on structured rectangular meshes. In this paper, we extend the original SDCT method to resistive MHD equations by adding an artificial resistive term directly acting on the magnetic potential instead of the magnetic field. This approach does not affect the smoothness of the solution and provides enough dissipation to damp spurious discontinuity of the magnetic field. This resistive version of SDCT method can be then applied to simulations of magnetic reconnection, large-scale magneto-convection, etc. Moreover, the solution accuracy is tested when the computational grids are unstructured. It is found that the high-order accuracy is still preserved. Meanwhile, the divergence-free constraint is kept under some threshold and the divergence error does not accumulate with time integration. The divergence error is proved to decay exponentially with the reduction of the mesh size.

High-Order Hybridizable Discontinuous Galerkin Methods for Computational Fluid Dynamics with Applications to Multiphysics Problems

Andrea La Spina[1*] **and Jacob Fish**[2]

[1] Columbia University, New York, al4188@columbia.edu
[2] Columbia University, New York, jf2695@columbia.edu

Key Words: Hybridizable discontinuous Galerkin, Compressible flows, Magnetohydrodynamics, Fluid-structure interaction, Finite element coupling

In this contribution, we present high-order hybridizable discontinuous Galerkin (HDG) formulations for computational fluid dynamics and recent applications to multiphysics problems. A novel weakly compressible fluid formulation [1], featuring the velocity and the pressure as primal variables, is first introduced. Its superior features with respect to density–momentum-based approaches [2] are highlighted on a simple example, especially regarding the good conditioning of the resulting linear system over a wide range of compressibility levels. Such flow solver is then combined with Maxwell's equations for the solution of magnetohydrodynamic problems [1]. The convergence properties of the resulting coupled multiphysics problem are demonstrated on several numerical examples on structured and unstructured meshes and at low and high Hartmann numbers.

A strategy to couple HDG and standard finite element discretizations is also presented [3]. Devising different spatial discretizations can be of particular interest in the context of multiphysics simulations, as well as for multimaterial problems in which different regions of the computational domain feature distinct physical properties. The proposed method exploits the definition of the numerical flux and the trace of the solution on the mesh skeleton to impose the coupling conditions solely in the global problem by means of Nitsche's method. The key advantage is the minimal intrusiveness in terms of computer implementation that makes it suitable to be integrated in existing finite elements libraries. This strategy is thus successfully applied for the solution fluid-structure interaction problems [2].

High-Order Implicit Shock Tracking for Compressible Viscous Flows

Tianci Huang[1] **and Matthew J. Zahr**[2*]

[1] University of Notre Dame, Notre Dame, IN 46556, thuang5@nd.edu

Reference link: https://www.wccm2022.org/submission.html

Shock tracking, as an alternative method to shock capturing, aims to generate a mesh such that element faces align with shock surfaces and other non-smooth features to perfectly represent them with the inter-element jumps in the solution basis, e.g., in the context of a finite volume or discontinuous Galerkin (DG) discretization. These methods lead to high-order approximations of high-speed flows and do not require nonlinear stabilization or extensive refinement in non-smooth regions because, once the non-smooth features are tracked by the mesh, the high-order solution basis approximates the remaining smooth features. In previous work [1, 2], we introduced the High-Order Implicit Shock Tracking (HOIST) method that recasts the geometrically complex problem of generating a mesh that conforms to all discontinuity surfaces as a PDE-constrained optimization problem. The optimization problem seeks to determine the flow solution and nodal coordinates of the mesh that simultaneously minimize an error-based indicator function and satisfy the discrete flow equations. A DG discretization of the governing equations is used as the PDE constraint to equip the discretization with desirable properties: conservation, stability, and high-order accuracy. By using high-order elements, curved meshes are obtained that track curved shock surfaces to high-order accuracy. The optimization problem is solved using a sequential quadratic programming method that simultaneously converges the mesh and DG solution, which is critical to avoid nonlinear stability issues that would come from computing a DG solution on an unconverged (non-aligned) mesh.

In this work, the HOIST method is further extended to simulate viscous flows. To accommodate for the viscous shocks (sharp gradients), a continuation strategy for viscosity is integrated into the SQP solver to promote mesh compression towards the sharp gradient. In contrast to the inviscid problems where shocks are represented by inter-element solution jumps, a layer of compressed elements provides sufficient resolution for the sharp solution gradient. The method is demonstrated on a series of increasingly complex viscous, compressible flows.

Key Words: High-order Methods, Shock Capturing, Shock Instability, Hypersonic

The accurate and robust prediction of hypersonic heating is still challenging. One of the primary difficulties is robust capturing of strong shock waves in hypersonic flows[1, 2]. At present, shock-capturing schemes used in hypersonic flow simulations often encounter numerical shock instabilities, which greatly limits the accuracy and efficiency of hypersonic heating computations. For high-order shock-capturing schemes, the shock instability problem is even more difficult to deal with[3, 4]. In the current study, a matrix stability analysis method[5] is developed for high-order WENO schemes to quantitatively analyze the shock instability problem. The mechanism of hypersonic numerical shock instability for third-order, fifth-order and seven-order WENO schemes are presented. Results of numerical stability analysis show that the shock instability is not only closely related to the upstream Mach number, but also to the reconstruction stencil and the numerical dissipation of WENO schemes. The effect of the computational grids on shock wave stability is also presented. Such an analysis is useful for developing more robust and reliable high-order methods for hypersonic heating computations.

The Importance of Temporal Adaptation in High-Order Unsteady Simulations

Krzysztof J. Fidkowski

[1] University of Michigan, 1320 Beal Avenue, Ann Arbor, MI 48109, USA, kfid@umich.edu
https://aero.engin.umich.edu/people/fidkowski-krzysztof/

Key Words: Unsteady adjoint, Output-based adaptation, Arbitrary Lagrangian Eulerian, Discontinuous Galerkin

The combination of high-order spatial schemes and output-based mesh adaptation has yielded a robust steady simulation approach that produces highly accurate output predictions even in the presence of singular solution features. Less effort has been devoted to unsteady problems, for which high-order spatial methods are paired with high-order temporal schemes. In the presence of non-smooth temporal solutions or output definitions, which are commonplace in practical engineering problems, high-order accuracy in time can be difficult to obtain. We present a study of the importance of output-based adaptation to address these difficulties. The demonstration suite consists of unsteady fluid dynamics simulations of the compressible Navier-Stokes equations on deforming domains [2], discretized with the discontinuous Galerkin method in space and high-order multi-stage methods in time, with motion that is reasonably smooth but not infinitely differentiable. Spatial and temporal output-based adaptation is performed using discrete-in-space and continuous-in-time adjoints [1]. On a benchmark problem suite [3], we show that proper isolation of temporal singularities is important for high-order accuracy, and that it is achievable within a space-time adaptive framework.

Key Words: model order reduction, Cahn–Hilliard equation, particle model, coarsening process

The Cahn–Hilliard equation [1] is a model equation to describe phase separation phenomena, which is notorious for its difficulty in obtaining stable numerical solutions. The phase separation phenomena consist of two processes: rapid separation process and slow coarsening process. We focus on the latter. There are several previous studies on reduction models for coarsening process. Argentina et al. [2] construct some mathematical representations to approximate solutions to Cahn–Hilliard equation and investigate coarsening process via the representations.

This work proposes a reduction model for Cahn–Hilliard equation's slow coarsening dynamics process. The model is to mimic the movement of multiple concentrated phases ("bubbles"). To design the model, we assume that a "force" governs the movement and that the force depends on the distance between bubbles. Via some preliminary numerical computations, we observed that these assumptions seem to be satisfied virtually for the movement of similar two bubbles in two-dimensional problems. Furthermore, we found that an inverse square law governs the movement. In addition, we also assume that the "work," which is the application of force along with a displacement, equals the variation of total energy. In the presentation, we will discuss the validity of the proposed model through some numerical computations.

We note that the numerical computation has been conducted for only two-dimensional problems. We have to investigate if the proposed model is valid for one- or three-dimensional problems. Of course, we also plan to design some reduction models for the rapid separation process.

Enforcing physical structure in Bayesian learning of dynamical systems: stability and energy conservation

Alex Gorodetsky[1*], **Nicholas Galioto**[2]

[1] University of Michigan, Ann Arbor, MI, USA, goroda@umich.edu
[2] University of Michigan, Ann Arbor, MI, USA, ngalioto@umich.edu

Key Words: Bayesian Inference, Data-driven modeling, Structure-preserving learning

We describe a Bayesian probabilistic formulation for system identification of dynamical systems. The approach uses an approximate marginal Markov Chain Monte Carlo algorithm to directly discover a system from data. Here, we demonstrate that the posterior distribution simultaneously accounts for unknown parameters, model form uncertainty, and measurement noise. As a result of this feature, we show that our approach becomes more robust than current state-of-the-art methods that rely on heuristic least-squares optimization objectives. Our approach is also approximation-format agnostic and works with both linear and nonlinear dynamical system parameterizations. We show numerous examples demonstrating that we outperform more standard operator inference and vector-field inference approaches when data becomes noisy.

Next we extend our approach to direct identification of system Hamiltonians. Here, our approach improves upon existing approaches by encoding the fact that the data generating process is symplectic directly into our learning objective. This objective is the log marginal posterior of a probabilistic model that embeds a symplectic and reversible integrator within an uncertain dynamical system. We demonstrate that the resulting learning problem yields dynamical systems that have improved accuracy and reduced predictive uncertainty compared to existing state-of-the-art approaches. Simulation results are shown on several Hamiltonian benchmarking systems.

Key Words: Structure-preserving model reduction; Hamiltonian systems; Physics-informed machine learning; Data-driven modeling; Operator inference

This work presents a nonintrusive physics-preserving method to learn reduced-order models (ROMs) of Hamiltonian systems. Traditional intrusive projection-based model reduction approaches utilize symplectic Galerkin projection to construct Hamiltonian reduced models by projecting Hamilton's equations of the full model onto a symplectic subspace. This symplectic projection requires complete knowledge about the full model operators and full access to manipulate the computer code. In contrast, the proposed Hamiltonian operator inference approach embeds the physics into the operator inference framework to develop a data-driven model reduction method that preserves the underlying symplectic structure. Our method exploits knowledge of the Hamiltonian functional to define and parametrize a Hamiltonian ROM form which can then be learned from data projected via symplectic projectors. The proposed method is 'gray-box' in that it utilizes knowledge of the Hamiltonian structure at the partial differential equation level, as well as knowledge of spatially local components in the system. However, it does not require access to computer code, only data to learn the models. Our numerical results demonstrate Hamiltonian operator inference on a linear wave equation, the cubic nonlinear Schroedinger equation, and a nonpolynomial sine-Gordon equation. Accurate long-time predictions far outside the training time interval for nonlinear examples illustrate the generalizability of our learned models.

Learning dynamical models from data plays a vital role in engineering design, optimization, and predictions. Building models describing dynamics of complex processes (e.g., weather dynamics, reactive flows, brain/neural activity, ...) using empirical knowledge or first principles is frequently onerous or infeasible. Moreover, these models are high-dimensional but spatially correlated. It can, however, be often observed that the dynamics of high-fidelity models evolve in low-dimensional manifolds. Furthermore, it is also known that for sufficiently smooth vector fields defining the nonlinear dynamics, a quadratic model may be able to describe the dynamics of the model accurately in an appropriate coordinate system, conferring to the McCormick relaxation idea in nonconvex optimization. Here, we aim at finding a low-dimensional embedding of high-fidelity dynamical data, similar to [2], ensuring a simple quadratic model to explain its dynamics. To that aim, this work leverages deep learning to identify low-dimensional quadratic embeddings for high-fidelity dynamical systems. Precisely, we identify the embedding of data using an autoencoder [3] to have the desired property of the embedding. We also embed a Runge-Kutta method as in [1] to avoid the often challenging time-derivative computations. We illustrate the ability of the approach by a couple of examples, arising in describing flow dynamics and the oscillatory tubular reactor model.

Key Words: *Stochastic Symplectic Methods, Superiority, Large Deviations Principle, Rate Function, Asymptotical Preservation*

Plenty of numerical experiments show that stochastic symplectic methods are superior to non-symplectic ones especially in long-time computation, when applied to stochastic Hamiltonian systems. In this talk, we attempt to give an explanation on the superiority of stochastic symplectic methods by means of large deviations principle. We prove that stochastic symplectic methods are able to asymptotically preserve the large deviations principles for some observables of the exact solution, while non-symplectic ones do not. This indicates that stochastic symplectic methods are able to preserve the asymptotic results on rare event probabilities of the original system, and may provide an effective approach to approximating rate functions of large deviations principles.

Key Words: Model reduction, uncertainty quantification, structure-preservation

A system of ordinary differential equations (ODEs) is a fundamental tool for modelling a dynamical system. ODE models often include unknown system parameters or unknown initial states, and thus, estimating them is a fundamental task in, for example, data assimilation. The task usually requires solving ODEs numerically, and thus, unless the numerical computation is sufficiently accurate, the estimation is biased due to the error in numerical integration. Recent studies suggest that quantifying the forward uncertainty, i.e. the error in numerical integration, would be beneficial in this context [1]. Most of them assume a statistical model for the error, but it is usually quite large because the size is proportional to the system dimension times the number of time points, such as the number of observations or time steps of numerical integration. Therefore, it is essential to reduce the size of the statistical model while preserving the structure of the error behaviour. This talk presents an approach for this kind of model reduction. The key idea is to use generalised versions of isotonic regression, and the cost for the forward uncertainty quantification based on our approach is negligible compared to the single numerical integration of ODEs.

This talk is based on our recent papers [2, 3].

Key Words: Structure preserving model reduction, balanced truncation, nonlinear systems, port Hamiltonian systems

Many physical systems can be represented as port-Hamiltonian systems (PHSs) [1], and various control methods utilizing the PH structure have been developed. Nowadays, models of physical systems can easily be high dimensional, e.g., large scale circuits, discretized PDE models, such as from flexible beams, etc. To simplify analysis or control of such systems by obtaining the benefit from the structure of a PHS, it is natural to develop a model reduction method preserving the PH structure. However, the traditional nonlinear balanced truncation method proposed by [2] does not preserve the PH structure. In this talk, we establish a balancing procedure for PHSs based on the controllability function and the internal energy given by the Hamiltonian, i.e., a combination of balancing and modal analysis. That is, for standard balancing [2], the controllability and observability Gramians are used, whereas in modal analysis the eigen modes of the system related to the internal energy are considered [3]. To the best of our knowledge, this has not been done elsewhere. When using such procedure for truncation, the port Hamiltonian structure is preserved naturally, whereas this is not the case in any other balancing procedure.

Structure-Preserving Model Order Reduction on Manifolds

Patrick Buchfink[1*], **and Bernard Haasdonk**[1]

[1] Institute of Applied Analysis and Numerical Simulation (IANS), University of Stuttgart, Stuttgart, Germany, {patrick.buchfink,haasdonk}@ians.uni-stuttgart.de

Key Words: Model Order Reduction, Structure-Preserving, Differential Geometry

Model Order Reduction (MOR) with non-linear approximants has been introduced in various contexts, e.g. [1, 2, 3]. Following the terminology in [2], we call this approach MOR on Manifolds whereas MOR with linear approximants is referred to as classical MOR. The motivation of MOR on Manifolds is to apply MOR to systems that cannot be sufficiently reduced with classical MOR due to slowly decaying Kolmogorov n-widths, e.g. for linear advection [4]. To our best knowledge, none of the previous work has introduced this formulation in terms of a differential geometric framework. In this talk, we fill this gap and present the theory of MOR on Manifolds from the viewpoint of basic differential geometry. This contribution firstly connects two fields in mathematics, MOR and differential geometry. Moreover it provides a unified framework how to extend existing techniques for structure-preserving classical MOR to MOR on Manifolds for Lagrangian systems, Hamiltonian systems and other structures. The newly introduced connection gives rise to innovative ideas how to extend the training of the non-linear approximants, e.g. by including tangent information in the training process. We investigate such techniques in a numerical experiment for the one-dimensional Burger's equation.

In this talk, we consider numerical computation of dissipative gradient systems, such as Hamiltonian systems with friction, and systems that arise as discretizations of certain dissipative partial differential equations (such as the diffusion equation, or the Cahn–Hilliard equation for phase separation problems.) Such systems are often equipped with some energy functional that decays with time, which is important in that it controls asymptotic behavior of solutions.

The energy decay property could be preserved by "structure-preserving numerical methods." Their use is often preferred for better qualitative behaviors of the solutions and the stability of the numerical computations themselves. Structure-preserving methods are, however, in many cases fully-implicit, and prohibitive as is for large systems. It encourages us to introduce some model reduction techniques (for example, the proper orthogonal decomposition [1]), but it in turn generally destroys the important mathematical structure (the gradient structure, in the present case), which makes the overall strategy very problematic.

In this talk, we show a new structure-preserving model reduction technique for dissipative gradient systems, which successfully reduces the size of the system without destroying the gradient structure and the negative semi-definiteness of the preceding matrix. The technique is partially inspired by an existing technique for Hamiltonian systems (without friction) [2], but provides more general guiding principle for structure-preservation. With some numerical examples we illustrate that in fact such a structure-preserving model reduction provides us efficient, stable numerical computations.

Key Words: Interpolation, Bilinear Systems, Quadratic Systems, Projection, Structured Interpolation

Interpolatory methods are one of the most widely used techniques for model reduction of large-scale dynamical systems [1]. In the case of linear dynamical systems, transfer function of the resulting reduced model interpolates that of the full (original) model at selected points in the complex plane. In many applications, the original system has a physical structure that needs to be retained in the reduced model so that the reduced model is physically meaningful. These structures range from the classical mass-spring-damper formulations to internal delays and more. For linear dynamics, based on the concept of generalized coprime factorization [2], structure-preserving interpolation has been extended to a wide class of structures so that the reduced model not only provides interpolation but also retains the underlying physical structure. In [3], these ideas has been recently extended bilinear dynamical systems, a special class of nonlinear dynamical systems.

In this talk, we will focus on quadratic-bilinear dynamical systems, a prominent class of nonlinear dynamical systems arising a wide range of applications. We will develop the concept of structured generalized transfer functions for quadratic systems and derive the necessary subspace conditions on the model reduction bases so that the reduced quadratic-bilinear system has the same physical structure/meaning as the original one and satisfies a variety of interpolation conditions on the leading subsystem transfer functions. We will illustrate the the underlying theory on various structured nonlinear models.

Key Words: Model reduction on manifolds, Hamiltonian systems, convolutional autoencoders.

Traditional model reduction techniques project the governing equations onto linear subspaces of the high-dimensional state-space. This works well if the underlying problem admits fast decaying Kolmogorov-n-widths. However, for problems with slowly decaying Kolmogorov-n-widths such as certain transport-dominated problems [1], classical linear-subspace reduced order models (ROMs) of low dimension might yield inaccurate results. Thus, the reduced space needs to be extended to more general nonlinear manifolds. Moreover, as we are dealing with Hamiltonian systems, it is crucial that the underlying symplectic structure is preserved in the reduced model, see [2, 3].
To the best of our knowledge, existing literatures addresses either model reduction on manifolds or symplectic model reduction for Hamiltonian systems, but not their combination. In this talk, we bridge the two aforementioned approaches by providing a novel projection technique called *symplectic manifold Galerkin*, which projects the Hamiltonian system onto a symplectic nonlinear manifold such that the reduced model is again a Hamiltonian system. We derive analytical results such as stability, energy-preservation and a rigorous a-posteriori error bound. In addition, we propose a computationally practical approach to obtain a symplectic reduced manifold. To this end, we construct a weak symplectic convolutional autoencoder. We provide numerical results for a linear wave equation for which a slow decay of the Kolmogorov-n-width can be observed, see e.g. [4, 5].

Key Words: *Ferrohydrodynamcis; Two-phase; Phase-field; Unconditional energy stability, Magnetic field.*

Abstract: In this talk, we present numerical approximations of a phase-field model for two-phase ferrofluids, which consists of the Navier-Stokes equations, the Cahn-Hilliard equation, the magnetostatic equations, as well as the magnetic field equation. By combining the projection method for the Navier-Stokes equations and some subtle implicit-explicit treatments for coupled nonlinear terms, we construct a decoupled, linear, fully discrete finite element scheme to solve the highly nonlinear and coupled multi-physics system efficiently. The scheme is provably unconditionally energy stable and leads to a series of decoupled linear equations to solve at each time step. Through numerous numerical examples in simulating benchmark problems such as the Rosensweig instability and droplet deformation, we demonstrate the stability and accuracy of the numerical scheme.

A Discontinuous-Galerkin-in-Time Framework for Multirate Time Integration of Interface-Coupled Problems

Jeffrey M. Connors[1*] **and K. Chad Sockwell**[2]

[1] University of Connecticut, 341 Mansfield Road, Storrs, CT, USA, jeffrey.connors@uconn.edu, https://personal.math.uconn.edu/ connors

Key Words: multirate, multidomain, time stepping

A framework is presented to design multirate time stepping algorithms for two dissipative models with coupling across a physical interface. The coupling takes the form of boundary conditions imposed on the interface relating the solution variables for both models to each other. The multirate aspect arises when numerical time integration is performed with different time step sizes for the component models. We describe a unified approach to develop multirate algorithms for these problems. This effort is pursued though the use of discontinuous-Galerkin time stepping methods, acting as a general unified framework, with different time step sizes. The two models are coupled across user-defined intervals of time, called *coupling windows*, using polynomials that are continuous on the window. The coupling method is shown to reproduce the correct interfacial energy dissipation, discrete conservation of fluxes, and asymptotic accuracy. Also, the method could provide a limit for the total communication needed between components, independent of the number of time steps on a coupling window. In principle, methods of arbitrary order are possible. As a preliminary step, we focus on the presentation and analysis of monolithic methods for advection-diffusion models coupled via generalized Robin-type conditions. The monolithic methods could be computed using a Schur-complement approach. We also discuss some recent progress for partitioned algorithms and different types of coupling conditions.

A mathematically rigorous and physically consistent approach to the treatment of imperfect interfaces with nonlocal models

Key Words: *Interface problems, imperfect interfaces, nonlocal models, nonlocal mechanics, asymptotic behavior of solutions.*

Nonlocal, integral models have become viable alternatives to partial differential equations (PDEs) when the effects of long-range interactions affect the global behavior of a system. As an example, in continuum mechanics, nonlocal equations accurately model multiscale effects and anomalous behavior such as discontinuities and singularities in the solution.
The presence of long-range interactions and the integral nature of nonlocal operators create several modeling and computational challenges that may hinder the usability of nonlocal equations. A major challenge is the treatment of interfaces; while in the classical setting an interface is a sharp entity separating two domains, in the nonlocal setting an interface is a thick layer between domains. This fact makes the treatment of interface conditions for the solution and its flux a nontrivial problem.
Building on previous efforts by the same authors focused on the treatment of "perfect interfaces" (for which the solution and the flux are continuous through the thick interface), we propose a novel approach for the treatment of "imperfect interfaces", i.e. interfaces that feature jumps in the solution and in the flux.
Our approach is mathematically rigorous, in the sense that the resulting interface problem is well-posed, and physically consistent. The latter statement, in the context of nonlocal models, implies that when the extent of the nonlocal interactions vanishes, the nonlocal interface problem and its solution converge to their classical counterparts, i.e. to the solution of the corresponding PDE.
The applicability of this method and our theoretical findings are illustrated via several one- and two-dimensional numerical tests.

Key Words: Optimization, Inverse Problems, Model Discovery

The problem of minimizing multi-modal loss functions with a large number of local optima frequently arises in model calibration, architecture design and machine learning problems. Since the local gradient points to the direction of the steepest slope in an infinitesimal neighborhood, an optimizer guided by the local gradient is often trapped in a local minimum. To address this issue, we develop a novel nonlocal gradient to skip small local minima by capturing major structures of the loss's landscape in black-box optimization. The nonlocal gradient is defined by a directional Gaussian smoothing (DGS) approach. The key idea of DGS is to conducts 1D long-range exploration with a large smoothing radius along d orthogonal directions in $\mathbb{R}^d$, each of which defines a nonlocal directional derivative as a 1D integral. Such long-range exploration enables the nonlocal gradient to skip small local minima. The d directional derivatives are then assembled to form the nonlocal gradient. We use the Gauss-Hermite quadrature rule to approximate the d 1D integrals to obtain an accurate estimator. We demonstrate the superior performance of our method in several benchmark tests as well as data-driven discovery and design problems.

Comparison of Methods for Coupling a Lagrangian Discrete Element Sea Ice Model to an Eulerian Ocean Model

Kara Peterson[1*], Adrian Turner[2], Svetoslav Nikolov[1], and Dan Bolintineanu[1]

[1] Sandia National Laboratories*, Albuquerque, NM, USA, kjpeter@sandia.gov, snikolo@sandia.gov, dsbolin@sandia.gov

[2] Los Alamos National Laboratory, Los Alamos, NM, USA, akt@lanl.gov

Key Words: Discrete element method, particle to grid coupling, sea ice, ocean

Coupled Earth system models require methods for accurate and conservative transfer of fields between submodels such as sea ice and ocean. Typically, sea ice and ocean submodels are solved with Eulerian PDE-based methods that are often discretized on the same underlying grid, which significantly simplifies data transfer between submodels. A new sea ice model, the Discrete Element Model for Sea Ice (DEMSI), is under development that relies on a Lagranigan particle-based discretization. DEMSI treats collections of ice floes as Lagrangian particles that interact through contact forces and their trajectories are determined by directly integrating the equations of motion. In contrast to standard Eulerian continuum models of the sea ice cover, this method enables the capture of the anisotropic sea ice deformation and fracture in response to ocean and atmospheric forcing. Integrating this type of Lagrangian model into a coupled Earth system model with a traditional Eulerian PDE-based ocean code requires new methods for accurate and conservative interpolation from discrete particles onto grids.

We will describe two approaches for coupling a discrete element sea ice model to an Eulerian ocean model discretized on a global Voronoi grid. In the first approach, we use a geometric interpolation method where intersections between Voronoi cells associated with Lagrangian sea ice particles and ocean grid cells are used to define interpolation weights between the particles and grid cells. A similar method has already been implemented within DEMSI for particle-to-particle remapping applications [1]. The second method utilizes a moving least squares approach implemented with the Compadre Toolkit [2]. A comparison of the accuracy and conservation properties of both methods will be presented.

Key Words: Coupled problems, High-order time stepping, Multi-rate time stepping, Black-box coupling

For multiphysics simulations the robust and accurate coupling of different simulation codes is often required. Code coupling libraries, such as preCICE [1], allow the user to easily couple codes following a data-driven black-box approach, which ensures high flexibility and ease-of-use. However, the coupling of simulation codes that are working on different time-scales or using different time stepping schemes remains a big challenge [2].

To be able to combine the black-box coupling of preCICE with heterogeneous time stepping methods we designed a waveform iteration-based coupling scheme [3]. Additionally, we developed a software to facilitate the coupling of the off-the-shelf finite element solver FEniCS with preCICE – a so-called adapter [4].

In this talk, we present how these two components – the waveform iteration-based coupling scheme and the FEniCS-adapter – are combined to be used in a simulation setup that is close to a real application. This allows us to solve coupled problems with heterogeneous time stepping methods or time-scales in FEniCS. We introduce a test case to assess the accuracy of the whole software stack. With the overall architecture and a scheme for thorough evaluation in place, this marks a starting point for applying the proposed methodology to more complex problems.

Fourth-Order Accurate Partitioned Schemes for Conjugate Heat Transfer and Advection

J. W. Banks

Department of Mathematical Sciences, Rensselear Polytechnic Institute, Troy, NY 12180

Key Words: Partitioned Solvers, Conjugate Heat Transfer, Incompressible Flow

Here we discuss the development and analysis of fourth-order accurate partitioned solvers for conjugate heat transfer (CHT) problems that also involve advection. CHT with advection is a critical component of many important physical systems, for example thermal exchange along an ablating surface, and accurate robust treatment of these coupled systems has been a numerical challenge. The approach advocated here treats the governing temperature equations in different material domains using implicit time-stepping, while the interface coupling is explicit. The new approach, called the CHAMP scheme (Conjugate Heat transfer Advanced Multi-domain Partitioned), is based on a discretization of the interface coupling conditions using a generalized Robin (mixed) condition. The interface treatment combines ideas from optimized-Schwarz methods for domain-decomposition problems together with the interface jump conditions and additional compatibility jump conditions derived from the governing equations. The focus of the present work is primarily the development and analysis of a fourth-order accurate scheme, which is designed to be stable and accurate with minimal sub-iterations at each time step. Complicated geometrical domains are considered using overlapping grids, and results for a representative set of problems are presented. Time permitting, results coupling the new capability with high-order accurate incompressible flow solvers will also be discussed.

NS-ω-C Model for Fluid-Fluid Interaction Problems at High Reynolds Numbers

Mustafa Aggul * Alexander E. Labovsky† Kyle Schwiebert‡

November 8, 2021

Abstract

We consider a fluid-fluid interaction problem, where two flows are coupled through a nonlinear rigid lid condition, and one or both of these flows are at high Reynolds numbers. A method is proposed, that introduces the NS-ω-C turbulence model and combines it with a partitioning method called Geometric Averaging (GA) - so that the resulting model is efficiently decoupled, allows for the usage of preexisting solvers (e.g., air and water domain solvers), and is capable of resolving the flows at high Reynolds numbers. The NS-ω-C turbulence model, that we introduce in this report is a member of the newly proposed class of LES-C turbulence models, where a defect correction algorithm allows for the reduction of the modeling error. The resulting NS-ω-C-GA model is shown to be unconditionally stable and have optimal convergence properties. The model also allows for the non-filtered velocity in the interface terms; it has been shown recently that filtering the velocity in the interface terms could corrupt the quality of the model's solution.

On the Stability of Interface Conditions for Ocean–Atmosphere Coupling

Hong Zhang[1*], Zhengyu Liu[2] Emil Constantinescu[1] and Robert Jacob[1]

[1] Argonne National Laboratory, hongzhang@anl.gov, emconsta@anl.gov, jacob@anl.gov
[2] Ohio State University, liu.7022@osu.edu

Key Words: stability analysis, coupled system, partitioned algorithm, ocean-atmosphere

Numerical stability is of critical importance in general circulation models (GCM) because it affects the design of algorithms, time to solution, and computational costs associated with the simulations, which are very expensive in practice. Each component inside the coupled system is often associated with different time scales, posing a great challenge on time integration. In this work, our objective is to characterize the influence of different coupling strategies on the stability and accuracy of the fully coupled system.

We have analyzed the stability of different coupling strategies for multi-domain PDEs that arise in GCM. This study focuses on fully coupled ocean-atmosphere models that are needed to represent and understand their complicated interactions. In particular, we will discuss the stability of the coupled ocean-atmosphere models for various interface conditions such as Dirichlet-Neumann condition and bulk condition, which is unique to climate modelling. By analyzing a simplified model, we will show how the parameterization of the bulk condition and other physical parameters affect the coupling stability. By extending the analysis to a more realistic model that includes horizontal advection, we find that advection has a stabilizing effect in scenarios common to climate models when bulk interface condition and explicit flux coupling are used in tandem.

Key Words: *partitioned schemes, reduced order models, Lagrange multipliers*

Partitioned methods for multiphysics applications allow independent solution of computational models for each constituent component, thereby increasing computational efficiency of the simulation. This efficiency can be further increased by utilizing reduced order modeling (ROM) on select subdomains. In a series of two talks we present formulation and analysis of new partitioned schemes, which extend the approach in [1] and [2] to couplings of combinations of conventional Finite Element (FEM) and ROM sub-models. In Part 1 we present the formulation of a partitioned scheme for a model interface problem which couples a ROM with a conventional finite element method and extend the scheme to the case of coupling a ROM with a ROM. The proper orthogonal decomposition (POD) approach is implemented to construct a low-dimensional reduced basis on half the domain and solve the subdomain problem in terms of this basis using POD/Galerkin projection. The solutions on each half of the domain are coupled using a Lagrange multiplier representing the interface flux. The multiplier at the current time step can be expressed as an implicit function of the state solutions through a Schur complement. As a result, application of an explicit time integration scheme decouples the subdomain problems, allowing their independent solution for the next time step. We show numerical results that demonstrate the proposed method's efficacy in achieving both ROM-FEM and ROM-ROM coupling.

Key Words: Domain Decomposition, Fluid-Poroelastic System

We consider decoupling iterative algorithms based on domain decomposition for the time-dependent Stokes-Biot model, in which different time steps can be used in the flow region and in the poroelastic medium. The coupled system is formulated as a space-time interface problem based on either physical interface conditions or equivalent Robin-Robin interface conditions. The interface problem is then solved by an iterative method which involves parallel solution of time-dependent homogeneous Stokes and Biot problems. Consequently, local discretization in both space and time can be used to efficiently handle multiphysics systems with discontinuous parameters. Numerical results with nonconforming time grids are presented to illustrate the performance of the proposed methods.

Key Words: Contact, Schwarz Alternating Method, Coupling, Multiscale

We introduce and evaluate numerically a fundamentally new approach to simulate mechanical contact based on the Schwarz alternating method. The new approach leverages our previous work in Schwarz multiscale coupling and addresses two well-known problems in computational simulation of contact: (1) the accuracy of the contact constraint enforcement, and (2) the multiple scales involved. Rather than introducing contact constraints into the variational form of the problem, as done in conventional contact techniques, the Schwarz alternating method decomposes the problem domain into two or more subdomains and prevents interpenetration by applying transmission (boundary) conditions in an iterative and alternating fashion on the subdomain boundaries. The Schwarz alternating method has a number of desirable qualities, including its ability to use different element topologies and time integrators in different subdomains. We demonstrate herein that these advantageous properties carry over to the contact variant of the method.

Key Words: Schwarz alternating method, domain decomposition, projection-based reduced order model (ROM), heterogeneous coupling

Although projection-based model order reduction is a promising approach for enabling real-time and multi-query analyses, reduced order models (ROMs) have been known suffer from a lack of robustness, stability and accuracy, especially in the predictive regime. This talk describes a new methodology for improving the predictivity of projection-based ROMs by coupling these models conventional full order models (FOMs) using the Schwarz alternating method. The Schwarz alternating method [1] is based on the simple idea that if the solution to a partial differential equation (PDE) is known in two or more regularly-shaped domains comprising a more complex domain, these local solutions can be used to iteratively build a solution on the more complex domain. Leveraging recent work that adapted the Schwarz alternating method to enable consistent and concurrent multi-scale coupling of finite element FOMs in solid mechanics [2, 3], we present a new extension of the Schwarz formulation that enables ROM-FOM coupling. The new approach is based on the following ingredients: (i) a decomposition of the physical domain of interest into two or more overlapping subdomains, (ii) the construction of either a FOM or a projection-based ROM in each of the subdomains, (iii) the definition of appropriate transmission boundary conditions (BCs) which will propagate information between the overlapping subdomains, and (iv) the introduction of a Schwarz iteration process in which the ROM and FOM solutions on each subdomain are successively updated (to convergence) in an iterative and alternating fashion, with information between subdomains propagating through the transmission BCs. After describing the method's formulation and theoretical properties, we evaluate its performance on several numerical examples from the field of solid mechanics. Specifically, we demonstrate that the method is capable of producing a more accurate solution than the classical single-domain Proper Orthogonal Decomposition (POD)/Galerkin ROM approach, while still achieving a computational savings with respect to a typical FOM discretization.

Key Words: *Discrete element method, Parameter sensitivity, Parameter estimation*

Determining the correct pairwise parameters in a Discrete Element Method (DEM) contact force model is a non-trivial undertaking. Difficulty in parameter estimation is in part due to correlation between parameters and observed system responses[1]. Additional considerations include the process conditions, for instance, if a system is in a friction-driven regime then any contributions from non-friction parameters in the model are masked to an extent, which can hinder estimation.

This work analyses DEM model parameter sensitivities following the methodology outlined by Yan, et al.[1], applied to a stirred milling system instead of a cylinder with an orifice; thus, energy is imparted into the system via the geometry and not solely gravity. Further, the process settings of the stirred milled are varied. This is to both identify the difference between particle-particle and particle-geometry term sensitivities and to link differing process regimes with changes in parameter sensitivity. The methodology considers 3 increasingly detailed levels of statistical analysis:

1. Analysis of fitting parameters for empirical model.
2. Principal Component Analysis (PCA) on simplified contact model derivatives.
3. Analysis of sensitivity matrix constructed from full contact model derivatives.

In this work, the Hertz-Mindlin[2] and Constant Directional Torque[3] (CDT) contact models are used to describe collisions of the milling grinding media for a dry operation simulation. Varied parameters are the coefficient of restitution, sliding and rolling friction. Additionally, the analysis is applied to 4 varied process settings corresponding to different filling levels and attritor speeds. The variable used during this analysis is the grinding media Root-Mean Square (RMS) velocity, a relevant variable within milling[2]. The analysis for each level showed that:

1. A fully packed system showed little variance in parameter dependency, the opposite was true when the filling level was reduced.
2. The equation of mass terms varied more with fill level than for moment of inertia.
3. Particle-geometry terms had greater impact than particle-particle terms. The equation of mass is dominated by coefficient of restitution and moment of inertia by rolling friction.

Thus, the process conditions chosen can have an impact on the present sensitivities of the utilised DEM model, and care should be taken to determine the regimes present that are within the modelling scope, with estimation data taken from each regime. Hence, the estimation will improve as the parameters exhibit noticeable variance that can be identified by a minimisation routine.

Key Words: Particle Finite Element Method, Discrete Element Method, Coupled Models, Stirred Media Mill

In the mining industry, comminution is the single most energy-intensive process accounting to approximately 4 % of the global produced electric energy [1] and as much as 50 % of the electric energy consumed in a mine can be attributed to comminution [2]. Stirred media mills have a high energy efficiency compared to other commonly used mills, such as ball mills. Modelling a wet comminution process is challenging since it requires consideration of the complex multi-physics in the mill. It requires the simultaneous treatment of feed material, grinding fluid and media, and rotating internal agitator elements. In this study, a model of a pilot vertical stirred media mill with a nominal power of 7.5 kW is developed. The model utilizes a particle-based coupled solver approach, where a Particle Finite Element Method (PFEM) [3] model is coupled with a Discrete Element Method (DEM) [4] model and a Finite Element Method (FEM) model. PFEM is used to model the grinding fluid, DEM to model the grinding media and FEM to model the mill structure, i.e., the agitator elements. The models are coupled by a loose (or weak) two-way coupling strategy. A Reynolds number dependent drag coefficient is used in the PFEM-DEM coupling and the grinding fluid is modeled as a non-Newtonian, shear thinning fluid. By the coupled PFEM-DEM-FEM models the complex dynamics inside the stirred media mill are predicted. The model is used to quantify the power consumption, wear distribution on agitator elements, inter-particle collisions and grinding media and fluid dynamics in the stirred media mill. The model is validated against experimental measurements of power consumption on a pilot mill with good agreement.

Key Words: *Calibration, Discrete Element Method, Automated Workflows, Granular Materials*

Although the discrete element method (DEM) is widely used to study granular materials in diverse scientific and engineering applications, the choice of the DEM input parameters is still a challenge. On the one hand, it is often difficult to measure individual particle or particle-particle interaction parameters. On the other hand, due to key simplifications made in existing contact models or the shape and deformation of particles, these measured properties would not reproduce the actual bulk behavior with sufficient accuracy. In addition, advanced closure models for the DEM have been developed, e.g., contact force closures for very densely packed granular materials [1], [2].

Following any of the existing calibration methods, i.e., either the direct bulk calibration [3] or response surface generation methodology [4], demands (i) conducting multiple simulations and (ii) a comparison with experimental or relational data[5]. In our newly developed tool "DEMvironmnet", Orange3 [6] workflows and Python modules are integrated to set up, manipulate and run calibration workflows. The Aspherix® Calibration software is used as the numerical heart of our calibration workflow, realizing a comfortable direct bulk calibration. Moreover, DEMvironment provides a graphical interface to demonstrate the flow of data and visualize the data handling strategy. Our tool follows four main steps in a calibration workflow: (i) data handling, (ii) calibration, (iii) data storage, and (iv) validation. Step (i) assists the user in input data preparation, processing output data from simulations, and interactions with a central database. Step (ii) performs the actual calibration of parameters, and steps (iii) and (iv) help in storing and validating a calibrated DEM-based simulation.

DEMvironment expedites the often demanding calibration procedure, and facilitates the reusability of valuable data from experimental studies of granular matter. In our presentation, this tool is explained in greater detail, as well as providing application use cases. We close our presentation by highlighting how DEMvironment could be used to calibrate parameters of an advanced multi-contact force closure for highly compacted granular materials [2].

Key Words: DEM, Particle-Properties, Calibration

Discrete-Element-Method (DEM) simulations are a valuable tool for research and industry to model experiments or industrial processes involving particulate media. These simulations can predict the anything from the strength of a con- crete block to the damping efficiency of granular dampers, as well as helping us better understand complex phenomena such as the granular Leidenfrost effect or the Brazil-Nut Effect.

While they are capable of quantitatively reproducing the dynamics of real- world systems, their validity depends strongly on the calibration of the simula- tion – i.e. the implementation of exact particle properties such as the Coefficient of Restitution or the Young's Modulus. These properties usually are defined by the material and shape of the used particles which must typically be determined through multiple, complex and highly labour-intensive experiments. Indeed, this calibration process can be the most time consuming part in modelling of a scientific or industrial system – a significant problem in industry in particular, where time efficiency is paramount.

To address this issue, we have developed a series of open source DEM Digital Twins of widely used powder characterisation tools, namely the FT4 Powder Rheometer with its dynamic and shear cell methodology, the Schulze shear cell and the GranuTools GranuDrum and GranuHeap. Each of our Digital Twins extracts realistic data – as each real device would – which can be used to fine tune powder properties in your simulation. The open source package features a coupling to the LIGGGHTS simulation engine, advanced mesh control to allow the quick change between mesh movements and specialised image extraction techniques from DEM data. We show a example application of the digital twin on a common calibration problem using coarse grained particles.

Key Words: Discrete element method, Polygonal shapes, Polyhedral shapes, Schneebeli Material

Discrete Element (DEM) simulations in two dimensions reproduce characteristic features of three-dimensional experiments as long as the system is a cross section with respect to a symmetry. Examples are central pressure "dips" for heaps built in a wedge - but not in a layered - sequence [1] as well as characteristics of stress-strain curves (linear regime for small strains, maximum for non-spherical particles, lack of maximum for spherical particles [2], higher strength for non-convex than for convex particles [3]). Experimentally, quasi-two dimensional systems have been realized by "Schneebeli-Material", parallel rods of even cross-section, which have been used for shear- and failure experiments for a long time. However, it is far from clear how much two-dimensional simulation results will match experimental data in three dimensions, as there is a crucial difference in the dynamics of two and three dimensions: Straight lines "nearly always" intersect in 2D, so that vectors of strong forces will meet in the force networks and can so destroy the stability of the assembly. Skewed lines in three dimensions do not intersect, and so vectors of strong forces will not meet. As a consequence, the mechanical stability of 3D assemblies (mostly, but not perfectly parallel rods) should be higher than that of polygons in 2D for the same cross sections. In this research, we investigate the stress-strain diagrams with DEM-simulations for rods with polygonal cross sections in three dimensions[4] and of polygons in two dimensions for two-axial compression.

Key Words: *PEPT, tumbling mills, granular rheology, coarse-graining*

Depth-integrated formulations underpinned by the linearised $\mu(I)$-rheology [1,2] and the *shallow flow approximation* [3] offer useful qualitative insights into rotating drum flows operated in regimes spanning straight and minimally curved free surfaces characterised by Froude numbers less than 0.3. Beyond these regimes (Fr > 0.3) the solution fails to recover a realistic bed geometry and flow field. To extend the theory to Fr > 0.3 we relax the shallow flow approximation and apply corrections to the velocity field before reconstituting the mass, momentum and energy balances. Positron Emission Particle Tracking (PEPT) experiments of a 476 mm diameter drum (length of 200 mm) filled to 50 percent of drum volume with 3 mm glass beads was used to validate the updated theory. To ensure equitable comparison, the PEPT data is coarse grained [4] into voxels of dimensions 2.5 times the particle diameter. Using the same averaging window, the theory is tuned against the PEPT solution. Quantitative comparisons of the velocity field, bed geometry (free surface and basal interface), energy dynamics and principle stresses show statistical agreement for all drum speeds investigated. The tuned theoretical parameters—slope of the linearised rheology χ, dilated fill fraction ζ, and bed repose angle α—are then correlated with drum speed. The aforementioned procedure allows for full flow field prediction of a given granular material flowing in rotating drums operated at Fr > 0.3.

Particle Flow and Heat Transfer in Pharmaceutical Operations

Benjamin J. Glasser[1,*]

[1] Department of Chemical and Biochemical Engineering, Rutgers University, Piscataway, NJ 08854, United States, bglasser@scarletmail.rutgers.edu, http://cbe.rutgers.edu/~bglasser

Key Words: *Granular Flows, Discrete Element Method, Heat Transfer, Drying, Conduction.*

Processing of particulates plays an important role in a wide variety of industries, including the pharmaceutical industry, the bulk chemical industry, and the food industry, to name a few [1]. Yet, despite the ubiquity of particulate systems, a strong fundamental understanding of their behavior is lacking. We have focused on heat transfer in granular materials in order to better understand the drying of particulates. Drying is an important manufacturing step in the production of active pharmaceutical ingredients (APIs) [2]. Several approaches exist to carry out the drying procedure, but a common method used by the pharmaceutical industry is agitated drying. During the process, a wet bed of API is heated in a jacketed cylindrical vessel while being mixed by a rotating impeller until the moisture content is reduced to a desired level. This geometry can be simplified as a vertical cylindrical vessel in which wet particles rest at the bottom of the unit. Heat is typically supplied via conduction through a heated jacket around the wall of the vessel while an impeller, which can also be heated, mixes the particles to help improve the distribution of heat and promote evaporation throughout the bed. This geometry offers several notable benefits in terms of design, such as its high thermal efficiency, low cost of operation, and environmental advantages. Another significant advantage is that it can be equipped with a filter and thereby enable API filtration to be carried out in the same unit prior to drying. This reduces the potential for product loss that can occur when transferring material to a different equipment and decreases the risk for worker exposure to potent and possibly toxic materials.

The complexity of the process stems from the fact that heat transfer, mass transfer, and changes in physicochemical properties can occur simultaneously throughout drying. Complications often plague the procedure, including issues such as lengthy drying times, over-drying, nonuniform drying, agglomeration, attrition, and form changes. These circumstances make agitated drying a complicated process to understand and control. When considering scale up, these challenges are coupled with the difficulties typically associated with transferring knowledge from lab scale to pilot or manufacturing scale. As a result, it can be difficult to design an appropriate drying protocol that optimizes heat transfer and can be translated from scale to scale while minimizing the risk for adverse conditions. In this work, we decouple the problem and focus on studying the heat transfer aspect of agitated drying. More specifically, we investigate the influence of process and material parameters on heat transfer in an agitated bed of particles. Our approach consists of employing a combination of experiments and discrete element method (DEM) modeling techniques to analyze how heat transfer scales with flow, mixing and bed parameters. We have carried out a design of experiments and computed heating times as well as heat transfer coefficients and temperature distributions for the different conditions. We find that scaling influences the flow and compressibility of the bed and therefore creates a balance between conduction and granular convection as the dominant mode of heat transfer.

ABSTRACT

Through continuous development in the past century, radar (radio detection and ranging system) technology has advanced into a versatile approach being widely used in various disciplines, from conventional moving target indicator radar via ground penetration radar to synthetic aperture radar for space exploration and satellite imaging [1]. In particular, the development of semiconductor industries enables the integration of a whole radar system on a silicone chip, thus dramatically facilitates the application of radar systems in non-destructive testing (NDT) as well as in consumer products (e.g., smartphone) to enhance human-machine interactions.

Here, we describe the possibility of using radar particle tracking technique as an alternative approach to track projectile motion inside granular media. After a brief description of the advantages and disadvantages of the small scaled multi-static continuous wave radar system, the implementation of this approach in monitoring granular drag will be presented [2]. Subsequently, we focus on the implementation of this approach in the calibration of DEM simulations for a better understanding of the influence of gravity on granular drag [3]. Eventually, a brief outlook into the future of radar systems in verifying large scale computer simulations will be provided to trigger further discussions and potential applications.

Key Words: *Coffee Roasting, Heat and Mass Transfer, Simulation, PEPT, CFD-DEM, DEM.*

Understanding physicochemical coffee bean development during roasting is integral to unlocking key flavour and aroma characteristics, as well as improving process efficiencies and translating products from one roaster to another. Simulation of roasting time-temperature profiles currently rely on semi-empirical heat and mass transfer models. These empirical models alone cannot quantify the variation of air-to-bean heat transfer induced by particle flow patterns. By identifying coffee bean particle motion within a roaster, particle dynamics can be coupled with heat and mass transfer models to improve both the accuracy and robustness of time-temperature profile simulations.

Experimental flow studies of coffee beans have been performed using Positron Emission Particle Tracking (PEPT) to capture particle motion within two roaster designs: (i) rotating drum, (ii) spouted bed. These experimental data were then used to rigorously calibrate (i) a DEM simulation of the rotating drum, (ii) a CFD-DEM simulation of the spouted bed, thus quantitatively acquiring the complex dynamics of aspherical particle motion in process equipment.

Determination of occupancy and velocity profiles revealed two distinct regions for both systems (i) a dense bean bed of high occupancy with low particle velocity (ii) a dilute freeboard of lower occupancy with higher particle velocity. By examining the boundaries of the delineated bean bed and freeboard, and how they transform due to changes in coffee density and applied process parameters, heat and mass transfer properties of the system can be inferred. Established empirical properties can thus be integrated with heat and mass transfer models to indicate regional heat transfer contributions.

PEPT validated CFD-DEM/DEM simulations provide fundamental knowledge of system dynamics that have been used to develop more accurate and robust physics-driven models of coffee roasting. Commercial implementation of these models thus has the potential to virtualise the roasting process and overcome trial and error approaches to product and process development.

Statistical comparison of coarse-grained kinematic fields derived from Postron Emission Particle Tracking (PEPT) Experiments and Discrete Element Method (DEM) simulations in rotating drums

Taswald Llewelyn Moodley[1,2*] and Indresan Govender[1,2,3]

Key Words: *PEPT, DEM, tumbling mills, granular rheology, coarse-graining*

In the absence of a universally accepted, fundamental theory that describes dense granular flows, researchers must resort to dimensional analysis to understand the drivers of the system. Leading theories on granular flow [1,2] are underpinned by dynamic properties like the shear rate and granular temperature; the shear rate is vital to quantify the slurry viscosity—a key parameter controlling slurry transport in rotating drums, for example. Such properties are readily derived from numerical DEM simulations which are capable of producing discrete, microscale data at a timestep of 10^{-6}s. We argue that one can trust this dynamic data if-and-only-if it is validated against experimental measurement. In this regard PEPT, a Lagrangian, nuclear imaging technique, is capable of producing full 3D kinematic data (solids fraction, velocity) at ~10^{-3}s. To this end, we perform PEPT measurements and DEM simulations of three and five millimetre monosize glass beads in a 300mm, 30% filled rotating drum at high Froude regimes. The resultant PEPT kinematic data is coarse-grained [3] to produce continuum kinematic fields; this process requires tedious calibration, in an iterative sense, by choosing the optimal smoothing radius such that a continuous profile is generated. These PEPT fields (solids fraction, velocity maps) are then subjected to statistical comparison against DEM-based continuum fields. The shear rates are subsequently evaluated by applying approaches proposed by [3] and [4] to the now validated PEPT and DEM velocity fields. The latter approach [4] is more favourable because it does not require tuning of any parameters, i.e., smoothing radii. In the event of poorly sampled data, one is better off using the [3] model which incorporates neighbouring cell data to produce a smooth continuum description. Statistical comparison of continuum data at in high Froude regimes is seminal and as such, this work offers useful insights into the coarse graining of Lagrangian kinematic data to produce continuum fields.

1. Abstract

This paper presents a simplified implementation of the arc-length method for computing the equilibrium paths of nonlinear structural mechanics problems with equality restrictions imposed by the augmented lagrangean method. In this work, the predictor is based on extrapolation from two previously converged load steps and the lagrangian multiplier is updated in the usual way, in relation to the penalty parameter and the penetration. The extrapolation being a simple linear relation renders a simple method of update that additionally serves as way of identifying the forward movement along the equilibrium path, without the need of any complex technique commonly employed for explicit tracking. The capability of the algorithm to correctly describe the equilibrium path is verified in static structural mechanics problems through benchmarks from the literature. The results indicate that the algorithm is fully capable of reproducing all of the verified examples.

Development of 3D visualization system from 2D Plane Figures

Contents using AR (Augmented Reality) and VR (Virtual Reality) are expected to be useful in various fields including scenes of broadcasting and education. The combination of visual information and reality increases volume of information and enhances the human capability. In particular, the introduction of ICT into school education have been active and the value is drawing increasing attention over the recent years. Under the circumstances, we considered a system that supports learning by assisting spatial ability with AR[1].

Spatial ability is the capacity to recognize relations or appearances of objects in a 3D space. This ability depends on individual in its accuracy or speed of understanding. Learning methods are changing on the stages of development of learners. For examples, during childhood, putting the blocks together or making solid model physically are performed to acquire spatial ability, but the middle and high school use only texts generally. Learning using real objects like blocks help to understand 3D intuitively because it can link real movements with vision. However, learning using only text requires a higher level of spatial ability.

In this paper, we developed an application to reduce the effects of differences in spatial cognitive ability in learning by using AR to visualize 2D figures in 3D and help learners to acquire spatial ability and grasp the image of the plane-to-three-dimensional transformation. The system generates 3D data automatically based on the features of a 2D plan view and then displays it as AR. The feature point extraction and coordinate recognition are performed by the OpenCV library and figure identification is performed by machine learning technology. Based on these results, 3D model is generated and displayed as AR on a web browser by AR.js.

Key Words: *Microwave Analysis, E-Method, Parallelized Finite Element Method, Domain Decomposition Method, ADVENTURE_Fullwave.*

Electromagnetic field analysis based on a numerical analysis method, such as the finite element method, has become widespread [1] due to recent improvements in computer performance and numerical calculation technology. In the case of accurately reproducing an analysis model of complicated shape, it is necessary to use many small the elements. In the case of analyzing the state of electromagnetic waves propagation in a wide range, a wide analysis domain is examined. Furthermore, to perform a high-accuracy analysis, it is necessary to model the analysis domain with a sufficiently small element for the wave-length, and, in this case, the number of elements also increases. Increasing the number of elements increases the scale of the problem. Therefore, a method that can calculate large-scale problems has come to be demanded. Moreover, large-scale problems must be solved with high accuracy.

In this presentation, a huge-scale microwave analysis software based on an iterative domain decomposition method is explained that is named ADVENTURE_Fullwave [2]. A stationary vector wave equation for the high-frequency electromagnetic field analyses is solved taking an electric field as an unknown function. Then, to solve subdomain problems by the direct method, the direct method based on the LDL^T decomposition method is introduced in subdomains [3][4][5]. The simplified Berenger's PML is introduced which these eight corners are given the average value of all PML's layers.

Key Words: Bio-heat transfer; whole body model; tissue temperature; finite element and ADVENTURE_Thermal.

Metabolic heat generation, blood perfusion and surrounding conditions have effect on the human body temperature. Considering these effects, the natural thermoregulatory system maintains the comfortable body core temperature.

The aim of this study is to investigate the effect of metabolic heat generation, blood perfusion rate and ambient temperature on the body temperature during different physical activities. Penne's bio-heat equation is being widely used for the simulation of the skin burn [1] and temperature controlled thermal ablation [2]. For the current investigation, three dimensional finite element model of bio-heat equation has been developed and added in the ADVENTURE_Thermal [3].

The heat transfer analysis was performed in the three dimensional skin and simple human body model using the developed system. The skin temperature was investigated with a hot disk and hot coffee in touch separately. A simple human whole body model has been developed and the effect of the mentioned physiological parameters on the body temperature was measured.

The numerical results depict that blood perfusion rate acts as a heat sink when the extra metabolic heat is generated. The body temperature variates with different metabolic heat generation and ambient temperature during cooking, walking and running at different velocities. The developed model and the system will help investigate the body temperature in the clinical treatments.

ADVENTURE AutoLinAS (pronounced as 'O-to-li-na-shi') is a linear algebraic solver library, dedicated for simulation-based research and development. It is designed for the simulation users to develop their own solvers. Currently, the library is used among many researchers and simulation users, mainly in universities and national research centers. Its functionalities and supported platforms are explained. AutoLinAS applications of various kinds of simulation methods are demonstrated also.

Implementations of the library for various kinds of high performance computing platforms, such as Intel x86, Intel Xeon, AMD EPYC and Fujitsu PRIMEHPC FX-1000/Fugaku, as well as NVIDIA GPU, are available. Each of them is highly tuned for the underlying hardware architecture.

Key Words: *Marching Cube, Mesh Smoothing, Geometric Multigrid Method, Electrostatic analysis*

In electrostatic field analysis using a numerical human body model constructed with voxels, the electric field strength is overestimated near the staircase boundary of different materials (called staircasing errors)[1]. To reduce these staircasing errors, mesh smoothing based on the marching cubes method is developed and applied to the numerical human body model [2]. The extended marching cube method is proposed in this research, which can perform mesh smoothing of three kinds of boundaries, and most of the 90-degree angle points of the boundary of different materials in the numerical human body model can be smoothed.
In addition, in order to cope with the increase of computation time due to the increase of DOFs by mesh smoothing, the geometric multigrid method [3] for unstructured grids is applied to the numerical human whole-body model, and the computation time per subdivision is compared with that of the CG method solver with preprocessing. As a result, it is found that the geometric multigrid method can reduce the increase of computation time per subdivision compared with the CG method with preprocessing. In terms of computation time, the geometric multigrid method achieves a maximum computation time of about 1/20 of that of ILU-CG for voxel models and about 1/15 for smoothing models.

Key Words: *Noh, Traditional dance, Motion analysis, Motion capturing*

Noh is one of the most representative traditional art forms in Japan. Since the 14th century, *Noh* has continuously been inherited for more than 700 years. *Noh* also has been registered as an intangible cultural heritage by UNESCO. A previous study showed that *Noh* movements can be used to keep elderly people's health. Today *Noh* is not only for people to enjoy in the theatre, but *Noh* is also useful for health promotion. The benefits are both on maintaining health and beautiful standing posture.

Hakobi (Sliding walk) is one basic movement pattern of walking in *Noh*, which refers to walking with the feet sliding on the floor slowly. The sliding walk is very different from the walking in daily life and can be used to exercise the psoas major muscle. In this research, we analyzed the features of sliding walk. We also compared the motion of sliding walk and walking.

For motion tracking techniques, the traditional marker-based motion capture system is constrained by the utilization of the environment. For example, a stage costume is important for any dance performance, but markers are not suited for a dancer's stage costume. Therefore, we use artificial neural network-based motion capture technology to recognize human pose without markers. In this research, OpenPose[1], one of the most popular open-source libraries, is used for pose estimation from video images.

ACKNOWLEDGMENTS

We acknowledge *Noh* actor and the holder of Important Cultural Property (*Noh*) Hikaru Uzawa for teaching and supporting *Noh*.

Key Words: Uncertainty Quantification, Non-Intrusive Method, Monte Carlo Simulation, Large-Scale Analysis, Parallelized Finite Element Analysis

In numerical analyses of physical phenomena, it is necessary to analyze stochastically if geometries, material properties, and boundary conditions of the analysis objects have uncertainties. The field of evaluating the influence of uncertainties of parameters in simulations is called Uncertainty Quantification or UQ in short. UQ has attracted more attention in recent years because it can be used for reliability evaluation, optimization, and safety evaluation in the design of systems and devices.

One of the most widely used methods for UQ is the Monte Carlo simulation. The method evaluates probability distributions of output parameters by generating random numbers which follow a specific probability distribution of input parameters and then calculating the output value for each random number. While a deterministic simulator can be utilized as a black box, the application of the method is limited to small-scale analysis because of the need for a quite large number of samples to achieve good approximation. Therefore, Spectral Stochastic Finite Element Method [1] was devised by Ghanem and Spanos. In this method, input and output random fields are discretized by spectral expansions in probability space, and the probability distribution of the output can be evaluated by a single matrix calculation. Although having high computational efficiency, it takes much labor to modify existing codes.

The purpose of this paper is to quantify uncertainties in the large-scale analysis of physical phenomena using a non-intrusive method, which has the advantages of both of the above two methods. The non-intrusive method has reusability of existing codes and high computational efficiency, and therefore it is easy to apply to large-scale problems. In the present study, we integrated the non-intrusive method with the ADVENTURE [2], a deterministic simulator based on a parallelized finite element method, to perform a large-scale electromagnetic wave analysis with uncertainties. Specifically, we stochastically evaluated the electromagnetic fields in the human body whose permittivity and conductivity have uncertainties.

Multilevel and domain decomposition methods for solving large scale phase-field fracture simulations

Alena Kopaničáková[1*], **Rolf Krause**[2]

[1] Università della Svizzera italiana, Switzerland, alena.kopanicakova@usi.ch
[2] Università della Svizzera italiana, Switzerland, rolf.krause@usi.ch

Key Words: Phase-field fracture, Non-convex optimization, Multilevel and domain decomposition methods

One of the state-of-the-art strategies for predicting crack propagation, nucleation, and interaction is the phase-field approach. In this approach, a damage variable is introduced to characterize the material state from intact to fully broken. Although the phase-field approach is a robust tool for predicting crack propagation, it gives rise to strongly nonlinear coupled systems of nonlinear equations that have to be solved at each time step. This is computationally challenging due to the non-convexity of underlying energy functional, a large number of degrees of freedom, and the severe ill-conditioning caused by the local changes in the damage variable.

In this work, we propose to solve the arising nonlinear problems efficiently using multilevel [2] and domain decomposition [1] methods. The proposed methods are designed to solve the arising non-linear problems in a monolithic manner by taking advantage of the underlying structure of the coupled problem. In particular, we discuss different techniques to construct a hierarchy of suitable subspaces, related to different levels or subdomains. In the multilevel settings, we employ novel level-dependent objective functions, that combine a fine-level description of the crack paths with the coarse level discretization. For the domain decomposition, we take advantage of partitioning the degrees of freedom into two sets, related to the displacement and the phase-field. Eventually, we combine both, multilevel and domain decomposition, techniques with the trust-region globalization strategy in order to ensure global convergence.

We will demonstrate the convergence behavior of the proposed multilevel and domain decomposition methods using several benchmark problems. A comparison with the widely-used alternate minimization method will be presented, showing a significant reduction in the number of iterations and the execution time. In the end, we will also illustrate the strong and weak scaling properties of the overall simulation framework.

Key Words: *Mixed-dimensional model; Mixed-mode fracture propagation; Contact mechanics; Coupling discretization methods; Hydraulic stimulation; Poroelasticity; Multiscale simulation; Open-source software.*

Fractures play an essential role in the enhancement of geothermal reservoirs through hydraulic stimulation, where the overall reservoir permeability can be enhanced both by slip and dilation of existing fractures and by fracture propagation. We present a mathematical model and numerical strategy to investigate the interaction between fluid flow, deformation, fracture shearing, and fracture propagation during low-pressure fluid injection. Deformation and fluid flow are represented based on a mixed-dimensional model, considering fractures as co-dimension one objects in the domain. The matrix surrounding the fractures is poroelastic, and a contact mechanics model govern the deformation of existing fractures. Mixed-mode fracture propagation is modelled by the maximum tangential stress criterion.

The solution approach is based on a multiscale strategy, expanding on the work by Dang-Trung et al. [1]. In the macroscale model, flow in and poroelastic deformation of the matrix are coupled with the flow in the fractures and fracture contact mechanics [2], allowing fractures to frictionally slide. Fracture propagation is handled at the microscale. Simulations show how the shearing of a fracture due to fluid injection is linked to fracture propagation, including cases with hydraulically and mechanically interacting fractures.

Analytic Solutions of 2-D Transient Heat Conduction Problems by the Symplectic Superposition Method

Dian Xu[1*]

[1] State Key Laboratory of Structural Analysis for Industrial Equipment, Department of Engineering Mechanics, and International Research Center for Computational Mechanics, Dalian University of Technology, Dalian 116024, China, dianxu@mail.dlut.edu.cn

Key Words: *Heat Conduction, Heat Source, Symplectic Superposition Method, Analytic Solution*

In view of the important role in providing benchmarks and rapid parametric analyses for preliminary designs, analytic solutions gain permanent interest for heat conduction problems. In this study, the 2-D transient heat conduction problems with or without heat sources in a rectangular domain under different combinations of temperature and heat flux boundary conditions are studied by a novel symplectic superposition method (SSM) [1-4]. The solution process is within the Hamiltonian system framework such that the mathematical procedures in the symplectic space are implemented, which provides an exceptional direct rigorous derivation without any assumptions or predetermination of the solution forms compared with the conventional inverse/semi-inverse methods. The distinctive advantage of the SSM offers an access to new analytic heat conduction solutions. The accuracy of the SSM is confirmed by comprehensive transient heat conduction results, including both numerical and plotted temperatures, as validated by the finite element method. This study is the first one on extending the SSM to heat conduction problems, which may pave the way to more benchmark analytic solutions in the field.

Key Words: *Computational Grains, Fiber Composites, Papkovich-Neuber solutions; parallel computation.*

In this study, 3D fiber computational grains (CGs) are developed for the micromechanical modelling of fiber-reinforced composites. The microstructure of a fiber composite can be divided into several CGs, each of which contains a long fiber. And a compatible displacement field is assumed at the outer-boundary and the fiber-matrix interface in each CG. Trefftz trial displacement fields in each element are expressed in terms of Papkovich-Neuber solutions, by employing cylindrical harmonics as Papkovich-Neuber potentials. A new scaling method for the cylindrical harmonics is proposed to avoid solving ill-conditioned equations. And the element stiffness matrix of each CG is derived by a new kind of multi-field boundary variational principle. By several numerical examples, we demonstrate that the developed CG is an efficient and accurate numerical method for computing the equivalent material properties and the micro-scale stress distribution of fiber composites. Moreover, the computational efficiency of the CG is enhanced with the use of the parallel computation. In this way, a RVE with 2500 fibers can be simulated within 10 hours on an 8-core laptop.

New Straightforward Benchmark Solutions for Bending and Free Vibration Solutions of Clamped Anisotropic Rectangular Thin Plates

Dongqi An[1*]

[1] State Key Laboratory of Structural Analysis for Industrial Equipment, Department of Engineering Mechanics, and International Research Center for Computational Mechanics, Dalian University of Technology, Dalian 116024, China, adq96@mail.dlut.edu.cn

Key Words: *Anisotropic Plate, Bending, Vibration, Benchmark Solution, Finite Integral Transform*

This study presents new straightforward benchmark solutions for bending and free vibration of clamped anisotropic rectangular thin plates by a double finite integral transform method [1]. Being different from the previous studies that took pure trigonometric functions as the integral kernels [2–6], the exponential functions are adopted, and the unknowns to be determined are constituted after the integral transform, which overcomes the difficulty in solving the governing higher-order partial differential equations with odd derivatives with respect to both the in-plane coordinate variables, thus goes beyond the limit of conventional finite integral transforms that are only applicable to isotropic or orthotropic plates. The present study provides an easy-to-implement approach for similar complex problems, extending the scope of finite integral transforms with applications to plate problems. The validity of the method and accuracy of the new solutions that can serve as benchmarks are well confirmed by satisfactory comparison with the numerical solutions.

Symplectic Superposition Method for Analytic Solutions to Plate and Shell Problems

Rui Li*

State Key Laboratory of Structural Analysis for Industrial Equipment, Department of Engineering Mechanics, and International Research Center for Computational Mechanics, Dalian University of Technology, Dalian 116024, China, ruili@dlut.edu.cn

Key Words: *Symplectic superposition method, Plate, Shell, Analytic solution*

Plates and shells are widely used in various fields such as civil engineering, mechanical engineering, ocean engineering, aeronautics and astronautics. Solution for bending, vibration and buckling of plates and shells has been one of the important research topics in engineering. However, it is hard to obtain the analytic solutions to most of these problems till now due to the mathematical challenge. Using an up-to-date symplectic superposition method, we obtain the analytic solutions of plates and shells with various boundary conditions, by which the ability of the method to yield solutions via step-by-step derivations from the governing equations without predetermining any forms of solutions is demonstrated. The essential difference between the current method and the other ones is that the solution procedure is conducted in the symplectic space rather than in the classical Euclidean space. This extends the scope of application of eigen expansion, and paves the way for more analytic solutions of similar problems. The application of the method to novel stretchable electronics is also reported, which provides a theoretical basis for fracture-safe design of stretchable electronics.

An industry-relevant implicit LES via spectral/hp element methods

Gianmarco Mengaldo, David Moxey, Michael Turner, Rodrigo C Moura, Ayad Jassim, Mark Taylor, Joaquim Peiro, Spencer J Sherwin

We present the successful deployment of high-fidelity Large-Eddy Simulation (LES) technologies based on spectral/hp element methods to a real automotive car, namely the Elemental Rp1 model [1]. The simulation presents the common challenges of an industry-relevant simulation, namely high Reynolds number and complex geometry. To the best of the authors' knowledge, this simulation represents the first fifth-order accurate transient LES of an entire real car geometry. Moreover, this constitutes a key milestone towards considerably expanding the computational design envelope currently allowed in industry, where steady-state modelling remains the standard. In this talk, we highlight the key developments that were required to achieve the simulation, from mesh generation to improvements in solver and numerical technology.

Entropy Stable Strong Imposition of the No-slip Condition for the Compressible Navier-Stokes Equations

Anita Gjesteland[1*] **and Magnus Svärd**[2]

[1] University of Bergen, P.O. Box 7803, 5020 Bergen, Norway, anita.gjesteland@uib.no
[2] University of Bergen, P.O. Box 7803, 5020 Bergen, Norway, magnus.svard@uib.no

Key Words: compressible Navier-Stokes, no-slip, entropy stability, injection method

We consider the compressible Navier-Stokes equations which models the motion of a compressible, viscous and heat conducting fluid, in contact with walls. Thus, the equations are augmented with the no-slip condition, leading to the formation of boundary layers, which in turn may become turbulent.

Here, we propose a numerical scheme approximating the compressible Navier-Stokes equations subject to no-slip adiabatic wall boundary conditions. The spatial discretisation is based on the standard second-order finite-difference Summation-by-Parts (SBP) operator. The boundary conditions are imposed using both a weak and strong implementation technique. That is, the Neumann condition for the temperature is imposed weakly using a Simultaneous Approximation Term (SAT), while the no-slip condition for the velocities is imposed strongly via injection. In particular, we focus here on the boundary treatment for the no-slip condition. This weak-strong combination was shown to be stable for the symmetrised, constant-coefficient Navier-Stokes equations in [1]. By using the notion of entropy, we show that it additionally leads to non-linear stability for our proposed scheme.

Numerical simulations are provided to demonstrate the robustness of the boundary treatment for the no-slip condition. A simulation using a fourth-order SBP operator, which yields a linearly stable scheme, is also included.

[4] Rensselaer Polytechnic Institute, Troy, NY, 12180, mishrs2@rpi.edu

Key Words: Entropy-stable discretization, active-flow control, passivity

We are interested in active-flow control of fluid dynamical systems. Our preliminary goal is to formulate the fluid-control system in such a way that the coupled system remains stable. We leverage passivity theory, which guarantees that the flow-control system is stable with feedback if both the flow and control dynamical systems are independently passive [4]. We briefly show how entropy-stability theory ensures passivity of the continuous fluid system. We then turn our attention to the discretized system and, in particular, stable imposition of boundary conditions at the interface between the actuator and the fluid. To maintain entropy stability, the discretization uses high-order summation-by-parts operators [5] and two-point, entropy-conservative flux functions [6]. Such entropy-stable discretizations are now well established; see, for instance, [3, 2, 1]. The fluid-control framework is demonstrated using an airfoil at a high angle of attack.

[3] University of Waterloo Department of Applied Mathematics, 200 University Ave W, Waterloo, ON, ssivaloganathan@uwaterloo.ca

Key Words: Mulitiphase, Entropy Stability, Summation by Parts, WENO, Finite Difference

The multiphase description of flow phenomena represents an attractive option for modeling complex flows because fluid flow over the entire region is modelled using one set of governing equations as opposed to separate sets of equations for each phase [3]. For compressible flow equations in conservative form, in the last decade there have been important advances in the development of provably nonlinearly-stable schemes by combining summation-by-parts (SBP) operators [4] and symmetric two-point flux functions [1]. In this work we look to WENO schemes to automatically provide appropriate upwinding near discontinuities. WENO schemes are capable of attaining arbitrarily high orders of accuracy while sustaining stable and sharp discontinuity transitions [2]. Our goal is to develop provably-stable high-order schemes that render sharp shock interfaces for multiphase flows in non-conservative form. For this purpose, we combine the entropy-stable SBP-WENO framework of Fisher [1] with the entropy-stable framework of Renac [5] to develop entropy-stable SBP-WENO schemes for multiphase flows in non-conservative form. In this presentation, we detail the resulting schemes and present numerical tests on canonical smooth and shocked flows.

High-Order Implicit Shock Tracking for Time-Dependent Flows

Charles Naudet[1]* **and Matthew J. Zahr**[2]

[1] University of Notre Dame, Notre Dame, IN 46556, cnaudet@nd.edu
[2] University of Notre Dame, Notre Dame, IN 46556, mzahr@nd.edu

Key Words: Shock Fitting, Discontinuous Galerkin, PDE-Constrained Optimization

Reference link: https://www.wccm2022.org/submission.html

Shock tracking, as an alternative method to shock capturing, aims to generate a mesh such that element faces align with shock surfaces and other non-smooth features to perfectly represent them with the inter-element jumps in the solution basis, e.g., in the context of a finite volume or discontinuous Galerkin (DG) discretization. These methods lead to high-order approximations of high-speed flows and do not require nonlinear stabilization or extensive refinement in non-smooth regions because, once the non-smooth features are tracked by the mesh, the high-order solution basis approximates the remaining smooth features. In previous work [1, 2], we introduced the High-Order Implicit Shock Tracking (HOIST) method that recasts the geometrically complex problem of generating a mesh that conforms to all discontinuity surfaces as a PDE-constrained optimization problem. The optimization problem seeks to determine the flow solution and nodal coordinates of the mesh that simultaneously minimize an error-based indicator function and satisfy the discrete flow equations. A DG discretization of the governing equations is used as the PDE constraint to equip the discretization with desirable properties: conservation, stability, and high-order accuracy. By using high-order elements, curved meshes are obtained that track curved shock surfaces to high-order accuracy. The optimization problem is solved using a sequential quadratic programming method that simultaneously converges the mesh and DG solution, which is critical to avoid nonlinear stability issues that would come from computing a DG solution on an unconverged (non-aligned) mesh.

In this work, the HOIST method is further extended to simulate time-dependent, inviscid flows. We use a space-time formulation of the governing equations and perform shock tracking over a space-time slab for two reasons: 1) it reduces to a steady shock tracking problem over the $(d+1)$-dimensional space-time domain, which allows most of the HOIST framework to be recycled and 2) complex shock-shock interactions simply manifest as triple points. The overall approach is equipped with adaptive time slabs, a procedure to extrude d-dimensional simplex elements over a time slab and split the resulting $(d+1)$-dimensional prism into simplices, and resolution-based h-refinement. The method is demonstrated on a series of increasingly complex unsteady inviscid flows in one and two dimensions.

Nonlinearly Stable Split Forms for Weight-Adjusted Flux Reconstruction High-Order Methods in Curvilinear Coordinates

Alexander Cicchino[1], **Siva Nadarajah**[2]

[1] Ph.D. Student, McGill University, Montreal, QC, H3A 0C3, Canada,
alexander.cicchino@mail.mcgill.ca
[2] Associate Professor, McGill University, Montreal, QC, H3A 0C3, Canada,
siva.nadarajah@mcgill.ca

Key Words: Discontinuous Galerkin Methods, Flux Reconstruction, Entropy Stability

The flux reconstruction (FR) method has gained popularity in the research community as it recovers promising high-order methods through modally filtered correction fields, such as the discontinuous Galerkin (DG) method, on unstructured grids over complex geometries. Under a class of energy stable flux reconstruction (ESFR) schemes, FR allows for larger time-steps than DG while ensuring stability for linear advection on affine elements [1]. Alternatively, for nonlinear problems, split forms and two-point entropy conserving fluxes have emerged as the popular approach for unsteady problems on coarse unstructured grids – albeit only having proved stability for the strong form DG scheme and the g_2-lumped Lobatto ESFR scheme for the Euler equations [2, 3]. In this work, we show that incorporating split forms with ESFR schemes, alike Ranocha *et. al.* [2] and Abe *et. al.* [3], generally lead to unstable discretizations. This work is an extension of Cicchino *et al*. [4], where they derived general nonlinearly stable FR schemes in split form for the one-dimensional Burgers' equation and proved stability. This new approach simplifies to ESFR schemes for linear problems, but for nonlinear problems, it ensures nonlinear stability and the correct orders of convergence. This work takes advantage of low-storage weight-adjusted approximations for curvilinear coordinates. The stability of all nonlinearly stable FR schemes are verified with three-dimensional Euler flow in curvilinear coordinates.

Key Words: Entropy stable schemes, Robust Runge–Kutta schemes, Cloud Computing

Discontinuous Galerkin (DG) methods are usually infamous for being computationally complex and having robustness issues. However, during the last few years, thanks to the development of entropy stable spatial schemes of any order with the summation-by-parts property, robust and efficient entropy stable nodal versions of the DG schemes have been proposed. However, stability constraints usually limit severely the time step size that can be used to integrate in time the system of ordinary differential equations arising from the spatial discretization with high-order algorithms. These constraints are drastically exacerbated by the i) the mesh element aspect-ratio used to resolve "economically" turbulent flows, and ii) the poor quality of the mesh element for complex geometries.

We present a detailed analysis of the performance of relaxation Runge–Kutta schemes and Runge–Kutta time integration schemes optimized for the spectrum of the semidiscretization of the Euler equations in this paper. The CFL condition or an embedded Runge–Kutta pair are used to combine both time-stepping families with time step adaptivity. When compared to standard and widely used methods for complex industrially relevant turbulent test cases, the new optimized schemes demonstrated an overall speedup of more than 35

Finally, we present a detailed analysis of the performance of the in-house KAUST SSDC framework on the Amazon web service (AWS) cloud computing. The industry is very interested in using this on-demand technology for performing engineering simulations. Thus, testing and assessing the performance of a prototype of next-generation compressible CFD solvers, such as SSDC, is relevant. The results indicate that SSDC scales quite well on the most recent and exotic computing architectures available on the AWS cloud computing platform.

Space-time hybridizable discontinuous Galerkin methods for incompressible Navier-Stokes

Sander Rhebergen, Tamas Horvath, and Keegan Kirk

In this talk I will discuss a class of space-time hybridizable discontinuous Galerkin method that we introduced and analyzed in [1,2,3,4,5] specifically for the incompressible Navier-Stokes equations. The space-time framework is motivated by our interest in solving the Navier-Stokes equations on time dependent domains, while the hybridizable framework was used to design a space-time discontinuous Galerkin method that is exactly mass conserving (i.e., the discrete velocity field is exactly divergence free on the elements and globally H(div)-conforming) even on moving domains. The exact mass conservation of our discretization has several consequences, such as: local momentum conservation and energy-stability; and the velocity error estimates are independent of the pressure and inverse powers of the viscosity.

A Data Driven Approach to Improved Exchange-Correlation Functionals in DFT

The need for improved exchange-correlation (XC) functionals in density functional theory (DFT) that can provide quantum accuracy can hardly be overemphasized. To that end, we adopt a data-driven approach to constructing XC functionals by using accurate ground-state densities ($\rho(\mathbf{r})$) from many-body calculations. The key idea is to use the $\rho(\mathbf{r})$ and its corresponding exchange-correlation potential ($v_{\text{xc}}(\mathbf{r})$), from various molecules, as training data to model the XC functional. We present an accurate and robust approach to solve the inverse DFT problem of obtaining the exact $v_{\text{xc}}(\mathbf{r})$ from a given $\rho(\mathbf{r})$, which had, heretofore, remained an open challenge owing to various numerical instabilities in previous attempts. The exact XC potential for seven molecule—dihydrogen at four different bond-lengths, lithium hydride, water, and ortho-benzyne—are computed from full configuration interaction reference densities. These are compared to model XC potentials from non-local (B3LYP, HSE06, SCAN0, and M08-HX) and semilocal/local (SCAN, PBE, and PW92) XC functionals. While for most systems the relative errors in the ground-state densities are $\mathcal{O}(10^{-3} - 10^{-2})$, the model XC potentials have much higher errors of $\mathcal{O}(10^{-1} - 10^{0})$. This finding establishes the utility of the XC potentials—which exhibit greater sensitivity in comparison to the densities—in the design and development of future XC functionals. Subsequently, we use the exact XC potentials to develop neural network (NN) based local and semi-local XC functionals. We provide a comparative study of the NN-based XC functionals against several widely used XC functionals, in terms of their prediction of various thermochemical properties (e.g., atomization energies, reaction barriers, etc).

Development of structure optimization method by quantum annealing

Key Words: *structure optimization, quantum annealing, quadratic unconstrained binary optimization*

The topology optimization problem is a problem of finding a combination of components that can achieve high performance at low cost. When solving combinatorial optimization problems such as topology optimization problems, local solutions may occur during computation, and the computational cost becomes high if the computation is repeated to obtain the overall optimal solution. Therefore, it is becoming more and more important to develop a computational method to avoid falling into local solutions.

Recently, quantum annealing, a method specialized for solving combinatorial optimization problems, has been attracting attention. Quantum annealing uses the tunneling effect caused by quantum fluctuations to find a solution. Initially, the quantum fluctuation is increased so that the energy exceeds the maximum value due to the tunneling effect, and then the quantum fluctuation is gradually decreased to find the point where the potential is minimized. For example, the previous researches on combinatorial optimization problems using quantum annealing treated applications to traffic volume management and nurse scheduling problems.

Focusing on the minimization of the energy, it is expected that quantum annealing can be used to efficiently obtain globall optimal solutions for topology optimization problems as well. However, no such method currently exists. In this study, we aim to develop a new method for structural topology optimization of solids using quantum annealing. As an example, we take the optimization problem of a truss structure. Specifically, in order to use quantum annealing, the energy of the truss structure is replaced by a Hamiltonian in quadratic unconstrained binary optimization (QUBO) form. The real displacements and cross-sectional areas of the elements need to be expressed in binary variables. Optimization calculations by annealing machine are carried out using the Hamiltonian constructed in this way, and its performance is evaluated.

Kohn-Sham density functional theory (DFT) calculations have been instrumental in providing many crucial insights into materials behavior. However, the stringent accuracy requirements in DFT needed to compute meaningful material properties, in conjunction with the asymptotic cubic-scaling computational complexity with number of electrons, demand huge computational resources. Thus, these calculations are routinely limited to material systems with at most few thousands of electrons. In the first part of this talk, I will present a massively parallel real-space DFT framework (DFT-FE) [1, 2], which is based on a local real-space variational formulation of the Kohn-Sham DFT energy functional discretized with higher-order adaptive spectral finite-element and handles pseudopotential and all-electron calculations in the same framework. We will present the efficient and scalable numerical algorithms in conjunction with mixed precision strategies for the solution of Kohn-Sham equations, that has enabled computationally efficient, fast, and accurate DFT calculations on generic material systems reaching ~100,000 electrons and demonstrate an order of magnitude performance advantage over widely used plane-wave codes both in CPU-times and wall-times. In the second part of this talk, I will present the application of DFT-FE to study the core energy difference between the <c+a> screw dislocations on pyramidal I and II planes in pure magnesium (EpyrI-II). EpyrI-II forms a crucial and sensitive input to a quantitative model predicting the ductility of magnesium alloys. However, accurate estimation of EpyrI-II using explicit DFT calculations has so far been out of reach using plane-wave codes as large system sizes containing thousands of atoms are required to accurately resolve the relevant physics in the dislocation core. Using DFT-FE, we conduct a systematic cell size study of EPyrI-II till ~3,500 atoms (35,000 electrons) per periodic layer along the dislocation line. We find that a cell-size of ~2,700 atoms is required to obtain EPyrI-II under a cell-size error of 5 meV/nm. We also find strong influence of external macroscopic uniaxial deformations on EPyrI-II. Obtaining EPyrI-II accurately has significant implications for designing highly ductile magnesium alloys.

Key Words: *Quantum Computing, Quantum Annealing, Finite Element Method, Iterative, Cosine Measures*

Quantum computing is a rapidly developing area of research with potential applications extending over scientific and engineering computation. Current work in quantum computing for partial differential equations is sparse and limited in scope with presently available Noisy Intermediate Scale Quantum (NISQ) hardware. Quantum annealers are NISQ devices designed to minimize the Ising Hamiltonian. Current demonstrated applications of quantum annealers suffer from various forms of inefficiencies. Here, we explore the application of quantum annealing to finite element problems and develop a unified general framework to iteratively solve linear partial differential equations with examples problems solved on D-Wave quantum annealer.

A general methodology to map finite element problems to the Ising Hamiltonian is developed by a novel generalization of the Ising Hamiltonian and posing the finite element problem as a minimization problem. Several novel mapping options are developed, and their strengths and weaknesses explored. Procedures that efficiently map one unknown to one qubit with sparse graphs are presented. A time-efficient scheme is presented to calculate the mapping by parallelizing over the elements.

Novel iterative procedures are developed to iteratively carry out the finite element minimization problem using quantum annealers, dubbed as the single step "2^N Search", "3^N Search", and the two-step "Hyperoctant Search". A general framework to develop higher order iterative procedures is presented in the context of Nested Iterations. Since these iterative procedures differ significantly from classical procedures by sampling from exponentially large sets, their mathematical properties are explored with proofs of their cosine measures to outline their effectiveness compared to classical methods. An exponential increase in cosine measures is demonstrated, highlighting the potential for quantum annealing to iteratively solve minimization problems with classically intractable numbers of unknowns.

The iterative procedures are carried out for example problems using classical simulated annealing and quantum annealing for a head-to-head comparison of classical and quantum techniques. The annealing time for simulated annealing grows as O(N), whereas it is O(1) for quantum annealing [1] (King et al., 2015), though they have similar convergence rates. The Hyperoctant Search procedure demonstrated the best convergence properties with some instances of super-convergence with only 10^1 anneals per iteration compared to 10^3-10^6 anneals typically needed for other methods.

Quantum modeling of materials, in particular density functional theory (DFT) calculations have provided many crucial insights into materials behavior over the past few decades and occupy considerable fraction of world's computational resources today. However, asymptotic cubic-scaling computational complexity with number of atoms in conjunction with stringent precision requirements for accurate material property prediction demand huge computational resources for these calculations. Thus, these calculations are routinely limited to material systems with few hundreds of atoms, employing plane-wave discretizations despite its limitations. The development of DFT-FE [1,2], a massively parallel open-source DFT code addresses these challenges by making use of higher-order spectral finite-elements alongside with novel HPC centric numerical strategies focusing on significantly reducing the data movement costs and increasing arithmetic intensity on evolving hybrid CPU-GPU architectures. These methodologies enabled systematically convergent, fast and scalable norm-conserving pseudopotential DFT calculations using real-space finite-element (FE) based methods on material systems involving tens of thousands of electrons for both metallic and insulating systems, on massively parallel computing architectures, while allowing for arbitrary boundary conditions and complex geometries. However these recent advances are limited to norm-conserving pseudopotentials (ONCV, TM) and are not applicable to DFT calculations using projector augmented wave (PAW) method in a straight forward way. The widely used PAW frozen-core method for DFT is shown to be highly transferable and deals with much smoother electronic fields thereby resulting in huge reduction in degrees of freedom in comparison to their norm-conserving pseudopotential counterparts. To this end, we will present a real-space DFT formalism within the PAW framework amenable to higher-order spectral finite-element discretization. Furthermore, accuracy and performance of the proposed approach on hybrid CPU-GPU architectures will be demonstrated on a variety of benchmark examples including large-scale materials systems involving few thousands of electrons

Although density functional theory (DFT) is a powerful tool to clarify the atomic and electronic structures of materials, DFT studies of complex nanostructures are usually very difficult because conventional DFT methods cannot treat large systems containing many thousands of atoms. To overcome this problem, we have developed a large-scale, linear-scaling DFT code CONQUEST, which has recently been released under an open-source MIT license. The code uses local orbital and linear-scaling methods, and has high efficiency on massively parallel computers.

In this presentation, we explain the theory behind the code and survey the recent developments and applications of CONQUEST. It will be demonstrated that CONQUEST can calculate the atomic positions of the realistic models of nano-scale materials observed in experiments and can clarify the unique electronic properties of these complex materials. A new method based on the machine learning techniques to analyze the local atomic structures observed in large-scale DFT-MD simulations will be also discussed.

Key Words: *Boundary Conditions, Symmetry, Density-Functional Theory*

Computational materials design is an active area of research which aims at predicting physical and chemical properties of various materials from first-principles electronic structure calculations. To keep the computational costs manageable, the Schrödinger equations are often approximated by Kohn-Sham equations within the framework of density-functional theory [1]. These Kohn-Sham equations are solved numerically either by a basis set expansion or real-space discretization under given boundary conditions. In the case of a plane-wave basis set, it is common practice to apply periodic boundary conditions in all directions [1], while isolated boundary conditions are more common for the atomic basis set. However, there are many other options besides these standard boundary conditions. In this talk, we will explore several non-standard boundary conditions which exploit the characteristics of each system, such as surfaces, interfaces, and cyclic/helical structures, to minimize the computational costs of electronic structure calculations. Most of these boundary conditions are easily implemented by minor modifications of existing electronic structure codes. Numerical examples on a few model systems are also presented for the validation of these boundary conditions.

Key Words: *Quantum Annealing, Ising Machine, Microtructure, Diblock Polymer, Computer Simulation Acceleration*

A diblock polymer is a polymer in which two different homopolymers are connected to form a single polymer. In diblock polymers, the phase separation of the two different homopolymers forms microstructures. The microstructures change depending on the experimental conditions, such as lamellar, cubic, hexagonal, and gyroid structures. Since the microstructures have a significant effect on the mechanical properties of the polymer, it is important to predict which type of microstructure will appear under the given experimental conditions. To date, several methods have been developed to predict the microstructures[1], however, conventional methods sometimes take a long time to obtain the prediction.

In recent years, Ising machine have attracted much attention to solve the combinatorial optimization problems. Ising machine solves quadratic unconstrained binary optimization (QUBO), which is one of the formalized combinatorial problems; in QUBO, the variables is a set of binary states, and the objective function, called Hamiltonian in the context of the Ising machine, consists of up to a quadratic polynomial of the binary states. Since the Ising machine solves the states where the value of the Hamiltonian is minimized, the problem to be solved should be mapped to a QUBO-style problem, in other words, the coefficients of the quadratic polynomial of the Hamiltonian are configured.

In this work, we proposed a new method to perform two-dimensional simulations of the phase-separation structure of a diblock polymer using the Ising machine. We mapped the problem of performing the simulation to the Hamiltonian as a sum of four quadratic terms that represent different physical behavior of diblock polymers: the sum amount conservation term, the Flory-Huggins interaction energy term, the gradient energy term, and the Ohta-Kawasaki long-distance interaction energy term. By adjusting each term, different experimental conditions can be represented.

Using the proposed method, we observed several types of phase separation such as dotted and striped patterns, which correlate to lamellar and cubic or hexagonal structures. Together with other results, the proposed method was shown to be successful to predict the microstructures. Furthermore, each simulation using the Ising machine takes less than 1s, which is hundreds of times faster than conventional methods.

[2] Department of Computer Science, College of Staten Island, City University of New York, feng.gu@csi.cuny.edu

Key Words: *Deep Learning; Plane wave; Deep Neural Network; Loss; High frequency; Helmholtz equation.*

We develop a mesh-less, ray-based deep neural network method to solve the Helmholtz equation with high frequency. This method does not use an adaptive mesh refinement method, nor does it design a numerical scheme using some specially designed basis function to calculate the numerical solution, but it has the advantages of easy implementation and no mesh. We have carried out various numerical examples to prove the accuracy and efficiency of the proposed numerical method.

[3] Advanced Computing, Mathematics and Data Division, Pacific Northwest National Laboratory, Richland, WA 99354, USA

Key Words: Spectral methods, deep operator networks

A major obstacle in the deployment of spectral methods is the choice of appropriate bases for trial and test spaces. If chosen suitably, these basis functions lead invariably to well-posed discretized problems and well-conditioned linear systems, while the resulting approximate solutions are provably high-order accurate [1]. However, barring domain decomposition approaches, devising such functions for arbitrary geometries from scratch is a hugely challenging task [2]. Fortunately, the recently developed DeepONet approach is a highly promising device for generating machine-learned basis functions [3]. In this talk, we propose a Galerkin approach for time-dependent PDEs that is powered by basis functions gleaned from the DeepONet architecture. We shall outline our procedure for obtaining these basis functions and detail their many favourable properties. Next, we shall present the results of numerical tests for various problems, including advection, advection-diffusion, viscous Burgers' equations, as well as some highly intriguing preliminary results from the low-viscosity regime. Finally, we will identify potential pitfalls in the course of generalization to higher dimensions and suggest possible remedies.

Key Words: Deep learning, Neural Networks, Ritz method, Least-Squares method, Quadrature rules.

Neural Networks have been widely used to solve Partial Differential Equations (PDEs). In there, definite integrals are required to be solved. Deep Neural Network (DNN) techniques present several advantages and limitations with respect to traditional PDE solvers based on Finite Elements, Finite Differences, or Isogeometric Analysis. Among the advantages of DNNs, we encounter the nonnecessity of generating a grid. In general, DNNs use a dataset in which each datum is independent from others. In contrast, in the linear system that produces the FEM method there exists a connectivity between the nodes of the mesh. Furthermore, DNNs provide the possibility of solving certain problems that cannot be solved via traditional methods, like high-dimensional PDEs, fractional PDEs, and multiple nonlinear PDEs. However, DNNs also present limitations when solving PDEs. For example, the convergence of the method is often assumed (see, e.g., [1]) since it cannot be rigorously guaranteed due to the non-convexity of the loss function. Another limitation is the lack of proper quadrature rules for integrating functions coming from DNNs [2].

This works analyzes the problems associated with quadrature rules in DNN methods when solving PDEs. In particular, we illustrate with a simple one-dimensional Poisson problem the disastrous consequences that may appear as a result of an inadequate selection of a quadrature rule. We propose an alternative to overcome the quadrature problems: adaptive integration. We are able to control the quadrature errors by adding new quadrature points to the training dataset. Implementation of this strategy requires the use of meshes, which posses a limitation on high-dimensional integrals. As an alternative to generating a mesh, one can add points using clustering algorithms to the training set, but this entails difficulties when designing an adaptive algorithm.

Key Words: Bayesian Optimization, Constrained Optimization, Multi-Scale Simulation

The muscle simulation framework OpenDiHu [3] consists of many numerical components on multiple scales [1]. Their combination and interaction directly influences the simulation accuracy and computational time. However, finding an optimal combination of these components that balances accuracy and computational resources can be a difficult and time consuming process.

Model-based Bayesian optimization is a useful tool to tackle such problems [2]. We present a Bayesian approach to optimize the temporal discretizations on multiple scales of the simulation for a minimal error under run time constraints. In each step of the Bayesian optimization, a model for the simulation error and the run time is improved. This model uses already known samples of the simulation behavior and incorporates prior knowledge of the simulation such as a-priori convergence orders and run time scaling of the components. To update the model with a new data sample, the simulation is executed with new discretization parameters. These are selected by an acquisition function based on the model prediction and uncertainty. A new data sample should not only help to approach the optimum of the objective function, but also improve the models that are used for the optimization. As the simulation error and the run time are unknown for unevaluated samples, the acquisition function also has to select samples that improve the model quality, i.e., the models for both the discretization error and the run time. We discuss our optimization approach, modeling aspects and choices for the acquisition function.

Key Words: Neural Networks, r-adaptivity, Deep Ritz Method, Partial Differential Equations

In the last five years, the research on the use of Deep Neural Networks (DNNs) to solve partial differential equations (PDEs) has intensified [1]. Some traditional methods used in this context are: the Deep Ritz method [2], the Deep Least-Squares method [3], and the Deep Galerkin method [4]. These methods are often mesh free due to the use of a Monte Carlo type integration. However, in low dimensions (three or below), Monte Carlo integration may lead to slow convergence rates and other integration methods may be preferred. In particular, mesh-adaptive methods may deliver faster convergence while ensuring proper integration in context of DNNs.

Herein, we propose an r-adaptive DNN method. For illustration, we consider a Deep Ritz method with a piecewise-polynomial solution over a tensor product mesh. During the training of the DNN, we simultaneously optimize the node positions (r-adaptivity) and the solution. This method does not require a posteriori error estimation. It also allows to fix some mesh points, which may be convenient for establishing material boundaries. Our method allows for topological changes and does not need to maintain the connectivity between elements as in the Finite Element Method. Numerical results show the behaviour of the method in one- and two-dimensional domains for solutions that are smooth, singular, or have a strong gradient.

Key Words: *Deep Neural Networks, Isogeometric Analysis, Physics Informed Neural Networks*

We compare the application of Deep Neural Network (DNN) for approximation of the solution of Partial Differential Equations (PDE) using three different methods. The first method is based on our proposition of using the linear combination of higher-order and continuity B-spline base functions and employing the DNN to approximate B-splines' coefficients. The second method is based on using the DNN for direct approximation of the solution of PDE obtained from isogeometric analysis (IGA) (finite element method employing B-spline base functions).
Solving differential equations with neural networks has been proposed by Maziar Raissi et al. in 2017 [1] by introducing Physics-informed Neural Networks (PINN), which naturally encode underlying physical laws as prior information. Thus, we also compare the first method to the PINN approximation. Approximation of coefficients using a function as an input leverages the well-known capability of neural networks being universal function approximators, as shown by Hornik et al. in [2]. In essence, in the PINN approach, the network approximates the value of the given field at a given point. Alternatively, the DNN can approximate the IGA solution pointwise. We present an alternative approach, where the physical quantity is approximated as a linear combination of smooth B-spline basis functions, and the neural network approximates the coefficients of B-splines. This research compares results from the DNN approximating the coefficients of the linear combination of B-spline basis functions, with the DNNs approximating the solution directly. We show that our approach is cheaper and more accurate when approximating smooth physical fields [3].

A Dynamically Aggregated Decomposition Strategy for High-dimensional Global Optimization

Qineng Wang [1*], Liming Song [1] and Zhendong Guo [1]

[1] Institute of Turbomachinery, Xi'an Jiaotong University, Xi'an, 710049, China

Key Words: *Efficient global optimization，Large-scale optimization，Surrogate model*

Abstract The efficient global optimization (EGO) algorithms, which are well-known to be sample-efficient, have been extensively used for solving expensive black-box problems in various scenarios. However, due to the "curse of dimensionality", most EGO algorithms can only work well for optimization over domains of less than 15 dimensions [1], it is quite challenging to scale EGO algorithms for solving problems of even higher dimensions (e.g., d > 30). Divide and conquer is a common idea to address the above issue [2], which decomposes the original problem into several low-dimension subspaces and handles each sub-problem independently with EGO. Considering the interactions of variables, the decomposition strategy is of vital importance. However, the subspaces are determined before the optimization process in most of the previous studies, which can be quite expensive to achieve it.

To address this problem of decomposition in a more efficient way, a new optimization algorithm with novel decomposition strategy is proposed, called dynamically aggregated EGO algorithm (abbreviated as DA-EGO). The characteristic of this method is that accurate decomposition is achieved step by step in the optimization process rather than in one shot. At the beginning, the high-dimensional problem is completely divided into one-dimensional sub-problems. And then, the strongly correlated variables are aggregated into groups, while the weakly correlated variables are pruned directly. More specifically, the global and local surrogates bear the functions of nomination and confirmation respectively. The global model is established with Polynomial chaos expansion（PCE) using all evaluated samples, whose coefficient directly represents the interactions between variables. When a pair of variables is nominated, they will jointly establish a local Kriging model and confirm their relevance in the next round of optimization. More and more correlations are determined as the optimization progresses. Under this operation, the optimization gradually changed from a general independent optimization of all variables to a focused optimization of several clusters of aggregated groups.

We test our proposed DA-EGO algorithm on 12 benchmark functions. The results of DA-EGO are shown significantly better than other compared the state-of-the-art algorithms. And hence, the effectiveness of our proposed algorithm is well demonstrated.

Key Words: *Isogeometric analysis, Stiffener element, Degenerated element, Stiffened thin-walled structure, Buckling analysis*

Stiffened thin-walled structure is one of the most improtant structural forms in lightweight design. Highly accurate and efficient analysis methods are the basis of structural design. For the standard faceted finite element theory, typical finite element meshes introduces geometric imperfections. Only refinement of the mesh can reduce geometric errors. Therefore, accuracy and efficiency are contradictory in classical finite element analysis (FEA). This will require a change from classical FEA to an analysis procedure based on CAD representations. Hughes et al.[1] first introduced the isogeometric analysis (IGA) based on NURBS basis function. Considered as a feasible alternative to polynomial based finite element analysis, IGA effectively solves the problems of high cost, time-consuming and geometry error in the construction of standard finite element analysis mesh. Therefore, in this paper, a general, simple and efficient isogeometric analysis method for stiffener thin-walled structures is proposed. Both shell element[2] and stiffener element are based on degenerated 3D elements theory. The skin of stiffened thin-walled sturcture is a shell with arbitrary geometry. Therefore, NURBS surface is used to build an accurate geometric model of the skin. Stiffeners are modeled with NURBS curves. Degeneration theory started from continuous mechanics, avoiding complex theoretical assumptions and derivation of formulas. At the same time, high-order NURBS basis functions can avoid shear self-lockling of the shell element and stiffener element, so such theories are applicable to arbitrary thickness and section size. In this paper, the method proposed by Kapnia et al.[3] is used to couple the degrees of freedom of the skin and stiffener. NURBS surface can provide the normal vector at any point. These geometric algorithms greatly reduce geometric errors. Numerical results indicate the present method has good accuracy, efficiency and robustness.

Key Words: Buckling, Eigenvalue Analysis, Internal/External Pressure, Shell Element

Cylindrical shell is employed in a wide range of fields including pressure vessels, storage tanks, submarines, and aircraft fuselages. In these shell structures, buckling may occur due to various loading, such as compression, bending, twisting, shearing, and internal and external pressures. When the internal and external pressures are applied to both the top and bottom surfaces of these shell structures, the behavior is different from the case where the pressure acts on either the top or bottom surface[1].

Buckling phenomena of structures under pressure load are studied with the finite element analysis. Toscano et al.[2] proposed the finite element model discretized with shell elements for analyzing the buckling and buckling propagation of stiffened pipes, and verified the developed model by comparing the numerical results obtained using it with the experimental data. In this approach, the pressure load is evaluated at the midsurface of shell structure. On the other hand, in order to evaluate the pressure load appropriately, Zhu et al.[3] presented the numerical calculation considering the three dimensional finite deformation for the thick-walled cylindrical shell in the buckling analysis. However, it needs huge computational costs to represent the complicated behaviors using continuum elements.

In this work, we propose a numerical procedure using the special shell element[4], in which the external force is directly given to the additional nodes representing the thickness–stretch, to evaluate the buckling behavior of the cylindrical structure subjected to pressure load, in the framework of structural elements. Since the discontinuities of the thickness between elements are allowed, the number of unknowns in the resulting linear system of equations is coincide with that of conventional shell elements by employing static condensation in constructing the element stiffness matrix. In the case of applying a perturbative load under a certain stress state, bifurcation points are searched by solving a standard eigenvalue problem.

Global buckling design optimization of spatially graded grid-stiffened plates based on asymptotic homogenization

Liang Xu[1*]

[1] College of Aerospace Engineering, Nanjing University of Aeronautics and Astronautics, Nanjing, 210016, xuliang2018@nuaa.edu.cn

Key Words: *Grid-stiffened plates, spatial gradation, buckling optimization, asymptotic homogenization*

Grid-stiffened plates are widely employed in engineering applications due to light weight, high specific stiffness/strength and are quite competitive in terms of structural stability. Conventional grid-stiffened plates are designed to be uniformly distributed microstructures, and structural performance is significantly confined as spatial gradation of stiffener layout is prohibited in the design space.

In this work, a two-step multiscale optimization for spatially varying stiffener layout is conducted to enhance structural buckling resistance based on asymptotic homogenization. In the first step, the stiffener orientation and material layout are first optimized in the macro scale. In the second step, mapping functions are introduced to map the original uniform microstructure into a spatially varying stiffened plate, and geometric features of stiffener layout, such as stiffener spacing, stiffener length parameters, are established with mapping function parameters. Then a mixed optimization formulation, which integrates mapping functions into the eigenvalue buckling load factor, is proposed for maximum stability performance, and concurrent optimization for mapping functions and stiffener layout is conducted. The advantage of this formulation is two-fold. First, the design space is relaxed so that structural performance can be improved to a large extend. Second, a good agreement, in both shape and performance, between the projected single-scale stiffened plate and the homogenization results is expected. At last, de-homogenization procedure is carried out to visualize the graded stiffened plate and eigenvalue buckling analysis is performed to show the validity of the optimization results.

Several numerical examples are presented to show the validity of the proposed method and the results are compared with regularly distributed stiffened plates to demonstrate the potential of spatially graded stiffener configurations in improving structural stability performance.

Isogeometric Stability Analysis of Thin-Walled Structures

Yujie Guo[1*] and Ke Liang[2]

[1] Nanjing University of Aeronautics and Astronautics, Nanjing, 210016, China, yujieguo@nuaa.edu.cn
[2] Northwestern Polytechnic University, Xi'an, China, k.liang@nwpu.edu.cn

Key Words: *Shell Buckling, Isogeometric Analysis, imperfections, dynamic buckling*

The load carrying capacity of thin-walled structures is known to be significantly influenced by stability aspects such as buckling. A reliable prediction of buckling phenomena requires a robust and accurate analysis tool and consideration of a number of inherent structural imperfections which often dominate the overall non-linear elastic response.

In this contribution, we present buckling and post-buckling problems of thin-walled structures in the framework of isogeometric analysis of isotropic and laminate composite shells considering geometric imperfections. Our approach exploits the higher order approximation and continuity properties of NURBS modelled shell structures and considers arbitrary openings and cut-outs, as common in industrial applications, on the basis of the finite cell method. The latter proved to be an efficient fictitious domain extension to isogeometric analysis in the context of trimmed NURBS geometries. In particular, the fictitious domain extension allows for a simple and flexible consideration of multiple cut-outs of arbitrary shape from the shell body and at arbitrary location without any re-meshing. Thus, it provides a powerful tool for the systematic study of the buckling tendency of industry relevant models. We will present a number of challenging shell buckling problems to reveal and assess the reliability and accuracy of a fictitious domain extended isogeometric analysis approach of geometric imperfect thin-walled structures.

Model-Data-Driven Hybrid Computational Framework for Large Deformation Analysis

Zengtao Kuang[1*], Qun Huang[1#], Ping Li[1], Yichen Yang[1], Jie Yang[1], Qian Shao[1], Heng Hu[1]

[1] Wuhan University, 8 South Road of East Lake, Wuchang, 430072 Wuhan, PR China,
kuangzengtao@whu.edu.cn
#Corresponding author: huang.qun@whu.edu.cn

Key Words: *data-driven, model-driven, large deformation*

The Data-Driven Computational Mechanics, proposed by Kirchdoerfer and Ortiz[1], is a novel computing paradigm in which the constitutive model is replaced by the material data set. Compared to the conventional "model-driven" computing, it can eliminate the error and uncertainty in material modeling, but may have expensive computational cost and poor convergence in certain situations[2], such as instability under large deformation. Hence, We propose a novel hybrid computational framework for large deformation analysis, combining the "model-driven" and "data-driven" algorithms. In the "model-driven" part, an empirical constitutive model is firstly calibrated with material data set and the preliminary solutions are obtained based on the finite element method. The above solutions are used as the initial iterations in the "data-driven" part, where the distance-minimizing data-driven algorithm is implanted to find the best solutions in the material data set that are closest to satisfying the equilibrium. The equilibriums with large deformation are nonlinear and solved by the Newton-Raphson method. The advantages of both the two algorithms can be gathered, where the robustness is ensured and the uncertainty of material model is eliminated. Since the initial iterations under each loading stage have already been obtained in "model-driven" part and are independent of each other, parallel computing can be used to significantly improve the efficiency of the "data-driven" computing part. This work can provide an efficient and robust tool for analysis and design of advanced materials.

NEW CREATION OF ORIGAMI BASED ON BIFURCATION ANALYSIS FROM FULLERENE STRUCTURES

Ichiro Ario[1] and Dong Ma[2*]

[1] Graduate School of Advanced Science and Engineering, Hiroshima University, Japan,
mario@hiroshima-u.ac.jp
[2*] Graduate School of Advanced Science and Engineering, Hiroshima University, Japan,
m216966@hiroshima-u.ac.jp

Key Words: Post-buckling, Origami skill, Bifurcation, Fullerene, Imperfection

The form of the *Buckminster fullerene* as geodesic sphere and other fullerene molecular such as Carbon 60(C_{60}), nano-tubes in nano-micro-macro scale structures has become popular among architects and/or chemists[1, 2]. The icosahedral symmetry of its structure, which is rarely found in nature, is difficult to analyse in scale-range physics problem. The analysis of these highly symmetric structures gives rise to a nonlinear problem with a singularity such as bifurcation problem[3], post-buckling problem in engineering and science. The authors therefore put forward a method to analyse the perfect structures, however, its imperfect one is more complicate to analyse bifurcation problem of fullerenes. Compared with the perfect system, the small deviation of the initial value will have a great impact on the subsequent situation, making the buckling process evolve in a completely different way.

In this study, the fullerene structure is studied from local to global. The elastic post-buckling analysis of frame, hemisphere and whole model is carried out respectively. In other words, even if there is only one part of the structure, the state of local buckling is taken as the service limit and the state of buckling in other places is taken as the final limit, so that the dangerous state can be understood in stages. From the perspective of structural symmetry classification, the initial shape of the structure can be changed by adding the imperfection of different nodes to produce the expected local defects. By reducing the symmetry of the structure gradually, the stiffness curve corresponding to the buckling process of the structure is measured by using arc length method. It is found that based on the original primary path, there are different bifurcation paths.

In summary, the post-buckling process of the fullerenes adds imperfection through Origami mechanism[4] to track the geometric deformation in the bifurcation phenomenon. Analytical results are used to further improve the laws of bifurcation mechanism with imperfection problem in symmetric structures. It is possible to create a folding system and stronger design based on this approach[5].

Key Words: *Isogeometric analysis, Uncertain Analysis, Karhunen-Loève Expansion, Perturbation Method*

With the rapid development of advanced manufacturing technology, various complex thin-walled structures are fabricated and utilized in engineering fields such as aerospace. However, the traditional finite element method (FEM) produces geometric errors due to meshing. And at the same time, the randomness of system parameters is inevitable in the manufacturing process [1]. Herein, a new stochastic method, referred to as stochastic isogeometric analysis (SIGA) considering the uncertainty of the material properties, is proposed to solve the stochastic linear stability problem of complex thin-walled structures. Isogeometric analysis [2] is highly promising and efficient numerical analysis method, and is adopted as a deterministic solver for governing partial differential equations. The Gaussian random fields with spatial variability of material properties are represented by Karhunen-Loève expansion, which is a linear combination of a set of independent random variables and orthogonal functions. The orthogonal functions and corresponding eigenvalues are obtained by solving the Fredholm integral equation of the second kind by the Galerkin isogeometric method [3]. This method exploits the regularity of NURBS basis functions delivering globally smooth eigensolutions and the total mean squared error of the random field is minimized simultaneously. Since the autocovariance function of the response solution is unknown, the perturbation method is developed to solve the stochastic linear buckling equation and predict the second-moment statistics of the buckling load. To verify the validity and applicability of the proposed method, two numerical examples including metallic and composite shells are presented. The accuracy and efficiency of the results are assessed by independent Monte Carlo simulation based on the IGA algorithm, and proved that the proposed method can effectively obtain the mean and standard deviation of the buckling load, thereby efficiently determining the strength limit of the shell structures.

STRUCTURAL INSTABILITY OF MULTIPLE MICRO-PERIODIC STRUCTURES

I. Ario[1] and Ma Haicheng[2*]

[1] Graduate School of Advanced Science and Engineering, Hiroshima University,
mario@hiroshima-u.ac.jp
[2*] Graduate School of Advanced Science and Engineering, Hiroshima University,
g200219@hiroshima-u.ac.jp

Key Words: Hill-top bifurcation, Multiple bifurcation, Bifurcation theory

Fundamental mechanism for the global and local (un-)stabilities based on geometrically periodic micro-macro structures and/or materials such as porous bodies, honeycomb, between the scales of atomic lattice structure and crustal deformation of geological folding under compression loading are reviewed from a post-buckling perspective. This folding phenomenon in nonlinear mechanics appears beyond the physics of scales problem as multi-body dynamics [1, 2]. In the viewpoint of multi-body physics issues, the structure is assumed that the mechanical model of the multi-folding micro-structure (MFM) [3] in a closed boundary condition is allowed to fold to a stable state through sequential unstable states such as snap-through or snap-back phenomena and deflections are considered so far into the large-deformation range. It is well-known the classification of single bifurcation point such as limit point, symmetry/asymmetry or stable/unstable bifurcation and so on. There is a hilltop branching point occurring as a coincidence of a limit point and arbitrary many bifurcation points of a finite-dimensional, elastic, conservative and equivariant system to its symmetry. The mechanical and elastic model of the MFM are derived for finite dimensional elastic conservative systems exhibiting hilltop branching at which arbitrary many bifurcation points coincide with a limit point. We have investigated the classification and/or bifurcation paths of multiple bifurcation point at hilltop (un)stable bifurcation point for structural model with periodic structure. The imperfection sensitivity with the hill-top bifurcation point displays complex phenomena of the geometrical nonlinearlity of multi-folding elastic model. We have investigated structural instability of the multiple (a)symmetry bifurcation paths from hilltop limit point in MFM model with periodic symmetry and/or loss-symmetry in the case of bridge collapse and/or periodic micro-macro structures.

The Koiter-Newton method for thermal-mechanical buckling and postbuckling analysis of thin-walled structures

Ke Liang[1*] **and Zheng Li**[2]

School of Aeronautics, Northwestern Polytechnical University, Xian 710072, PR China,
k.liang@nwpu.edu.cn

Key Words: Koiter-Newton method, Temperature field, Thermal-mechanical buckling, Reduced-order model

Thin-walled structures suffer a complex buckling failure under the thermal-mechanical environment. The initial stresses induced by the thermal expansion may lead to an "early buckling" for the structure.

The reduced-order modeling method, termed as the Koiter-Newton method, is reformulated to be applicable for geometrically nonlinear thermal-mechanical analysis of thin-walled structures. The initial temperature field over the whole structure is converted into the thermal load imposed on the structural nodes. The thermal load is treated as the independently unchanged load corresponding to the initial temperature field. The internal force space is expanded using the mechanical load, the thermal load and the predefined perturbation loads. The thermal-mechanical reduced-order model is constructed using the first to fourth-order derivatives of strain energy with thermal effects in terms of the degrees of freedom. An additional degree of freedom related to the thermal load appears in the construction of reduced-order model based on the novel Koiter theory. The path-following scheme is proposed to make the method able to trace the entire geometrically nonlinear thermoelastic response. A much larger step size can be achieved benefiting from the favorable prediction of the reduced-order model, compared to the classical Newton-like methods.

Numerical results validate the excellent performance of the proposed method in thermal-mechanical buckling analysis. The flat plate and curved panel with isotropic or orthotropic materials are selected considering the initial temperature fields. Firstly, the accuracy of the proposed method on tracing the geometrically nonlinear thermoelastic response is well guaranteed compared to the classical Newton-like methods. Much less number of steps is required for the proposed method attributing to the favorable predictor provided by the reduced-order model. A single step is enough for the flat plate with almost linear prebuckling behavior, to achieve the response satisfactorily up to the buckling load as well as the initial postbuckling region, while a few more steps may be needed for the curved panel that shows significant prebuckling deformation. Then, the thermal-mechanical buckling and postbuckling analyses of thin-walled structures are carried out using the proposed method. The influences of boundary conditions, uniform/nonuniform temperature fields and temperature-independent/dependent material properties on thermal-mechanical buckling behaviors are carefully studied. We conclude that the proposed method is a general, highly efficient and robust numerical method for geometrically nonlinear thermal-mechanical buckling analysis.

Uncertainty quantification method for geometric imperfections of cylindrical shells based on multi-Chebyshev envelope model

Hao Yang[1*], Shaojun Feng[2]

[2] Department of Engineering Mechanics, Dalian University of Technology, Dalian 116023, China, fengshaojun@mail.dlut.edu.cn

Key Words: *geometric imperfections, uncertainty quantification，limited samples, cylindrical shell*

Thin-walled cylindrical shells are widely used as main load bearing structures in the aerospace industry. Considering the high sensitivity of the buckling load to initial imperfections, especially geometric imperfections, the prediction of the knockdown factor is crucial to both structural safety and lightweight design. However, the generation of geometric imperfections is influenced by many factors, particularly the manufacturing process, whose complex distribution and spatially varying uncertainties are quite difficult to be described. The inherent strong random characteristics of geometric imperfections seriously expose the drawbacks of conventional deterministic knockdown factor prediction methods. Therefore, to obtain the load-bearing characteristics of the cylind1er shell under stochastic imperfections, there is an urgent need to conduct in-depth research on uncertainty quantification methods of geometric imperfections first. To overcome abovementioned challenges, a novel multi-Chebyshev envelopes (MCE) model is proposed in this paper. It can cover the stochastic properties of geometric imperfections with limited samples. The numerical results demonstrate that the MCE model achieves excellent performance in the accuracy of uncertainty quantification of geometric imperfections. Finally, a high-fidelity uncertainty quantification model of measured geometric imperfections of cylindrical shells is obtained by proposed method in a rational and objective manner.

A Two-Step Quadratic Spline Collocation Method for the Biharmonic Dirichlet Problem in Two Dimensions

Bernard Bialecki[1], Graeme Fairweather[2*] and Andreas Karageorghis[3]

Key Words: Biharmonic Dirichlet Problem, Quadratic Spline Collocation, Fast Fourier Transforms, Optimal Global Convergence Rates, Superconvergence.

Optimal quadratic spline collocation (QSC) methods were first developed in [4] for solving second-order two-point boundary value problems. Two methods were considered, a one-step or extrapolated method, and a two-step or deferred correction method. Both methods were extended to second-order elliptic boundary value problems in two space variables in [3], and to parabolic problems in one space variable in [2]. In this presentation, a two–step QSC method is described for the solution of the Dirichlet biharmonic problem on the unit square rewritten as a system of two second-order partial differential equations. This is commonly known as the mixed approach. The method involves fast Fourier transforms and, in comparison to its one-step counterpart given in [1], it has the advantage of requiring the solution a symmetric positive definite Schur complement system rather than a nonsymmetric one. The total cost of the method on a $N \times N$ partition of the unit square is $O(N^2 \log N)$. Although third-order accurate globally, the QSC solution is fourth-order accurate at the nodes of the mesh on which it is defined. This is the same nodal accuracy as that of optimal methods based on cubic spline collocation, which involve four times as many unknowns. Numerical results demonstrate this accuracy of the QSC method.

Convergence of finite difference schemes for biharmonic time-dependent problems

Dalia Fishelov[1]*, Jean-Pierre Croisille[2]

[1] Afeka - Tel Aviv College of Eng., Tel Aviv, Israel, daliaf@afeka.ac.il
[2] Univ. Lorraine, CNRS, IECL, Metz, France, jean-pierrre.croisille@univ-lorraine.fr

Key Words: Finite differences, compact schemes, Stephenson scheme, biharmonic, Navier-Stokes equations, streamfunction

We consider various time dependent parabolic biharmonic problems in a square which appear in fluid dynamics, including models for the Navier-Stokes equations in streamfunction form. We approximate these time-dependent problems in space by finite difference compact high-order schemes. The finite difference scheme handle these problems without decoupling the biharmonic operator into two Laplacian operators. The compact high-order schemes which we apply to the biharmonic problems display interesting properties of stability and accuracy. Typically, our schemes exhibit fourth-order convergence rates, even when the truncation is less than fourth-order at certain nodes. We prove that for the semi-discrete problem, which is discrete in space and continuous in time, the scheme is fourth-order accurate. The proof invokes various matrix analysis techniques, which may be useful in other contexts. In the talk, we will review the diversity of these matrix techniques.

The talk is related to the references [1, 2].

Key Words: Biharmonic equation, H^2-conforming element, C^0 interior penalty method, mixed finite-element method

Fourth-order PDEs arise in many settings, including in models of thin plates and shells and of some liquid crystalline materials. The density variation of smectic A liquid crystals[4] is governed by such a fourth-order PDE, which exhibits two complications over the biharmonic or other typical H^2-elliptic fourth-order problems. First, the equation involves a "Hessian-squared" (div-div-grad-grad) operator, rather than a biharmonic (div-grad-div-grad) operator. Secondly, while positive-definite, the equation has a "wrong-sign" shift, making it somewhat more akin to a Helmholtz operator than an elliptic one. In this talk, we present three finite-element formulations for such PDEs, based on H^2-conforming elements[2, 6], the C^0 interior penalty method[1, 5], and a mixed finite-element formulation that explicitly introduces approximations to the gradient of the solution and a Lagrange multiplier[3]. Numerical results highlight the finite-element convergence for all discretizations, and the trade-offs between accuracy and efficiency, particularly for three-dimensional problems.

High-order embedded finite difference schemes for initial boundary value problems involving mixed derivatives terms in complicated domains

Adi Ditkowski[1], **Tomer Livneh**[1]

[1]Tel Aviv University, Tel Aviv 69978, Israel, e-mail: adid@tauex.tau.ac.il

Key Words: Finite differences, Embedded Finite differences, Initial boundary value problem, parabolic equation, biharmonic equation

Initial Boundary Value Problems (IBVP) arise in many fields, including heat transfer, elasticity, and fluid dynamics. In many cases, the problems' domains have complicated geometries that challenge imposing boundary conditions.

This work presents an approach for designing Bounded-Error Finite-Difference schemes to solve such problems when mixed derivative terms are involved. The general idea is to design a set of modular, one-dimensional operators and find a decomposition of the problem's spatial operator as a linear combination of such operators.

The case of Parabolic IBVP in a two-dimensional domain is analyzed. The limits of this decomposition are found and compared to previously obtained results. The method is then used to construct fourth-order schemes for parabolic IBVP, and the biharmonic equation and simulation results supporting the theory are presented.

Key Words: staggered discontinuous Galerkin, polygonal meshes, error analysis, a posteriori error, biharmonic problems

Recently, we have developed staggered discontinuous Galerkin methods for various problems on general polygonal meshes [1, 2, 3, 4]. In this talk, we present a staggered cell-centered discontinuous Galerkin method for the biharmonic problem with the Steklov boundary condition [5]. Our approach utilizes a first-order system form of the biharmonic problem and can handle fairly general meshes possibly including hanging nodes, which favors adaptive mesh refinement. Optimal order error estimates in L^2 norm can be proved for all the variables. Moreover, the approximation of the primal variable superconverges in L^2 norm to a suitably chosen projection without requiring additional regularity. Residual type error estimators are proposed, which can guide adaptive mesh refinement to deliver optimal convergence rates even for solutions with singularity. Numerical experiments confirm that the optimal convergence rates in L^2 norm can be achieved for all the variables. Moreover, all the provided residual type error estimators show the desired results.

Key Words: *Biharmonic operator, high-order compact scheme, eigenvalues*

The one-dimensional biharmonic operator is a basic model of a high order Sturm–Liouville problem. We study its approximation using a high-order compact discrete biharmonic operator. We find a fundamental connection between this discrete operator and cubic splines, allowing us to derive an explicit expression for the elements of the matrix representing its inverse. Using these results, we prove that the eigenvalues of the discrete operator converge to those of the corresponding continuous problem at an optimal $O(h^4)$ rate.

Adaptive Data-driven Reduced Order Modelling for Strut-braced Ultra-high Aspect Ratio Wing Configuration

Peter Nagy[1], **Marco Fossati**[1]

[1] University of Strathclyde, 16 Richmond St, Glasgow, G1 1XQ, United Kingdom,
peter.nagy@strath.ac.uk, marco.fossati@strath.ac.uk

Key Words: Reduced Order Modelling, Multi-fidelity Aerodynamics, Steady Flows, Transonic Flows

Reduced Order Modelling (ROM) approaches offer promising advantages over CFD simulations in the context of multi-query problems where many high-fidelity simulations must be computed in a repeated manner [1]. For example, in a parametric design and optimisation problem, a huge number of solutions must be obtained describing various geometrical configurations and flight conditions. This reliance on numerical methods is emphasised in the case of new aerodynamic designs where empirical and experimental data is not available. Despite advances in computing, costs can become excessive, especially when the aim is to accurately capture structures in complex three-dimensional flows. This limitation can be overcome by the introduction of ROM techniques that allow for CFD-like accuracy at a fractional cost.

In this work the use of an Adaptive ROM Framework [2] is demonstrated. The framework is adaptive in the sense that a number of ROM methods are used, and their reconstruction error is evaluated. When a new solution is to be computed an automatic selection is performed between the ROMs on the basis of this error metric, so that accuracy is maximised. Since in general no best-in-class method can be identified for a given problem, this approach ensures that for the reconstruction of a particular new solution the most appropriate method is selected. The reduced order methods are coupled with an interpolation technique so that new high-dimensional solutions are recovered non-intrusively. A linear and a nonlinear method will be compared; the latter adopted with the aim to better cope with nonlinear features present in this test-case treated here, e.g. transonic shocks.

Minimising environmental impact is of high interest in the community. To further this goal, aircraft with high-aspect ratio wings offer a promising avenue of development (due to the significant drag reduction) and are identified as a key enabling strategy for sustainable aviation. However, this new design brings additional challenges in terms of aeroelastics. To cope with increased loads and flexibility a strut brace can be introduced as in the configuration presented here. The resulting interference effects lead to additional complexity in the flow further emphasising the advantages of model order reduction.

Key Words: reduced order models, reproductive mechanics, maternal health

Maternal mortality is unacceptably high in many parts of the world, with 810 women dying each day due to complications of pregnancy and childbirth. Moreover, many mothers who survive pregnancy and childbirth suffer from lifetime morbidity, disabilities and ill-health. Though the causes of pregnancy-related death and illness are various, mechanical and structural changes of the reproductive organs contribute to their development. Currently, there are no science-based tools that can predict trauma during childbirth. Once the mother is in labor, the obstetrician has very limited time to evaluate the best course of action for delivery, including a C-section.

While recent advances in childbirth finite element (FE) simulations have quantified damage to the pelvic organs and tissues, the complexity of such simulations (geometry, boundary conditions, nonlinear materials, etc.) results in long run-times yielding an impractical resource for obstetricians. Reduced order modeling (ROM) is a mathematical numerical approach capable of solving very complex simulations with significant time-savings. In this study, we propose the use of the Galerkin projection-based ROM to describe the mechanical response of vaginal tissue in *ex vivo* mechanical tests as a first step towards implementing ROM for childbirth simulations. Efficient and accurate simulations of the pelvic organs and tissues could help save the lives of mothers and address preventable maternal morbidity and disabilities by providing science-based descriptive and predictive tools that can be used by obstetricians.

Geometric Structure-Preserving Design Space Dimensionality Reduction

Shahroz Khan[1*], Panagiotis Kaklis[1], Andrea Serani[2], Matteo Diez[2] and Konstantinos Kostas[3]

[1] University of Strathclyde, Glasgow, United Kingdom
[2] National Research Council-Institute of Marine Engineering, Rome, Italy
[3] Nazarbayev University, Nur-Sultan city, Kazakhstan

Key Words: Geometric moments, Dimensionality reduction, Shape optimisation, Parametric design

Shape optimisation problems often suffer from the curse of dimensionality: the computational complexity rises exponentially with the dimension of a design space [1]. One approach to cure this issue is to exploit the latent features, which forms a reduced dimensional subspace. The commonly used approaches, such as principal component analysis (PCA) [2], usually generate subspaces that often fail to accommodate physical information and preserve the intrinsic geometric structure of the shape, thus resulting in many invalid geometries.

In this work, we propose a Shape-Signature Subspace (SSS) technique for dimension reduction, which uses higher-level information about the shape in terms of its geometric integral properties. In our case, these integral properties are geometric moments [3] of varying order. Their usage is based on the fact that moments of a shape are intrinsic features of the shape's geometry, and they provide a unifying medium between geometry and physics. To maximise the geometric information retained in the subspace, we evaluate a set of composite moments, using the divergence theorem, for disintegrated sub-geometries of the shape. These moments are used with the shape modification function to form a shape signature vector (SSV), which act as a descriptor to uniquely represent each design in the design space. Afterwards, we use SSV to perform eigendecomposition, which results in spanning the basis of a subspace retaining the highest variance in terms of geometry, its underlying structure and physics.

The feasibility of the proposed method is tested for optimising a ship hull, parameterised with 27 design parameters, against its wave resistance coefficient (c_w). The results showed that subspace obtained with PCA results in 44% of reduction in the original design space dimensionality, whereas 70% of dimension reduction is achieved with SSS. The number of invalid geometries produced by the SSS-based subspace is 36% less with faster to the optimal solution compared to the subspace formed with PCA.

Improved gradient enhanced Kriging model for high-dimensional function approximation

Kai Cheng[1*], **Ralf Zimmermann**[1]

[1] Department of Mathematics and Computer Science, University of Southern Denmark (SDU), Campusvej 55, 5230 Odense M, Denmark, kai@sdu.dk, zimmermann@imada.sdu.dk

Key Words: Gradient-enhanced Kriging, global sensitivity analysis, hyper-parameter optimization

The statistical interpolation method Kriging, also known as Gaussian process regression, has been widely used to construct surrogates for approximating expensive computational models in various disciplines. However, the training sample size required to construct an accurate Kriging model rises rapidly with the input dimension. The gradient-enhanced Kriging (GE-Kriging) model has the potential to alleviate this problem known as the ”curse of dimensionality” by incorporating gradient information. However, GE-Kriging tends to get impractical for high-dimensional problems due to the large correlation matrix and the associated time-consuming hyper-parameters tuning procedure.

To address these issues, in this talk, an improved GE-Kriging model is proposed, reducing both the correlation matrix size and the number of hyper-parameters. This is achieved by performing a derivative-based global sensitivity analysis to detect a subspace within which the model response exhibits strong variability. The correlation matrix of GE-Kriging, in turn, is reduced by incorporating partial derivatives only within the identified subspace. Additionally, we transform the original high-dimensional hyper-parameter tuning problem into a low-dimensional counterpart by learning the relationship between the model hyper-parameters and the global sensitivity indices. The proposed method is validated with several benchmark problems of various dimension. The results show that the proposed GE-Kriging model features an accuracy that is comparable to the traditional one but comes with much less training costs, which makes it more practical for applications involving high-dimensional problems. Eventually, it is planned to employ this method in surrogate modeling-assisted process and energy optimization in the context of car body painting.

LEAST-ORDER MODELS BASED ON THE FLOW INSTABILITIES

Luc Pastur[1*], Nan Deng[1] and Bernd R. Noack[2]

[1] Unité de Mécanique, ENSTA Paris, Institut Polytechnique de Paris, 828 Bd des Marchaux, France
[2] School of Mechanical Engineering and Automation, Harbin Institute of Technology, Shenzhen 518058, China

Key Words: Fluid Dynamics, Reduced-Order Model, Bifurcations, Nonlinear Dynamics.

Fluid flows obey the Navier-Stokes equations, which are nonlinear partial derivative equations and make such dynamical systems of infinite dimension. Yet, the dynamical systems usually evolve on inertial manifolds of finite dimensions. Identifying the elementary degrees of freedom is highly desirable and challenging to construct meaningful reduced-order models (ROMs) for human understanding, dynamic prediction and control. Galerkin methods, commonly used to produce ROMs, neither tell how many modes should be considered, nor which modes should be considered. The least-order model based on the flow instabilities is addressed in the case of the fluidic pinball, a two-dimensional flow configuration consisting of three discs at the vertices of an equilateral triangle in the cross flow.

In this system, the steady solution undergoes a supercritical Hopf bifurcation at $Re_{HP} \approx 20$, resulting in the formation of a von Kármán street of vortices. Beyond $Re_{PF} \approx 70$, the system undergoes a secondary supercritical pitchfork bifurcation with the appearance of two additional mirror-conjugated (unstable) steady solutions, which break the reflectional symmetry of the configuration by twisting the jet behind the two downstream cylinders. Based on the normal forms of the two bifurcations, the ROM must be at least five dimensional, three degrees of freedom being associated with the Hopf bifurcation, two with the pitchfork bifurcation [1]. The coefficients of the model are determined partly by the physical inspection of the transient and post-transient dynamics, partly by the sparse identification with the SINDy algorithm under constraints [2]. This modelling strategy with sparse calibration embeds physical knowledge into Galerkin models, which is also applied to build a force-oriented ROM [3].

With only five degrees of freedom, the ROM reliably reproduces the dynamics of the fluidic pinball from the initial condition to the post-transient regime, including 3 steady and 3 periodic solutions. This ROM serves as example for similar flow dynamics and as a benchmark for future fully automated reduced-order modeling methods.

This work introduces a new approach to reduce the computational cost of solving partial differential equa- tions (PDEs) with convection-dominated solutions: model reduction with implicit feature tracking. Traditional model reduction techniques use an affine subspace to reduce the dimensionality of the solution manifold and, as a result, yield limited reduction and require extensive training due to the slowly decaying Kolmogorov n-width of convection-dominated problems. The proposed approach circumvents the slowly decaying n-width limitation by using a nonlinear approximation manifold systematically defined by composing a low-dimensional affine space with a space of bijections of the underlying domain. Central to the implicit feature tracking approach is a residual minimization problem over the reduced nonlinear manifold that simultaneously determines the reduced coordinates in the affine space and the domain mapping that minimizes the residual of the unreduced PDE discretization. This is analogous to standard minimum-residual reduced-order models, except instead of only minimizing the residual over the affine subspace of PDE states, our method enriches the optimization space to also include admissible domain mappings. The nonlinear trial manifold is constructed by using the proposed residual minimization formulation to determine domain mappings that cause parametrized features to align in a reference domain for a set of training parameters. Because the feature is stationary in the reference domain, i.e., the convective nature of solution removed, the snapshots are effectively compressed to define an affine subspace. The space of domain mappings, originally constructed using high-order finite elements, are also compressed in a way that ensures the boundaries of the original domain are maintained. Several numerical experiments are provided, including transonic and supersonic, inviscid, compressible flows, to demonstrate the potential of the method to yield accurate approximations to convection-dominated problems with limited training.

NONLINEAR MANIFOLD TO COMPONENT-WISE REDUCED ORDER MODELS TOWARDS MULTI-SCALE PROBLEMS

Youngsoo Choi[1]

[+]Lawrence Livermore National Laboratory
Livermore, CA 94550, USA
choi15@llnl.gov, https://people.llnl.gov/choi15

Key Words: *reduced order model, multi-scale problems, data-driven physical simulation*

Traditional linear subspace reduced order models (LS-ROMs) can accelerate physical simulations in which the intrinsic solution space falls into a subspace with a small dimension, i.e., the solution space has a small Kolmogorov n-width with a small n. However, for physical phenomena not of this type, e.g., any advection-dominated flow phenomena such as in traffic flow, atmospheric flows, and air flow over vehicles, there is no linear subspace that approximates the solution well with a small dimension. Furthermore, high-dimensional parameter space poses a serious issue of computationally expensive training cost due to the number of training data increasing exponentially with the parameter space dimension. To address cases such as these, I will present two different reduced order model techniques.

The first one is a fast and accurate nonlinear manifold ROM (NM-ROM) [1] that can better approximate high-fidelity model solutions with a smaller latent space dimension than the LS-ROMs. Numerical results show that neural networks can learn a more efficient latent space representation on advection-dominated data from 1D and 2D Burgers' equations. Speedup of 10x and relative error of less than 1% are achieved with an appropriate treatment of the nonlinear terms through a hyper-reduction technique.

The second one is a component-wise reduced order model (CW-ROM) [2] that resolves the challenge posed by a high-dimensional parameter space. The CW-ROM enables a smaller size and parameter set of training, resulting in an efficient training procedure. Furthermore, the accuracy can be tuned, so an arbitrarily accurate solution can be achieved with a considerable speedup. It is applied to a multi-scale topology optimization problem, i.e., lattice-type structure design optimization, achieving a speed-up of 1000x with a relative error less than 1%.

Reduced Order Modeling for a LES filtering approach

Annalisa Quaini[1]*, Michele Girfoglio[2] and Gianluigi Rozza[2]

[1] Department of Mathematics, University of Houston, Houston TX 77204, USA
[2] SISSA, International School for Advanced Studies, Mathematics Area, mathLab, via Bonomea, Trieste 265 34136, Italy

Key Words: Proper orthogonal decomposition, Reduced order model, Large Eddy Simulation, filter stabilization, projection-based methods, data-driven strategies

It is well known that the extension of reduced order models (ROMs) to turbulent flows presents several challenges. We choose to work with a large eddy simulation (LES) approach that describes the small-scale effects by a set of equations to be added to the discrete Navier-Stokes equations [1]. This extra problem acts as a low-pass differential filter. We propose a Proper Orthogonal Decomposition (POD)-Galerkin based ROM when a linear filter is used [2] and a hybrid projection/data-driven strategy in the case of a nonlinear filter [3]. The novelties of our ROMs include: 1) the use of a ROM differential filter, i.e. a ROM spatial filter that uses an explicit lengthscale, 2) the computation of the pressure field at the ROM level, 3) the use of a finite volume method for the space discretization, which is common in many commercial codes, and 4) the use of different POD coefficients and bases to approximate the intermediate and end-of-step velocities. The performance of the proposed methods is assessed through 2D and 3D test cases.

A C^0 FINITE ELEMENT METHOD FOR THE BIHARMONIC PROBLEM WITH NAVIER BOUNDARY CONDITIONS

HENGGUANG LI[†], PEIMENG YIN[‡] AND ZHIMIN ZHANG[†‡]

Abstract. We study the biharmonic equation with the Navier boundary conditions in a polygonal domain. In particular, we propose a method that effectively decouples the 4th-order problem into a system of Poisson equations. Different from the usual mixed method that leads to two Poisson problems but only applies to convex domains, the proposed decomposition involves a third Poisson equation to confine the solution in the correct function space, and therefore can be used in both convex and non-convex domains. A C^0 finite element algorithm is in turn proposed to solve the resulted system. In addition, we derive the optimal error estimates for the numerical solution on both quasi-uniform meshes and graded meshes. Numerical test results are presented to justify the theoretical findings.

Key Words: *Fitted Norms, Stability Analysis, Saddle-point Problems, LBB Condition, Poromechanics, Biot's Model.*

This talk provides a new abstract stability result for perturbed saddle-point problems which is based on a proper norm fitting. We derive the stability condition according to Bauska's theory from a small inf-sup condition, similar to the famous Ladyzhenskaya-Bauska-Brezzi (LBB) condition, and the other standard assumptions in Brezzi's theory under the resulting combined norm. The proposed framework allows to split the norms into proper seminorms and not only results in simpler (shorter) proofs of many stability results but also guides the construction of parameter robust norm-equivalent preconditioners. These benefits are demonstrated with several examples arising from different formulations of Biot's model of consolidation.

Key Words: Least squares, Saddle Point Systems, Mixed Methods, Optimal Test Norm

We consider a least squares method for discretizing singularly perturbed second order elliptic problems. Choices for discrete stable spaces are considered for the mixed formulation and a preconditioned conjugate gradient iterative process for solving the saddle point reformulation is proposed. We provide a preconditioning strategy that can be applied to a large range class of mixed variaional formultations. Using the concepts of optimal test norm and saddle point reformulation we provide a robust discretization strategy that works for uniform and non-uniform refinements for Convection-Reaction-Diffusion problems.

Key Words: Poroelasticity; Reduced Quadrature; Finite Elements; Monolithic Multigrid; Local Fourier Analysis

Advanced finite-element discretizations and preconditioners for models of poroelasticity have attracted significant attention in recent years. The equations of poroelasticity offer significant challenges in both areas, due to the potentially strong coupling between unknowns in the system, saddle-point structure, and the need to account for wide ranges of parameter values, including limiting behavior such as incompressible elasticity. The work presented in this talk was motivated by an attempt to develop monolithic multigrid preconditioners for a novel P1-P0-RT-stabilized discretization; we show here why this is a difficult task and, as a result, we modify the discretization through the use of a reduced quadrature approximation, yielding a more "solver-friendly" discretization. Local Fourier analysis is used to optimize parameters in the resulting monolithic multigrid method, allowing a fair comparison between the performance and costs of methods based on Vanka and Braess-Sarazin relaxation. Numerical results are presented to validate the LFA predictions and demonstrate efficiency of the algorithms. Finally, a comparison to existing block-factorization preconditioners is also given.

Key Words: Inf-sup condition, Finite elements, Poisson problem, Stability and convergence

It is well known that stable approximations of mixed problems rely on suitable inf-sup conditions [1]. Usually, non stable formulations are considered dangerous and people prefer to avoid them unless suitable stabilizations are used.

We consider a non-conventional mixed approximation of the Poisson problem for which the inf-sup constant is not uniformly bounded as the mesh is refined [2].

The behavior of the inf-sup condition is discussed and the convergence of the finite element approximation is studied. It turns out that, under appropriate hypotheses on the data, the discrete solution is stable and optimally convergent.

Several numerical tests confirm the theoretical results and shed some light on the links between the inf-sup condition and the convergence of the discrete solution.

Saddle Point Least Squares for Convection-Diffusion

Daniel Hayes[1*], **Constantin Bacuta**[2]

[1] University of Delaware, 501 Ewing Hall, dphayes@udel.edu
[2] University of Delaware, 501 Ewing Hall, bacuta@udel.edu

Key Words: Saddle Point Least Squares, Preconditioning, Mixed Methods

We consider a Saddle Point Lease Squares reformulation for the discretization of the Convection-Diffusion. A focus is placed in the convection dominated regime which is known to produce non-physical oscillations. We consider also streamline diffusion stabilization to remedy the oscillatory behavior. For the choice of stable pairs of spaces, we are able to equipt these spaces with an intentional choice of inner products to allow for the use of precondioners from Reaction-Diffusion equations. We couple this with the concept of optimal test norms to provide an efficient discretization strategy.

A Comparison of Three Iterative Solution Schemes for Elliptic PDEs

Reza Abedi[1*], Giang Huynh[1], and Robert B Haber[2]

[1] University of Tennessee Space Institute/Knoxville, Ferris Hall, 1508 Middle Dr, Knoxville, TN 37996, United States, rabedi@utk.edu, ghuynh@utsi.edu

[2]University of Illinois at Urbana-Champaign, 3051 Sidney Lu Mechanical Engineering Building, Urbana, Illinois 61801, rbh3@illinois.edu

Finite element and discontinuous Galerkin discretizations of linear elliptic PDEs require the solution of global systems of linear equations. The size of the stiffness matrix quickly increases with the number of elements, as does the condition number in certain cases. These properties pose serious challenges in the direct solution of elliptic PDEs. We investigate three iterative solution schemes for two classes of elliptic problems: those that arise as the steady-state limits of parabolic or hyperbolic PDEs and those that represent long-term solutions of hyperbolic PDEs driven by harmonic forces, in particular, the Helmholtz equation.

The first two schemes use a hyperbolic PDE solver, the causal Spacetime Discontinuous Galerkin (cSDG) method [1], to solve indirectly the underlying elliptic PDE. The cSDG method is very effective in this role due to its local conservation properties, linear computational complexity, unconditional stability, powerful space-time adaptive meshing capabilities, and other favorable properties. In the first scheme, applicable only to steady-state limit problems, we solve a damped hyperbolic PDE over a sufficiently long time interval to find its solution's steady-state limit. We tune viscous damping [2] or kinetic damping [3] parameters to accelerate solution convergence. In the second scheme, applicable to both classes of elliptic PDEs under consideration, we seek initial conditions for substitute hyperbolic problems that satisfy conditions specific to each elliptic problem class. The solution to the target elliptic PDE is obtained by applying certain projection operators to the hyperbolic solution for the converged initial condition. This method resembles the *WaveHoltz* method [4] for the Helmoltz equation. We propose a new method for steady-state limit problems based on matrix-free iterative linear system solvers such as GMRES. The third scheme does not involve a hyperbolic solution. We instead apply asynchronous aspects of the cSDG algorithm to develop a new indirect solver for elliptic problems in which we solve a series of localized elliptic problems until the global residual is sufficiently small. The localized solutions are ordered by the current local residual magnitudes, rather than a predefined geometric pattern as in Gauss-Seidel methods, and can be performed asynchronously in parallel.We compare the performance of the three solution schemes in terms of their accuracy and computational efficiency.

A coupled-mode theory for exterior scattering problems based on a non-orthogonal modal expansion

Kei Matsushima[1*], Yuki Noguchi[1] and Takayuki Yamada[1]

[1] The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo, Japan.

Key Words: *Coupled-mode theory, scattering analysis, exterior problem, Helmholtz equation*

This study presents a novel numerical method for exterior scattering problems. The proposed method is based on a coupled-mode approach, which formulates the scattering process in terms of resonance and radiation.

To this end, we separate an entire unbounded space into a ball (disk) and its exterior. The fictitious ball contains all inhomogeneity (scatterer); therefore, the exterior is homogeneous and supports cylindrical/spherical waves with a continuous spectrum. To represent a resonant field in the vicinity of a scatterer, we expand a scattered field in terms of normal modes in the ball with a discrete spectrum.

Unlike quasinormal mode expansion [1], the normal modes form a complete set in the ball when a suitable boundary condition is imposed on its surface. Although the most common choice for this auxiliary condition is the Neumann boundary condition [2], we suffer from severely slow convergence of the Neumann modal expansion due to a nonzero Neumann data on the surface.

In this study, we propose a rapidly convergent expansion for the resonant field. The proposed expansion is comprised of both the Neumann and Dirichlet eigenfunctions in the ball. Since the L2 orthogonality does not hold between Neumann and Dirichlet eigenfunctions, the proposed expansion is non-orthogonal. We perform some numerical verifications of the proposed method and demonstrate its effectiveness.

Key Words: Spacetime, Parallel, Adaptive Meshing, Discontinuous Galerkin, Hyperbolic PDEs

The causal Spacetime Discontinuous Galerkin (cSDG) method is a powerful scheme for solving hyperbolic systems of PDEs that features local conservation properties, linear computational complexity, unconditional stability for linear problems, powerful space-time adaptive meshing capabilities, and other favorable properties. The method has been applied to elastodynamics and stochastic brittle fracture [1, 2] as well as contact, conservation laws, electromagnetics, hyperbolic conduction and advection–diffusion. In lieu of synchronous time marching, it constructs unstructured spacetime meshes according to a causality constraint that localizes the solution process to small clusters of spacetime elements called patches [3]. The solution on each patch depends only on adjacent, previously-solved elements and prescribed initial and boundary data. This structure supports efficient patch-by-patch solution procedures.

This presentation introduces a new generation of cSDG software called *ParaSDG* that incorporates recent advances in parallel implementations of the cSDG method on distributed HPC platforms as well as adaptive spacetime meshing technologies in up to three spatial dimensions and time. The asynchronous distributed implementation features a fine-grained patch-wise parallel architecture in lieu of traditional domain decomposition and novel stochastic procedures for balancing distributed data storage and computational load. Nearly the entire algorithm, including spacetime patch generation, localized cSDG solution procedure, and adaptive meshing operations, is embarassingly parallel and executed in local process-private memory. ParaSDG's spacetime meshing extends adaptive causal meshing up to three spatial dimensions with a new adaptive refinement algorithm and the use of harmonic triangulation procedures. Numerical examples will demonstrate ParaSDG's capabilities and parallel performance.

An adaptive nonlinear elimination preconditioned space-time solution algorithm for hyperbolic partial differential equation problems

Feng-Nan Hwang[1*] **and Chang-Wen Liang**[1]

[1] Department of Mathematics, National Central University, Taoyuan City 320317, Taiwan
Presenter's e-mail: hwangf@math.ncu.edu.tw (FN Hwang)

Key Words: Fully-coupled space time algorithm, Hyperbolic partial differential equations, shock wave, Nonlinear elimination preconditioning, Inexact Newton method

As the computing power of the latest parallel computer systems increases dramatically, the fully coupled space-time solution algorithms for the time-dependent PDEs obtained their popularity recently for temporal domain parallelism. This space-time algorithm solves the resulting large, space, nonlinear systems in an all-at-once manner. A robust and efficient nonlinear solver plays an essential role as a critical kernel of the whole solution algorithm. This talk introduces some nonlinear preconditioned Newton algorithms for the space-time formulation of Burgers' equation with shock presented. In that case, the history of the nonlinear residual norm for the classical Newton method suffers from a long stagnation period due to strong local nonlinearity. To overcome the difficulties, we apply an adaptive nonlinear elimination preconditioning technique to enhance the robustness of the inexact Newton method, in the sense that the number of inexact Newton iterations required to converge is almost independent of both of the time-step and the mesh sizes. Some numerical results show that the proposed method is more robust and efficient than the commonly-used classical inexact Newton algorithm.

Implicit Trefftz discontinuous Galerkin method

Christoph Lehrenfeld[1], **Paul Stocker**[1,*]

[1] Georg-August-Universität, Göttingen, Germany
[*] p.stocker@math.uni-goettingen.de

Key Words: discontinuous Galerkin method, Trefftz method

We present a novel numerical method to reduce the discrete system size of discontinuous Galerkin (DG) methods, inspired by Trefftz methods. The main idea of Trefftz methods, originating from [1], is to choose optimal discretization spaces to reduce the number of unknowns. This usually requires the construction of specific test and trial functions that need to be tailored to the PDE in question. These approaches pair well with DG methods so that the basis construction of elements decouples.

The starting point for the approach presented here, will be a suitable DG scheme with polynomial test and trial functions. The knowledge of the Trefftz function space is then injected implicitly by finding a *Trefftz embedding* that maps the Trefftz space into the discretization space. Thus no basis for the Trefftz space has to be calculated, which makes it possible to apply this approach even if a basis for the Trefftz space is unknown. The embedding then allows to significantly reduce the size of the finite element matrix, allowing for faster solving times.

Fluid-rigid body interactions are often encountered in real-world applications, such as airflow around turbines, bridges, or tall antennas. In this talk, we present a Space-Time Embedded-Hybridized Discontinuous Galerkin method to solve the fluid subproblem that allows for an arbitrarily high order approximation in space and time. The rotation and the translation of the rigid body are described by ordinary differential equations, which are coupled to the fluid problem via the pitching and the lifting forces. We introduce a sliding grid technique for the rotational movement that can handle arbitrary rotation. The numerical examples will include galloping and fluttering motion.

Key Words: time-dependent Maxwell's equations, symplectic Hamiltonian finite element methods, mixed methods, discontinuous Gakerkin methods, hybridizable discontinuous Galerkin methods

We present a general approach for defining high-order accurate finite element methods for the Maxwell's equations which provide time-invariant, non-drifting approximations to the total electric and magnetic charges, and to the total energy. We devise these methods by taking advantage of two of the Hamiltonian structures of the Maxwell's equations. The first is based on the standard formulation of the equations in terms of the electric and magnetic fields, whereas the second is based on a wave-like rewriting of them in terms of the electric and the magnetic potential fields. For each of these Hamiltonian structures, we proceed as follows. First, we introduce spatial discretizations of the Maxwell's equations using mixed finite element, discontinuous Galerkin, and hybridizable discontinuous Galerkin methods to obtain a semi-discrete system of equations which display discrete versions of the Hamiltonian structure of the Maxwell's equations. Then we discretize the resulting semi-discrete system in time by using a symplectic integrator. This ensures the conservation properties of the fully discrete system of equations. There is a Symplectic DG method for the first formulation [J. Sci. Comput. 35, pp. 241–265, 2008] but all other methods are new. We show that there are no Symplectic HDG methods for the first formulation. In contrast, we devise Symplectic Hamiltonian mixed, DG, and HDG methods for the second formulation. Finally, for the Symplectic HDG method, we present numerical experiments which confirm its optimal orders of convergence for all variables and its conservation properties for the total linear and angular momenta, as well as the total energy. Finally, we discuss the extension of our results to other boundary conditions and to numerical schemes defined by different weak formulations.

Benchmarking the Regridding Functionality of Climate Modelling Coupling Software

Sophie Valcke[1*], Andrea Piacentini[1] and Gabriel Jonville[1]

[1] CECI, Université de Toulouse, CNRS, CERFACS, 42 Av. G. Coriolis

31057 Toulouse Cedex 01, France

Key Words: *Regridding, Remapping, Interpolation, Code Coupling, Climate Modelling,*

We present here the results of a benchmarking exercise performed on the SCRIP library [1], ATLAS [2], MOAB-TempestRemap [3], YAC [4], ESMF [5] and XIOS [6]. The motivation is to complement the SCRIP library regridding algorithms implemented in the OASIS3-MCT coupler.

In order to compare these libraries, several aspects had to be covered. In a preliminary analysis, we first enquired about available regridding methods and evaluated the software development environment, e.g. the coding language, project history and development plans, provision of support to external projects, and committed manpower.

Then we proceeded to a formal benchmarking of SCRIP, YAC, ESMF and XIOS. 5 regridding algorithms (nearest-neighbour, bilinear, bicubic, 1st and 2nd order conservative remapping) were evaluated with 4 different functions, some of them having strong gradients, for 14 couples of grids used in real ocean or atmosphere models. Metrics proposed by the CANGA project (https://github.com/CANGA/Remapping-Intercomparison) quantifying the sensitivity, conservation, consistency, monotonicity, and performances of the library were calculated.

After interactions with the library developers to solve specific issues, it is concluded that YAC, ESMF and XIOS show very good results for the regridding algorithm, functions and grids evaluated. A unified scripting environment for SCRIP, ESMF and XIOS is now available in the latest version of the OASIS3-MCT coupler so that users can test those three libraries on their own grid for their own regriddings. Detailed results of this benchmarking exercise are available in [7]

Efficient Multi-Material Remap in High-Order ALE Hydrodynamics

Veselin Dobrev[1], Tzanio Kolev[1], Robert Rieben[1], Vladimir Tomov[1], and Arturo Vargas[1*]

[1] Lawrence Livermore National Laboratory, 7000 East Avenue, Livermore, CA 94550, United States, dobrev1@llnl.gov, kolev1@llnl.gov, rieben1@llnl.gov, tomov2@llnl.gov, vargas45@llnl.gov

Key Words: Remap, ALE Hydrodynamics, High-Order Finite Elements, Matrix-Free Methods

We present a remap algorithm in the context of multi-material Arbitrary Lagrangian-Eulerian (ALE) hydrodynamics discretized with high-order finite elements [1]. The major mathematical challenges for this system include (i) conservation of the per-material volumes, masses, and energies, (ii) preservation of the minimum and maximum local bounds for all primary fields (e.g. density), which requires per-material synchronization between conserved fields (e.g. the ratio of mass and volume), (iii) synchronization between all material volume fractions, i.e., they must sum to unity at all degrees of freedom, and (iv) minimization of numerical diffusion and spreading of small volume fractions due to the nature of the finite element approach. We will discuss our latest methods for addressing the above challenges and demostrate them on standard ALE hydrodynamics benchmarks.

When high-order finite elements are used, the main limitation in terms of efficiency is the use of classical assembly and global sparse matrices. These scale poorly as the order of the finite element discretization increases and involve expensive data motion which is undesirable for the newest computer architectures. We will discuss our recently developed matrix-free remap formulation based on partial assembly [2] and demonstrate its performance benefits for practical ALE simulations.

Evaluation of Radial-Basis-Function Data Mappings of the Coupling Library preCICE

David Schneider[1*], Kyle Davis[1], Benjamin Uekermann[1] and Miriam Schulte[1]

[1] Institute for Parallel and Distributed Systems, University of Stuttgart
Universitätsstraße 38, 70569 Stuttgart, Germany
e-mail: *david.schneider@ipvs.uni-stuttgart.de*, web page: *http://www.ipvs.uni-stuttgart.de/*

Key Words: Multi-physics, Radial Basis Function, Coupled Simulation

In partitioned multi-physics simulation, multiple solvers interact together along a common coupling interface. This approach requires spatial data mapping methods, as each subsystem is discretized separately with potentially non-matching meshes at the common coupling interface. Radial-basis-function (RBF) mappings employ radially symmetric functions on an input mesh to perform the mapping to an output mesh [2]. We have implemented various mapping variants in the black-box coupling library preCICE [1]. In this work, we compare different RBF mappings with projection-based mapping methods.

In preCICE, the implementation of the RBF mapping method relies on PETSc as a parallel linear algebra solver [3]. We test the implementation in terms of efficiency as well as accuracy using a wind turbine blade geometry, a realistic geometry in practical applications. Results show that only for the coarsest meshes one can apply global basis functions due to the large memory storage requirements as well as the high computational complexity. Compact basis functions with a local support radius are able to provide accurate interpolation, while utilizing less memory space and being computationally cheaper. Projection-based interpolation methods can be implemented in a more efficient way compared to RBF mapping methods. However, the resulting mapping is typically less accurate or violates a strict black-box coupling approach operating solely on a point-cloud.

We further give an outlook on three current and future data mapping extension in preCICE: as a first variant, we introduce an in-solver mapping method, where the interface vertices of each solver are shared, and each solver directly performs the mapping request based on its own discretization. As a second variant, we investigate a RBF partition of unity method that is suitable for scalable data interpolation with minimal parallel communication. The third variant employs a nearest-neighbor mapping with additional gradient data in order to improve the accuracy of the plain nearest-neighbor mapping.

Remapping native fields for climate applications

Paul Kuberry[1&], Mauro Perego[1], Nat Trask[1], and Pavel Bochev[1]

[1] Sandia National Laboratories*, MS 1320, Albuquerque, NM 8718,

Key Words: *native field transfer, generalized moving least squares, CANGA*

Coupling global Earth system models requires passing information between sub-models that have been discretized independently and may employ different types of native field representations on different types of meshes. In E3SM's MPAS-Ocean, for example, velocities are represented with Raviart-Thomas basis elements on simplices and must be remapped to nodal spectral elements on hexahedral grids discretizing the domain for the atmosphere.

Generalized moving least squares (GMLS) is a non-parametric regression framework able to construct approximations to fields from scattered data. Judicious selection of sampling functionals and target functional for GMLS makes it is possible to approximate the embedded continuous functions represented by coefficients to a native field basis, e.g. Raviart-Thomas, Nedelec, or cell-averaged. This flexibility in GMLS makes it a prime candidate for general purpose coupling applications.

Remap over a sphere is performed by first approximating the tangent plane for each point where a field reconstruction is requested. The tangent plane approximation is then used as a local coordinate system on which sampling functionals are evaluated acting on a basis. After solving a local least squares problem, the field is then reconstructed in the local coordinate system, and transformed to the global coordinate system, if necessary.

The Compadre toolkit is used for the implementation of all described techniques. Numerical results will be presented demonstrating the accuracy of remap of several fields on grids where the degrees of freedom represent cell-averaged quantities and face normal averages (Raviart-Thomas).

Key Words: weighted least squares; data transfer; remap; cell-averaged data; superconvergence; discontinuities; Gibbs phenomenon; essentially non-oscillatory schemes

In multiphysics simulations, data are often transferred between different meshes at high-order accuracy. Jumps or discontinuities in the data or highly anisotropic meshes can pose significant challenges in data remap. In this work, we extend our earlier work on WLS-ENO Remap [2] for remapping node-based data to support cell-averaged data, such as those arising from finite-volume methods, including remapping between cell-averaged and node-based data. Based on the Weighted-Least-Squares-based Essentially Non-Oscillatory (WSL-ENO) schemes [1], WLS-ENO Remap achieves superconvergence when remapping smooth functions while overcoming overshoots and undershoots (aka Gibbs phenomena) for discontinuous functions. In addition, we introduce adaptive quadrature and adaptive stencils to overcome the potential loss of accuracy or conservation due to highly discrepant meshes or highly anisotropic meshes, such as those near the south and north poles of a longitude-latitude mesh of a sphere. We compare our technique with a conservative high-order remap to transfer functions on spheres. We show that our proposed technique is competitive in accuracy and conservation, despite not using a common-refinement mesh while being more flexible and easier to implement and more robust against discontinuities, anisotropic meshes, and rounding errors.

Key Words: Seepage problem, tailing dam, numerical stabilization, adaptive refinement

Seepage problems with free surfaces have been a matter of interest in engineering and mathematics due to the strong non-linearities involved. The significant difference in densities between the air and the water restricts the flow domain, producing a free surface. However, finding its exact location is still a challenge. Several numerical techniques are used to solve this phenomenon; nevertheless, some of these methods suffer from some instabilities when sharp changes in permeability occur if the mesh in the interface is not well defined, leading to unphysical oscillations in the numerical outputs.

Recently, a novel adaptive stabilized finite element method for linear problems is described in [1]. This method combines the residual minimization idea and the stability provided by the discontinuous Galerkin method approach. This leads to obtaining a stable continuous solution from the classical FEM and a residual representative that helps to develop mesh refinement adaptivity.

This project is divided into two parts: First, we discuss some numerical aspects of a non-linear adaptive approach for tailing dam application. Then, we implement the aforementioned numerical framework to find the correct position of the free surface scheme through an automatic adaptive procedure by using a solution-dependant permeability coefficient.

As a result, the residual estimative leads to obtaining a stable representation of the free surface and reducing the computational effort required by other approaches.

[2] Rutgers University, 607 Taylor Rd, Piscataway, NJ 08854, ryan.sills@rutgers.edu

Key Words: *Dislocation, Plasticity, Scale Bridging*

Scale bridging from discrete defects to continuum field descriptions is always a fundamental challenge in theory development. In the case of dislocation-mediated plasticity, the challenge is to identify a suitable coarse-grained descriptor of the dislocation network which still retains enough physics so that information obtained from discrete dislocation models can be folded into the coarse-grained governing equations [1]. We propose using dislocation length distributions as a coarse-grained descriptor for the network [2], coupled with discrete dislocation dynamics (DDD) simulations aimed at characterizing evolution behaviors of the network. This concept builds on a theory developed by Ardell and colleagues which has disappeared into the literature [3]. In this talk, we demonstrate the concept underlying our scale bridging framework along with preliminary results on its development. Specifically, we show how careful analysis of DDD simulations provides insights into junction formation and dissolution, plastic strain rate, and dislocation multiplication which serves as direct input into the coarse-grained model. Our approach provides a viable pathway towards constructing non-phenomenological models for plasticity.

A boundary element method for evaluating high-order frequency derivatives of acoustic wave scattering by periodic structures

Yuta Honshuku[1*] **and Hiroshi Isakari**[2]

[1] Nagoya University, Furo-cho, Chikusa-ku, Nagoya, Aichi, Japan
[2]Keio University, 3-14-1, Hiyoshi, Kohoku-ku, Yokohama, Kanagawa, Japan

Key Words: Fast frequency sweep, Acoustic scattering, Periodic structure, Boundary element method, Automatic differentiation, Ewald method

Emerging acoustic metamaterial and metasurface, as well as some existing acoustic structures such as sound-proofing walls, may often have periodic geometry. They exploit some resonance and interference peculiar to the periodic structures to manipulate sound waves. The anomalous behaviours can, however, be observed only if the excitation frequency is very close to the eigenfrequency unique to each structure, which may lead to the narrow working band of the structure. In practical use, more or less frequency fluctuation is expected, and the working band should be wide to some extent. We thus are motivated to develop a structural optimisation for the periodic acoustic structures with wide working bandwidth.

In recent years, various structural optimisation for acoustic design are reported. Some researchers have already addressed optimal design methods for wideband acoustic devices. Such attempts can be classified into two types; One is based on robust topology optimisation [1, 2], while the other defines the objective function as the frequency-averaged scattering response [3, 4]. In both methods, the frequency response of the amplitude is estimated with the Taylor series or the Padé approximation based on its frequency derivatives. We have reported that the boundary element method combined with the automatic differentiation [2, 4] would be an ideal choice to compute the derivatives especially when the underlying boundary value problem is defined in an exterior domain.

In the present talk, we shall extend the boundary element method with the automatic differentiation to the periodic scattering problem. The boundary integral equation for the sound pressure is formulated with the Green function that satisfies the quasi-periodic boundary condition, whose frequency derivatives give the integral equations of the derivatives of the pressure. The kernels of the differentiated integral equations thus obtained are the frequency derivatives of the Green function. We develop a numerical method based on the Ewald method and the automatic differentiation to compute the kernels. We further implement the boundary element method based on the present kernel computation method. In the talk, we shall present some validation results and discuss the future directions.

A preconditioner based on Calderón's formulae for isogeometric boundary element methods for Maxwell's equations

Kanta Tahara[1] **and Kazuki Niino**[2*]

[1] Kyoto University, Yoshidahonmachi Sakyoku Kyoto Japan
[2] Kyoto University, Yoshidahonmachi Sakyoku Kyoto Japan, niino@i.kyoto-u.ac.jp

Key Words: BEM, Isogeometric analysis, Collocation, Calderón's preconditioner

The Calderón preconditioner for the isogeometric BEM (boundary element method) discretised with the collocation for Maxwell's equations is investigated in this paper. The Calderón preconditioning for the EFIE with the Galerkin method in general requires the use of the dual basis function such as the Buffa-Christiansen basis functions, which causes much computational time. We show that a dual basis function in the isogeometric BEM can be introduced in the same way as the original basis function, and that the computational time of a matrix corresponding to the EFIO (Electric field integral operator) discretised with the dual basis function is as much as that with the original basis function. With some numerical examples, we verify that matrices preconditioned with the proposed method are well-conditioned.

An acceleration of the time-domain boundary element method for electromagnetic scattering problems in 3D

Toru Takahashi[1*]

[1] Nagoya university, Furo-cho Chikusa-ku Nagoya city, toru.takahashi@mae.nagoya-u.ac.jp

Key Words: Time-domain Boundary Element Method, Fast Multipole Method, Electromagnetics

The purpose of this study is to establish a fast and memory-efficient time-domain boundary element method (TDBEM) for 3D transient electromagnetic wave problems on the basis of our previous study for the 3D wave equation [1, 2]. In the previous study, we developed a fast algorithm that is a variant of the fast multipole method (FMM) [3] and exploits the interpolation of the fundamental solution (and its derivatives). Similarly, we will show that an interpolation-based FMM can be formulated for the 3D Maxwell equations by considering, in particular, the Rao–Wilton–Glisson basis [4] and its analytical integrals. The computational complexity of the resulting fast (and approximating) TDBEM can be theoretically estimated as $O(N_{\mathrm{s}}^{\delta} N_{\mathrm{t}})$, where N_{s} and N_{t} denote the number of boundary elements and time-steps, respectively, and the exponent δ is $4/3$ or $3/2$ according to the assumption of the distribution of the boundary elements in space [1]. This is essentially faster than the conventional TDBEM with the complexity of $O(N_{\mathrm{s}}^2 N_{\mathrm{t}})$. As well as the conventional method, the fast method can deal with the models (scatterers) in arbitrary shapes in free (unbounded) space. Therefore, it can outperform the finite-difference time-domain (FDTD) method, which is the standard numerical method for the unsteady electromagnetic problems.

In this talk, we will formulate the interpolation-based FMM for 3D electromagnetic and show some numerical examples to validate the formulation.

Key Words: *Boundary element method, Nonsingular dislocation theory, Dislocation loop, Void, Image stress*

Dislocations are known as line defects in metallic materials, whose formation and movement dictates the plastic deformation. Geometrically necessary dislocations are the ones to accommodate for the deformation in a crystalline material. In an infinite elastic solid, the stress field generated by a dislocation can be obtained using Green's function, which resulted in either a surface integral for unclosed dislocation curves or a contour integral for a general dislocation loop [1]. Interestingly, this methodology shares similarity with that of the boundary element method. More recently, the modification that contributed to the removal of singularity in the stress field near the dislocation core eases the usage of the formula [2]. In particular, the nonsingular dislocation integral is readily applicable for dislocation curves near an internal free surface such as a void. By using boundary element method, which converts governing equations into also boundary integrals, the image stress due to the existence of internal surface can be computed. The merit of applying boundary element method is that only dislocated surfaces and the void surface need to be discretised, and that the surrounding infinity can be easily treated.

Compared with the classical approach of discretized dislocation dynamics (DDD) that disregards the actual shape of the dislocated surface, the proposed boundary element approach respects the arbitrariness of the dislocated surface, which can affect the displacement field caused by the dislocation [3]. Two types of geometrically necessary dislocations, namely, the prismatic dislocation loop and the shear dislocation loop have been considered in this investigation.

This study should pave the way towards an improved computational approach of modelling geometrically necessary dislocations with the presence of internal free surfaces.

Key Words: Time-domain BEM, General anisotropic elastodynamics, Convolution Quadrature Method (CQM), viscoelastodynamics, 2-D pure inplane problem

This paper presents a convolution quadrature time-domain boundary element method (CQBEM) for 2-D pure inplane anisotropic viscoelastodynamics. Since the boundary element method (BEM) is known as a suitable numerical approach for wave analysis, time-domain transient problems have been solved by many researchers using the classical time-domain BEM. However, it is known that the use of a classical time-domain BEM (TD-BEM) sometimes causes numerical instability in time-stepping procedures. In addition, the TD-BEM cannot solve wave problems with dispersion properties, such as viscoelastic and poroelastic wave problems. To overcome these difficulties, the convolution quadrature time-domain boundary element method (CQBEM) has been developed for last few decades. In the CQBEM formulation, the convolution quadrature method, first proposed by Lubich [1], is applied to the time discretization of the time-domain boundary integral equations to improve the numerical stability. The Laplace-domain fundamental solutions are utilized for the CQBEM formulation. The elastic wave scattering in viscoelastic and poroelastic solids has been analyzed by the CQBEM so far. However, no numerical examples of application of the CQBEM to the anisotropic viscoelastic wave propagation can be found as far as the authors know.

Therefore, in this study, the CQBEM for 2-D pure inplane anisotropic elastodynamics is developed by extending the previous approach for 2-D pure antiplane one [2]. In the formulation, the standard linear viscoelastic model and the fundamental solution obtained by Wang and Achenbach [3] are considered for the expression of viscoelastic and anisotropic properties, respectively. Elastic wave scattering by a cavity in anisotropic viscoelastic solids is demonstrated using the proposed CQBEM. The anisotropic and viscoelastic effects are confirmed from the numerical results to validate the proposed CQBEM.

Key Words: *Time-Dependent Incompressible Viscous Flow, Dual Reciprocity Boundary Element Method, Fundamental and Particular Solutions*

In industrial numerical simulation of the complex and/or large scale fluid flow, the computation cost must be reduced. We develop the numerical low cost solver for the incompressible fluid flow based on the fundamental and particular solutions of the differential operator.

In the limited computational resources for the divergence of the target complexity and the size of computational fluid dynamics, the computational cost must be reduced with keeping their accuracy. The solutions for this kind problem are for example suitable modeling, the developing of computer power, the fast algorithm, or reduction of computational cell numbers.

We payed attention to the boundary element method (BEM) using fundamental solution of the diffusion operator as a potential method to solve above problem, although we know that it is effective only for the linear problems of the fluid flow, and that for the incompressible viscous flow, it needs the internal integration with the inner computational points, so BEM's potential for the reduction of computational points is not effective.

In this paper we adopt dual reciprocity boundary element method[1] as the method of transforming the internal integration to the boundary integration and boundary element formulation[2,3] which avoids using the time-dependent fundamental solution in the time integration, as the algorithm becomes simpler. By this method the transient incompressible viscous flow problems will be solved with low cost and high accuracy.

If safe autonomous driving is achieved, all passengers in a car, including the driver can participate in in-car entertainment. However, even if it is achieved, the space in a car cabin is not still ideal for listening to music because of its small space that amplifies the reflected sound from its window glasses and other road noises and vibrations. This claim has been investigated by many recent studies using computer simulations [1, 2]. The sound field within the boundaries of a car can be computer-modeled and its changes when a person enters the car. Furthermore, car loudspeakers are often located near the driver or passengers in the car. These are the focus of this study. We measured the sound field in the car when there's a person in the driver's seat. We used a traverser system and a microphone array to measure the sound pressure distribution in the car. In addition, the sound field of the analysis model was simulated using the boundary element method. The acoustic impedance of each member of the car interior was measured using the ensemble averaging method.

Key Words: *Radial basis function, Boundary element method, heat transfer*

The quality of the numerical solutions obtained by the Boundary Element Method (BEM) is directly affected by the type of interpolation function used for the temperature interpolation, its normal derivative and geometry along the boundary. Interpolation by radial basis function augmented with polynomials has been shown to be more accurate than Lagrange interpolation for a range of different functions.

Therefore, this paper is concerned with the application of such functions as the interpolation functions for all boundary values in the boundary element method for the numerical solution of 2d heat transfer problems. Numerical examples with different geometries and temperature distribuitions are presented and comparisons with both isogeometric and classical formulation are made to demonstrate the improved accuracy of the proposed method.

Key Words: Heat Radiation, Topology Optimization, Boundary Element Method, Level Set Method

Optimization problems related to heat transfers, such as heat flux maximization and thermal diffusion problems governed by Laplace's equation, are important in various engineering design applications. One of the strong approaches for solving such problems is the level-set based topology optimization method, in which the shape of the structure is updated in accordance with the distribution change of the level set function caused by updating a reaction diffusion equation of the level set function.

In the conventional studies, only Dirichlet, Neumann, and Robin type boundary conditions have been treated in the topology optimizations[1] of thermal problems, and the thermal radiation boundary condition may not have been considered so far. In the present work, we consider a topology optimization problem accompanying a thermal radiation boundary condition. The boundary element method is used for the numerical computation, because the radiation boundary condition can be written as the boundary integrals of the heat fluxes, written in the form of a double layer potential, caused by the thermal radiation, thus the BEM is advantageous in treating those boundary integrals. [2] Moreover, the BEM can be used for thermal radiation problems of an infinite space without any approximation. We consider the thermal radiation boundary condition in the augmented objective functional and take its variation when an infinitesimal cavity under the same radiation boundary condition is generated in the material. A boundary value problem accompanying only linear boundary conditions is derived as the adjoint problem, and the topological derivative expression is derived, consisting of the original radiative flux and adjoint temperature. The derived topological derivative is used as the inhomogeneous term, corresponding a source term, of a reaction-diffusion equation of the level set function. The iso-surface of distribution of the level set function is repeated by using the derived topological derivatives, which are calculated by using the BEM both for the original and adjoint boundary value problems.

Key Words: *Surrogate model, Gradient-enhanced Kriging, Adaptive infill sampling method*

Over the past few decades, surrogate models have been utilized to numerous engineering problems to increase computational efficiency, especially when optimization involves expensive computational simulations. To enhance the performances of the surrogate model, there are some representative strategies such as screening, mapping, space reduction, decomposition, auxiliary information, and hybrid methods, etc. Among the methods of using auxiliary information, gradient-enhanced Kriging (GEK), an extension of Kriging, is a good approach when cheap gradient information is available. Numerous studies show that the accuracy of GEK models is generally better than Kriging, considering the equivalent simulation time. However, unlike the Kriging, GEK modeling time is dramatically increased for high-dimensional problems, and studies are still being performed to solve this problem.
This paper proposes new adaptive infill sampling methods for GEK to efficiently build the surrogate model while maintaining accuracy. If the next infill sample is selected, the proposed method adaptively decides whether to obtain the response alone or the response and gradient together when building the surrogate modeling. The proposed methods are developed based on mean-squared error and expected improvement. Numerical examples show that the proposed methods produce better results than existing methods.

Abstract:

Polynomial chaos expansion (PCE) is widely used in the field of stochastic uncertainty quantification due to its accuracy and convergence. However, when the problems of interest are high-dimensional, PCE is usually confront with the well-known curse of dimensionality and overfitting. This study proposes an adaptive sparse learning method based on the automatic relevance determination (ARD) and the Bayesian model averaging (BMA) to solve this problem. Firstly, the sparse Bayesian learning is used to develop an analytical Bayesian compressive sensing algorithm, providing an efficient regression tool for establishing a sparse PCE model. Secondly, to improve computational accuracy and efficiency, we employ the dimension-reduction method (DRM) to reduce the size of the candidate PCE bases. Different from the common univariate and bivariate DRMs, the high-dimensional components are considered adaptively in the proposed method. Thirdly, a novel ARD method is proposed based on the concept of maximum a posterior estimation, which can prune the candidate PCE bases. The pruned PCE is regarded as an initial model, and then the BMA is used to refine the high-fidelity sparse PCE. Compared with the direct use of the noninformation prior in BMA, the initial PCE model pruned by the ARD method can improve the rationality of the prior, resulting in a better posterior estimation. For verification, two numerical examples and one engineering example are analyzed. The results show that the proposed method can achieve accurate uncertainty quantification for high-dimensional problems with limited computational budget.

Key Words: *High Dimensional Reliability Analysis, Adaptive Kriging, Hybrid High Dimensional Model Representation, Hierarchical Kriging,*

Reliability is one of the most important factors in designing of engineering systems. Although many adaptive Kriging methods for reliability analysis have been researched, these methods are limited when they are applied to high dimensional reliability analysis problem, which is also known as the curse of dimensionality. To solve this problem, new adaptive Kriging method for high dimensional reliability analysis is proposed by adopting the concept of multi-fidelity metamodeling method.

The proposed method is composed of two adaptive Kriging methods. At the first step, adaptive Kriging method about first-order high dimensional model representation (HDMR) is conducted by adding univariate samples. With univariate samples selected by the first adaptive Kriging method, hybrid HDMR model is constructed. The proposed method is premised on the assumption that the hybrid HDMR can predict high dimensional limit-state function roughly. At the second step, hierarchical Kriging model that considers the hybrid HDMR as low-fidelity model is constructed, and adaptive Kriging method about hierarchical Kriging is conducted by adding multivariate samples. Multivariate samples are utilized not only as high-fidelity samples in hierarchical Kriging but also for estimating hybridity parameter of the hybrid HDMR, which makes full use of limited resources. The results of numerical examples show that the proposed method can evaluate accurate probability of failure more efficiently than other reliability analysis methods.

Key Words: *System Reliability, Reliability Based Design Optimization, Active learning function*

Uncertainties exist in complex engineering systems such as operation environment, material properties, and product dimension. Ignoring the uncertainties, the product may not satisfy the desired specification and have short life expectancy. Reliability based design optimization (RBDO) is researched to resolve these issues and applied to various mechanical systems. RBDO performs reliability analysis with a distribution of input random variables and optimizes the variables. Recently, sampling based reliability analysis methods based on Monte Carlo simulation (MCS) are widely used, and in particular, adaptive Kriging based methods have been researched. However, researches extended to optimization are insufficient, and there has not been the general system simulation cases. To resolve these issues, new system reliability based design optimization method using a new active learning function is proposed.

This research aims to solve general system reliability based design optimization (SRBDO) problems, where responses of part of constraints can be obtained by running one simulation model. The proposed method selects new sample points near the limit state functions based on new active learning function according to three types of systems, series, parallel, and combined systems. The points whose signs are certain are not selected for each constraint. System failure probability is estimated by the MCS method, and the partial derivative with respect to input random variables is also calculated to derive the SRBDO optimum. The validation results show that the proposed method effectively selects sample points near each constraint or simulation model.

Adaptive probabilistic integration for estimation of Sobol's sensitivity indices under epistemic uncertainties

Jingwen Song[1*], Jingyu Lei[2]

[1] Northwestern Polytechnical University, Xi'an, China, jwsong0879@163.com
[2] Xi'an modern Chemistry Research Institute, Xi'an, China, 15829205876@163.com

Key Words: *Probability-box; Epistemic uncertainty; Bayesian inference; sensitivity analysis*

Owing to various sources of uncertainties existing ubiquitous in the structural parameters or external excitations, it is difficult to provide robust and reliable predictions of the behavior of engineering systems. In this regard, uncertainty quantification has been prosperously developed to properly incorporate those uncertainties in predicting system performances. This study focuses on one of the main sub-tasks of uncertainty quantification, global sensitivity analysis (GSA), for measuring how the uncertainties in model response are apportioned to model input variables, in this way to inform the relative contribution of input variables in prediction uncertainties. Among GSA techniques, variance-based sensitivity indices, which are also known as Sobol's indices, have received the greatest attention and have been widely studied by researchers from many scientific fields including computational mechanics. In classic Sobol's indices, all the input variables are assumed to follow precise probability distributions. However, due to the lack of information or limited data in many practical problems, both randomness and imprecision need to be considered in mathematic descriptions to represent aleatory and epistemic uncertainties simultaneously.

This work aims to develop an effective approach to analyze the global sensitivity of imprecisely distributed variables. Specifically, to estimate Sobol's indices of uncertain variables characterized by parametric probability-box (p-box) type. In recent years, similar problems have been investigated with a few representative research work [1][2], but they don't consider active learning strategies as well as the prediction errors in surrogate model or stochastic simulation. We propose a novel adaptive probabilistic integration procedure to explore the augmented space of both the random variables and their corresponding distribution parameters. A Gaussian process regression (GPR) model is constructed in the augmented space, then sensitivity indices of input variables are statistically inferred based on Bayesian probabilistic integration, and the marginal effects of uncertain parameters are reserved within the posterior. Utilizing the exponential squared kernel function, the formulation of posterior mean and posterior variance for Sobol's main and total indices can be analytically derived. Motivated by Ref.[3], two learning functions are designed and collaboratively work to determine the next best training point to be added into the training procedure. Once the stopping criteria are satisfied in learning both the optimization of distribution parameters and the integration of input variables, we are able to obtain accurate and robust estimations of the bounds of Sobol's indices. The ranking of the imprecise indices is further investigated based on the definition in Ref.[4]. The effectiveness of the proposed method is demonstrated with a numerical example and a Timoshenko beam.

Computing Upper Probabilities using Global Optimization Algorithms together with Importance Sampling Techniques

Thomas Fetz

Unit of Egineering Mathematics, University of Innsbruck, Austria, Thomas.Fetz@uibk.ac.at

Key Words: upper probabilities, importance sampling, global optimization

Let $(X_t)_{t\in T}$ be a family of random variables $X_t : \Omega \to \mathbb{R}^d$ parametrized by t with smooth densities f_t. Then the upper probability $\bar{p} = \max_{t\in T} p(t)$ of an event D is obtained by global optimization where $p(t) = \int \chi_D(x) f_t(x)\,\mathrm{d}x$ is the probability function and χ_D the indicator function of D. In [1] we introduced the estimator $\hat{p}_{\omega,s}(t) = \frac{1}{N}\sum_{k=1}^N w_{st}(X_s(\omega_k))\cdot\chi_D(X_s(\omega_k))$ for p where $w_{st}(x) = f_t(x)/f_s^I(x)$ are the importance sampling weights for importance sampling density f_s^I corresponding to f_s. This follows from the fact that $p(t) = \int \chi_D(x) f_t(x)\,\mathrm{d}x = \int \chi_D(x)\cdot f_t(x)/f_s^I(x)\cdot f_s^I(x)\,\mathrm{d}x$. We note that in this approach all sample points $X_s(\omega_k)$, $k = 1,\ldots,N$, are based on the same fixed random numbers $\omega = \{\omega_1,\ldots,\omega_N\}$ on Ω for all $s \in T$. The special case of $s = t$ leads to the estimator $\hat{p}_\omega(t) := \hat{p}_{\omega,t}(t)$ which means classical importance sampling and using different samples for each $t \in T$. For fixed $s \in T$ the smooth function $\hat{p}_{\omega,s}$ is an approximation of $\hat{p}_\omega$ which we used in [1] to compute upper probabilities $\bar{\hat{p}}_{\omega,s}$, while here the focus is on the global optimization itself and how $\hat{p}_\omega$ and $\hat{p}_{\omega,s}$ can be used in the algorithms to compute efficiently estimates of upper probabilities.

One of the main problems for using global optimization algorithms which are not derivative-free is to compute derivatives of $\hat{p}_\omega$ because $\hat{p}_\omega$ is a step function even if the involved densities are smooth. The idea is here to use the following approximation of the partial derivatives needed for optimization: $\partial\hat{p}_\omega/\partial t_i(t) \approx (\hat{p}_{\omega,t}(t+h^{(i)}) - \hat{p}_{\omega,t}(t))/h_i^{(i)}$ with components $h_k^{(i)} = 10^{-8}\,\delta_{ik}$ of the vector $h^{(i)}$ of step sizes. We note that both estimators in the formula are based on the same sample which means that we differentiate a smooth function. A further problem is that the evaluation of χ_D may be very time consuming, e.g. finite element computations. In [1] we have seen that $\hat{p}_{\omega,s}(t)$ may be a bad approximation of $\hat{p}_\omega(t)$ for t far from s on which the sample is based and therefore not suitable to replace $\hat{p}_\omega$ by one single $\hat{p}_{\omega,s}$. Running an optimization algorithm leads to a sequence $t^{(1)}, t^{(2)}, \ldots, t^{(i)}, \ldots, t^{(j)}, \ldots$ of values. Assuming that in step i the estimator is computed in the more exact way using $\hat{p}_{\omega,t^{(i)}}(t^{(i)})$ based on the sample corresponding to $t^{(i)}$ itself, then the idea is to use an approximation $\hat{p}_{\omega,t^{(i)}}(t^{(j)})$ at $t^{(j)}$ if $\|t^{(j)} - t^{(i)}\| < \mathsf{TOL}$. This saves us N evaluations $\chi_D(X_{t^{(j)}}(\omega_k))$ because no new sample points are needed. We will apply these two methods for the algorithms in the MATLAB global optimization toolbox including examples.

Stochastic finite element method (SFEM) is a kind of widely used approach for analysis of engineering structure with random properties, which can compute structural responses. For the geometrically nonlinear analysis of uncertain laminated composite plate, the existing intrusive SFEMs, such as perturbation method and spectral SFEM, have the limitations of low computational accuracy and efficiency. The versatile non-intrusive SFEM based on Monte Carlo simulation needs a great computational effort to implement a lot of expensive finite element simulations. In this paper, a novel non-intrusive SFEM is developed to achieve stochastic responses and reliabilities of laminated composite plates with geometric nonlinearity efficiently and uniformly. Firstly, the direct probability integral method (DPIM) is developed to obtain the probability density function of stochastic response of linear or nonlinear structure by solving probability density integral equation (PDIE) [1]. Secondly, the non-intrusive SFEM based on DPIM decouples the deterministic finite element analysis and PDIE to calculate the stochastic responses and reliabilities of uncertain laminated composite plates. The third-order shear deformation theory is employed to model the displacement field of laminated composite plate, and the discretization and quantification of random fields are implemented through Karhunen-Loève expansion. Finally, comparisons with the results from Monte Carlo simulation and literature show the high accuracy and efficiency of the proposed non-intrusive method. A few examples covering various features have been presented for uncertain laminated composite plates with different boundary conditions, correlation length, mean and variability of random field.

Key Words: *Industrial robot, Reliability analysis, Evidence theory, Positioning accuracy; Uncertainty*

As one of the important equipment of intelligent manufacturing, the positioning accuracy of industrial robots has become a common concern. As a complex mechatronics product, industrial robots system have extensive aleatory uncertainties which affects its positioning accuracy reliability. In order to study the influence of epistemic uncertainty on positioning accuracy of industrial robots, this talk includes two aspects. On the one hand, an evidence-theory-based reliability analysis method through Kriging model is proposed. Kriging model is used to replace the performance function in positioning accuracy reliability analysis of industrial robots, which can achieve high efficiency and high accuracy for reliability analysis. The popular U function is used to establish the Kriging model for evidence-theory-based reliability analysis. On the other hand, a probability-evidence hybrid reliability analysis method is proposed to deal with the coexistence of aleatory uncertainty and epistemic uncertainty in industrial robots. Probability theory and evidence theory are used to describe the aleatory uncertain parameters and epistemic uncertain parameters, respectively. Random variables and evidence variables are introduced into the probability-evidence hybrid model to obtain the reliability interval of positioning accuracy of industrial robots. The reliability of positioning accuracy of industrial robots is no longer a determined value but a more objective interval. The two aspects work present a possible way to solve the problem of epistemic uncertainty of industrial robots, which can help engineers have a clear understanding of the accuracy reliability of industrial robots.

Abstract: Computational stochastic mechanics involves the topics of simulation of random field or stochastic process, stochastic structural analysis, random vibration, reliability estimation and reliability-based design optimization. However, the existing methods only focus on parts of these topics, resulting in the complicated calculation and the absence of versatility. Nevertheless, the limited scope of application of approximation methods, inaccuracy and inefficiency of numerical approaches and the expensive computational cost of stochastic sampling methods restrict the development of stochastic mechanics. In this study, the novel direct probability integral method (DPIM) as a unified framework is proposed to solve the uncertainty quantification and reliability-based design optimization problems of static and dynamic structures. This method decouples the computation of probability density integration equation (PDIE) and governing equation of structures, and can achieve the probability density functions of stochastic responses and reliabilities for linear or nonlinear structural systems [1−3]. Firstly, the PDIE governing the propagation of randomness from input to output is derived based on the principle of probability conservation. The two key techniques, i.e., the partition of probability space and smoothing of Dirac delta function, are introduced to solve the PDIE. Then, the first-passage dynamic reliability based on the equivalent extreme value mapping and its sensitivity as well as reliability-based design optimization are addressed. Finally, several examples of static and dynamic structures illustrate that the DPIM is an accurate, efficient and unified methodology for uncertainty quantification and design optimization, especially for large-scale nonlinear structures under random excitation.

Inferential Uncertainty in Surrogate-based Inference - a Bayesian Estimate

Sascha Ranftl[1*] **and Wolfgang von der Linden**[1]

[1] Graz University of Technology, Petersgasse 16, 8010 Graz, Austria, ranftl@tugraz.at

Key Words: uncertainty quantification, uncertainty propagation, surrogates, meta-models, emulators, Bayesian probability theory, model adequacy, surrogate uncertainty, inferential uncertainty

Uncertainty quantification is a crucial aspect of model prognosis quality assessment and often only feasible by an approximating surrogate model. One powerful aspect of Bayesian approaches [1, 2] is that it allows to treat any kind of uncertainty, model error, numerical imprecision or randomness on the same footing and with the same set of computing rules; namely as propositions [3]. Through this, we introduce and quantify the uncertainty of the surrogate itself, or its trustworthiness, as a continuous variable. This is related to what Song et al. [4] recognize as epistemic uncertainty of sensitivity index estimates. Here, this aspect is investigated for a probabilistic, generalized linear surrogate model, which includes both Polynomial Chaos Expansions and Kriging [5] as special cases, by acknowledging the uncertainty of surrogate parameter estimates. As a result, we find expressions for the evidence for, as well as the uncertainty of, the surrogate itself [6]. Then, the surrogate uncertainty is propagated to the actual Quantity of Interest (QoI). As it turns out, the surrogate's uncertainty causes an additional inferential uncertainty in the QoI that can be solely attributed to the use of an approximative surrogate. As a consequence, model predictions are easily over-confident if these inferential uncertainties are naively neglected. This fact is demonstrated with a numerical example. From this finding, a novel quality measure for surrogate models emerges naturally, without ad-hoc assumptions. This measure compares the average surrogate prediction uncertainty to its inferential uncertainty and is based on both simulation and experimental data.

Key Words: Material design, uncertainty quantification, Inverse problem, active learning

By leveraging the power of modern high performance computing, significant advances have been made in understanding/building computational strategies for capturing nonlinear and multiscale nature of complex materials. Fewer efforts have been put into inverting the process-material-performance chain and to integrating uncertainties which are an indispensable component of materials' design. We propose a novel probabilistic framework to formulate the problem of optimization/design of material processing with respect to objectives pertaining to the performance of the systems in which material is used. A flexible, fully probabilistic formulation of such optimization problems accounts for the parameter-material property and material property-performance link and enables the identification of optimal, high-dimensional, process parameters.

We advocate the use of probabilistic data-driven surrogates for the parameter-material property and material property-performance link, that are capable of learning under Small Data, that incorporate physical constraints and are able to quantify their predictive uncertainty. Efficient tools are developed to integrate over this high-dimensional surrogates. These tools inform our novel active learning strategy, i.e. a self-supervised collection of data, which significantly improves accuracy while requiring small amounts of training data. We demonstrate the efficacy of the framework for different systems in which concrete is used and report on its performance.

Bayesian system identification determines the parameters of models from measurements of the system response. The underlying inverse problem is formulated in a probabilistic setting, and Bayes' rule is applied to update a prior conjecture on the parameters with the data. We apply the Bayesian framework to identify the parameters of structural systems using frequency domain measurement data. The likelihood function expressing the measurement information is formulated in terms of the misfit of the data and the model frequency response function. Often, it is assumed that the model misfit between different observations is uncorrelated. It can be shown, however, that this assumption does not hold in general and that neglecting the correlation between observations leads to poor estimates of the posterior distributions [1]. In this study, we focus on the investigation of correlation models that describe the autocorrelation of the model error in the spatial and frequency domain. Previous approaches have used standard correlation models, such as the exponential model, to account for the correlation between different points [1,2]. In [2], we interpret the model error as a complex random variable. In this contribution, we propose a complex-valued correlation function to describe the model error correlation. Furthermore, we investigate models that include a sinusoidal pattern to take into account the periodicity in the system response. The proposed models are successfully applied to identify the stiffness and damping parameters of a finite element model of a plate structure. We evaluate the performance of the different correlation models by comparing their evidence.

Real-time structural health monitoring represents a valuable service for airlines and the aeronautical industry in general. Indeed, planned preventive maintenance based on accurate forecasting would increase the safety of operations and reduce their costs. Structural health monitoring consists in the automated implementation of a strategy to determine the health status of a structure at regular intervals.

The present work investigates a methodology of real-time structural health monitoring of an aircraft engine fan blade equipped with a minimum set of sensors placed in an optimized way to detect and locate degradations. Recent technological advancements in sensors have led to a significant interest in data-driven modeling techniques for structural health monitoring [1]. Following this trend, an undamaged data-driven model that uses proper orthogonal decomposition to compress a database comprising static and dynamic displacements was developed. The proposed method relies on a sample of fluid structure simulations and provides good approximate solutions with a reduced calculation time by exploiting a pre-constructed reduced basis.

This reduced basis can also be used to define an optimized sensors placement on the structure. Indeed, the obtained data must allow the accurate reconstruction of the displacement field. However, usual methodologies used for optimal sensors placement, such as discrete empirical interpolation and QR-pivoting, are limited because the number of sensors is correlated with the truncation of the reduced basis. The present work proposes a new methodology for sparse sampling that allows a full signal to be reconstructed from a small subset of measurements. This subset is constructed assuming that the number of sensors is greater than the size of the reduced basis. The sensors can detect every damage and are placed in a non-redundant way to avoid aggregation problems on the physical structure [2]. The methodology provides a robust and instantaneous full-state reconstruction of the displacements and therefore allows a reliable detection and accurate localization of the onset of an anomaly on the structure.

Key Words: *proper orthogonal decomposition, tunnel lining, missing data, numerical simulation, mechanized tunnelling, real-time simulation*

Mechanized tunnelling is a flexible and efficient technology for the construction of underground infrastructure. As the main structure of a tunnel, tunnel linings are designed to permanently fulfil basic structural, serviceability and durability requirements throughout the lifetime of a tunnel. Therefore, it is important to correctly assess the response of the tunnel lining with respect to the loads from the ground and from the tunnelling process to which lining structures are subjected in order to ensure the structural reliability [1]. In general, tunnel lining deformations are monitored using only a limited number of sensors installed at specific locations around the tunnel.

In this work, a simulation-based approach is presented, which allows predicting the complete tunnel lining deformation using the limited sensors information in combination with the Gappy Proper Orthogonal Decomposition method [2]. In this approach, a numerical simulation model is employed to simulate the complete tunnel lining behaviour under different possible loading scenarios. The real sensor measurements at limited locations are then utilized together with the simulation data in the context of a reconstruction problem to predict the behaviours at other locations around the tunnel. This allows to get a real-time response of the tunnel lining deformation field, which can be used to assess the current structural reliability. Additionally, the approach can also provide suggestions of locations around the tunnel where the sensors should be installed in order to maximize the prediction accuracy of the presented approach.

Accelerating a Nonparametric Probabilistic Method for Physics-Based Data-Driven Modeling and Uncertainty Quantification

Marie Jo Azzi[1*], Chadi Ghantios[2] and Charbel Farhat[3]

[1] Stanford University, Stanford, CA, 94305, USA, mjazzi@stanford.edu
[2] Notre Dame University, Louaize, Lebanon, cghnatios@ndu.edu.lb
[3] Stanford University, Stanford, CA, 94305, USA, cfarhat@stanford.edu

Key Words: *data-driven modeling, stochastic optimization, uncertainty quantification*

The nonparametric probabilistic method (NPM) presented in [1] for modeling and quantifying uncertainty is a multi-faceted, data-enhanced, computational modeling method. Because it is grounded in projection-based model order reduction, it is data-driven – even in the absence of experimental data – and computationally tractable. Essentially, NPM is a physics-based, machine learning method for extracting from data fundamental information and/or knowledge that are not captured by a deterministic, high-dimensional computational model (HDM) of dimension N, and infusing them into a counterpart stochastic, projection-based reduced-order model (PROM). Starting from a deterministic HDM, NPM constructs in three steps a counterpart stochastic, hyperreduced PROM (SHPROM). First, it builds a deterministic PROM of dimension $n \ll N$ and hyperreduces it. Next, it substitutes the deterministic Reduced-Order Basis (ROB) underlying the PROM with a stochastic counterpart (SROB) that it constructs on a subset of a compact Stiefel manifold, using a number of hyperparameters that grows as of $O(n^2)$. Finally, it identifies the hyperparameters by formulating a statistical inverse problem such that the mean value and statistical fluctuations of some quantities of interest predicted using the resulting SHPROM match target values obtained from data; and solving the corresponding optimization problem.

While the potential of NPM for quantifying model-form uncertainties has been successfully demonstrated for a number of applications [2], its practicality is contingent upon the computational tractability of the solution of the optimization problem underlying the identification of its hyperparameters. This problem is non-convex, stochastic, and therefore computationally intensive. So far, it has been solved using gradient-based methods where the sensitivities of the objective function with respect to the hyperparameters are computed by finite differencing, which has raised robustness and performance issues. For highly nonlinear HDMs where the SHPROM has typically a dimension $n \geq 20$, these issues are exacerbated by the larger size of the stochastic optimization problem. Here, they are addressed by a two-pronged approach. First, NPM's inverse statistical problem – and therefore its number of hyperparameters – is reduced from $O(n^2)$ to $O(n)$ by developing a network of autoencoders that provide a nonlinear approximation of the dependence of the randomized reduced-order basis on its hyperparameters. Second, the sensitivities of the objective function of the optimization problem with respect to the hyperparameters are computed analytically, by tracking the complex web of operations underlying the construction of the stochastic objective function. The net result is an implementation of NPM whose robustness and performance are dramatically improved. These improvements and the potential of the enhanced NPM for the physics-based, data-driven modeling of solid mechanics / structural dynamics problems and the reduction of their model-form uncertainty is demonstrated on an application pertaining to a jet engine nozzle problem.

Key Words: Impact Problems, Dyadic Random Field, Wave Propagation, Response Amplitude

We report a study of impact problems on random fields. First, an impact model is formulated as a boundary value problem for a stochastic partial differential equation, where the randomness is incorporated into the differential operator with the help of two homogeneous and isotropic random fields, one of each is scalar-valued and describes the mass density, and another one is rank 2 symmetric tensor-valued and describes the stiffness. See [1] for detailed description of the above approach.

Our study is an extension of the previous studies [2, 3]. We suppose that the stiffness random field governing the impact dynamics is represented as the sum of the deterministic mean value and a positive-definite dyadic product of two vector-valued Gaussian random fields. For the latter fields, we suppose that their spectral densities belong to a prescribed parametric class. Using the Monte Carlo simulation approach, we study the mean response amplitude and the sensitivity of wave propagation for a wide range of parameters that describe the fractal dimension and Hurst parameter of the governing fields.

Information-Theoretic Stochastic Models for Uncertainty Quantification in Computational Plasticity

Shanshan Chu[1] **and Johann Guilleminot**[1*]

[1] Department of Civil and Environmental Engineering, Duke University, Durham, NC 27708, USA,
{shanshan.chu,johann.guilleminot}@duke.edu

Key Words: Anisotropic Plasticity, Hill Coefficients, Information Theory, Stochastic Modeling, Uncertainty Quantification

While uncertainty propagation through plasticity models has been studied quite extensively, either by means of Monte Carlo simulations or by using polynomial chaos expansions, contributions focusing on the proper modeling of stochastic input parameters in computational plasticity remain very scarce. In this work, we address the construction of information theoretic stochastic models, and focus on the case of anisotropic Hill plasticity. A formulation involving a low-dimensional parameterization is first laid down. We subsequently apply the framework to model variations observed in physical experiments on materials processed by additive manufacturing. Uncertainty propagation is finally conducted to gain insight about the impact of material variability on the structural response of complex structures.

A Painless Automatic *hp*-Adaptive Coarsening Strategy For Non-SPD Problems: A Goal-Oriented Approach

Felipe V. Caro[1*], Vincent Darrigrand[3], Julen Alvarez-Aramberri[1], Elisabete Alberdi Celaya[2] and David Pardo[2,1,4]

[4] IKERBASQUE, Basque Foundation for Science, Bilbao, Spain

Key Words: *hp*-Adaptivity, Goal-Oriented Adaptivity, Unrefinements, Finite Elements

In the context of *hp*-adaptivity, Darrigrand et al. [1] introduced a novel automatic mesh-refinement strategy based on a multi-level hierarchical data structure proposed by Zander et al. [2]. Darrigrand et al. [1] algorithm marks the basis functions with the lowest contributions to the energy of the solution. It removes them to achieve an automatic *hp*-adaptive strategy built upon an unrefinement process that optimizes the existing computational resources. However, the global energy of the problem may be a quantity of limited relevance. Thus, many engineering applications require the approximation of a specific Quantity of Interest (QoI). Mesh adaptive algorithms intended to approximate a specific QoI are known as Goal-Oriented adaptive algorithms (see, e.g., [3-4]). They look for an accurate approximation of the QoI using an error estimator to guide refinements based on the solution of the dual problem. In this presentation, we extend the previous work [1] to goal-oriented symmetric positive definite (SPD) and non-SPD problems, re-defining the contribution to the energy to take into account both the direct and the adjoint problem. We test and analyze our algorithm on two-dimensional (2D) Poisson and Helmholtz problems, and we describe the main features and limitations of the proposed method. In particular, our algorithm is robust and straightforward to implement; therefore, it can be used for industrial applications.

Key Words: Adaptive finite element methods, a posteriori error estimates, higher order methods

In a posteriori error analysis, the relationship between error and estimator is usually spoiled by so-called oscillation terms, which cannot be bounded by the error. In order to remedy, [1] devised a new approach for the standard linear finite element method where the oscillation has the following two properties. First, it is dominated by the error, irrespective of mesh fineness and the regularity of data and the exact solution. Second, it captures in terms of data the part of the residual that, in general, cannot be quantified with finite information. The new twist in the approach is a locally stable projection onto discretized residuals. In the case of the Poisson problem, the approach leads to an improved standard residual estimator and allows tackling problems with sources in H^{-1}.

We shall present a generalization of this approach to higher order methods.

Adaptive Concurrent Multiscale Modelling Using Hybridized Discretizations, Error Estimation and Machine Learning

Tim Wildey[1]

[1] Sandia National Labs, Albuquerque, NM, tmwilde@sandia.gov

Key Words: *Multiscale modelling, adaptive modelling, error estimation, hybridized discretizations, machine learning*

Multiphysics systems are often strongly coupled, highly nonlinear and characterized by multiple physical phenomena that span a large range of length- and time-scales. Performing direct numerical simulation of such systems that resolves all the relevant length- and time-scales is often prohibitive, even on the modern leadership-class computing platforms. Nevertheless, these fine-scale variations often impact the behaviour of the system on a much larger scale in non-negligible ways. Thus, one often seeks to model or approximate the subgrid scale phenomena to accurately and efficiently capturing their impact on the coarse scale solution. Multiscale formulations based on non-overlapping domain decomposition methods have the additional benefit of allowing different physical models and numerical discretizations in different regions. However, determining the optimal subgrid model within a coarse scale region that effectively balances accuracy and computational expense can be challenging for transient nonlinear multiphysics applications.

In this presentation, we describe our theoretical and computational frameworks that are based on a generalization of hybridized discretizations and are designed to exploit heterogeneous computational architectures to enable concurrent multiscale modelling on a range of transient nonlinear multiphysics applications. We will also describe our utilization of dynamic adaptive subgrid modelling and how we are utilizing a posteriori error estimation procedures and supervised machine learning strategies to determine the appropriate subgrid model for an element in the coarse scale partition. We will provide demonstrations on applications motivated by subsurface flow and mechanics in porous media and additive manufacturing.

Key Words: *uncertainty quantification, adaptivity, stochastic collocation, gas transport in networks, model hierarchy, balance laws, Euler equations at junctions*

In this talk, we will present recent results for the quantification of uncertainties that arise from intra-day oscillations in the demand for natural gas transported through large-scale networks [2]. The short-term transient dynamics of the gas flow is modelled by a hierarchy of hyperbolic systems of balance laws based on the isentropic Euler equations. We extend a novel adaptive strategy for solving elliptic PDEs with random data, recently proposed and analyzed in [1] to uncertain gas transport problems. Sample-dependent adaptive meshes and a model refinement in the physical space are combined with adaptive anisotropic sparse Smolyak grids in the stochastic space. A single-level approach, which balances the discretization errors of the physical and stochastic approximations, and a multi-level approach, which additionally minimizes the computational costs, are considered. Two examples taken from a public gas library demonstrate the reliability of the error control of expectations calculated from random quantities of interest, and the further use of stochastic interpolants to, e.g., approximate probability density functions of minimum and maximum pressure values at the exits of the network.

Anisotropic adaptive finite elements for aluminium electrolysis

Paride Passelli[1] **and Marco picasso**[1*]

[1] Institute of Mathematics, EPFL, SB-MATH, Station 8, 1015 Lausanne, Switzerland

Key Words: Aluminium electrolysis cells, anisotropic adaptive finite elements, anisotropic error indicator, nonlinear p-Laplace problem

Anisotropic, adaptive finite elements have shown to be very efficient for solving pde's with boundary or internal layers. The application to fluid flow in aluminium electrolysis cells will be presented, where two immiscible, incompressible and turbulent fluids are involved. Using the anisotropic error indicator presented in [1] for Stokes' problem, anisotropic adapted meshes will be used to produce accurate results with far less vertices than uniform meshes.

The error indicator will be justified on the simplified nonlinear problem (some kind of p-Laplace problem):

$$-\text{div}\,((\mu+|\nabla u|)\nabla u) = f,$$

where μ corresponds to the laminar (constant) viscosity and $|\nabla u|$ to a turbulent (Smagorinsky) viscosity. Numerical experiments will show that the use of quasi-norms as in [2] is needed to obtain effectivity indices close to one.

Key Words: Inverse analysis, Hierarchical model selection, Data-based enrichment

In the context of computational engineering, physical systems are classically represented by a mathematical model which can be picked in a hierarchical list of possible models, with increasing complexity, and which is then numerically processed to obtain a virtual twin. In such a framework, a critical error source comes from imperfect modeling. Therefore, for safe decision-making, there is a need for certification of the predicted outputs, with consistency between physical reality and numerical models; this is the matter of model parameter updating, but also model enrichment in order to correct model bias from data-based information (hybrid approach). On the other hand, there is a need for effectivity, in order to perform fast data assimilation and control as required in Dynamic Data Driven Application Systems (DDDAS) in which a continuous exchange between simulations and experimental measurements is implemented. The goal is thus to compute right at the right cost, with smart management of computing resources depending on the objective and complexity of the observed physical phenomena. This resorts to model adaptivity and suitable selection of a reference mathematical model in view of experimental data.
The talk addresses these various topics by using the Constitutive Relation Error concept. In its modified version [1, 2], it is a powerful, relevant, and robust tool to perform suitable modeling and simulation with respect to experimental information. During the presentation, the philosophy and performance of this tool will be shown on several recent mechanical engineering applications related to (sequential) model parameter updating with noisy data (e.g. [3]), but also data-based model selection and correction with regards to rich data coming from full-field measurements or distributed optic fiber sensing.

This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No. 101002857)

Key Words: Goal-oriented adaptivity, MLMC, Matérn random fields, ellptic random PDE

Multilevel Monte Carlo methods (MLMC) can dramatically reduce the computational cost of Monte Carlo simulations where each sample is computed using a discretization based numerical method, for example, when computing the expected value of a quantity of interest (QoI) depending on the solution to a partial differential equation with stochastic data.

Goal-oriented adaptive finite element refines the mesh based on the error contribution to the QoI. The method is effective, for instance, when the geometry presents a singularity, such as a non-convex domain.

The purpose of this work is to combine MLMC and adaptive finite element solvers, to efficiently solve a boundary-value problem of an elliptic partial differential equation with random coefficients on a non-convex domain. The QoI is a linear functional of the PDE solution, and the coefficient field is efficiently sampled from a regular coefficient random field. The adaptive refinement algorithm is based on [1]. This work can also be seen as an extension of [2].

Key Words: A posteriori Error Estimation, Optimal Transport, Minimization Problems with Constraints

The talk will deal with the development and analysis of optimal approaches for mesh adaptation for the discretization of classical boundary-value problems. One can mathematically show that some greedy adaptive methods provide optimal rates of convergence with respect to the energy norm or some quantity of interest for simple problems such as those given in terms of symmetric positive-definite boundary-value problems [1, 2, 3]. Performance of the methods for general problems is far less clear. The objective of the talk will be to reformulate mesh adaptivity in terms of minimization problems with constraints, based either on classical optimization theories [4, 5] or on concepts from optimal transport [6]. The performance of the different formulations will be compared on classical model problems.

Key Words: *Porous media, Computational Homogenizaition, Reduced Order Modeling, Error Control*

The problem of determining the mechanical response of heterogeneous fluid-saturated porous rock using computational homogenization is considered. One standard approach is the so-called "finite element squared" (FE^2) procedure, where a new boundary value problem for the coupled porous media problem is defined on a Representative Volume Element (RVE) in each macroscopic quadrature point. In the case of non-linear or transient effects, the effective response must be computed on the fly, making the strategy computationally intractable in practice for detailed RVE-structures. It is therefore of interest to reduce the cost of solving the individual RVE problems by introducing a reduced basis, here denoted Numerical Model Reduction (NMR).

Computational homogenization using NMR was presented by Jänicke et al. [1], considering Proper Orthogonal Decomposition (POD), and extended by Ekre et al. [2] where an a posteriori error estimator was presented. In addition to POD, Spectral Decomposition (SD) was also used for basis generation in the latter work. It was shown that the POD basis outperforms the SD basis in terms of accuracy, but the SD basis behaves better in that it did not overestimate the error as much.

In this contribution, we complete the computational strategy by presenting a novel procedure for adaptively enriching the NMR-basis with either POD- or SD-basis functions using a refinement indicator derived from the error estimator. Previous work is also extended by considering non-linear modelling in terms of deformation-dependant permeability. The generation of POD-basis is unaffected by the non-linearity and the generation of spectral modes can still be carried out based on a linearization. However, the accuracy of the reduced approximation typically reduces with the amplitude of the non-linearity. The previously developed error estimator is linearized in a manner that it presents guaranteed bounds on the error in the limit of infinitesimal loading.

We study a few numerical examples of 3D RVE-structures, where we seek the effective response during prescribed loading of varying amplitude. The robustness and accuracy of the linearized error estimate and the efficiency of the adaptive basis enrichment procedure are investigated.

Optimality of Adaptive Time-Stepping

Michael Feischl

TU Wien, Wiedner Hauptstraße 8-10, 1040 Vienna, Austria, michael.feischl@tuwien.ac.at
(www.asc.tuwien.ac.at/feischl)

Key Words: adaptive mesh refinement, optimality, error estimation, non-stationary problems

In the recent work [1], we prove new optimality results for adaptive mesh refinement algorithms for non-symmetric, indefinite, and time-dependent problems by proposing a generalization of quasi-orthogonality which follows directly from the inf-sup stability of the underlying problem. This completely removes a central technical difficulty in modern proofs of optimal convergence of adaptive mesh refinement algorithms and leads to simple optimality proofs for the Taylor-Hood discretization of the stationary Stokes problem, a finite-element/boundary-element discretization of an unbounded transmission problem, and an adaptive time-stepping scheme for parabolic equations. The main technical tool are new stability bounds for the LU-factorization of matrices together with a recently established connection between quasi-orthogonality and matrix factorization.

Key Words: equilibrated flux reconstruction, Maxwell's equations, Sobolev space $\boldsymbol{H}(\mathrm{curl})$, Sobolev space $\boldsymbol{H}(\mathrm{div})$, p-robustness, a posteriori error estimate, divergence-free decomposition

A posteriori error estimates by flux equilibration are nowadays well established for many model problems. This is, however, not the case for the curl–curl problem, as a simplification of Maxwell's equations. In this contribution, we describe two novel estimates for its Nédélec finite element discretization.

In the first case, we avoid the use of the Prager–Synge equality. We devise a "broken patchwise equilibration", relying on small patches of tetrahedra around the edges of the mesh. Mathematically, this is related to the localization of the residual with test functions in $\boldsymbol{H}_0(\mathrm{curl})$. The resulting estimators are reliable, locally efficient, and polynomial-degree-robust, but contain some (computable) constants.

In the second case, we design a full equilibration in that we construct a $\boldsymbol{H}(\mathrm{curl})$-conforming Nédélec piecewise polynomial with a prescribed curl. Our procedure relies on larger patches of tetrahedra around vertices and is mathematically related to the localization of the residual with test functions in $\boldsymbol{H}(\mathrm{curl})$ and to a divergence-free decomposition of a given divergence-free $\boldsymbol{H}(\mathrm{div})$-conforming Raviart–Thomas piecewise polynomial. The resulting estimators are here reliable, locally efficient, polynomial-degree-robust, and constant-free, since obtained via the Prager–Synge equality.

Stable extensions of piecewise polynomial data prescribed in a patch of tetrahedra sharing an edge/vertex are a central theoretical tool. Numerical results illustrate the theoretical developments. This is a joint work with Alexandre Ern (first case, [1]) and with Théophile Chaumont-Frelet (both cases, [1, 2]).

Key Words: *Topology optimization, Superconvergent Patch Recovery, statically admissible stress field, equilibrated tractions*

In 2-level topology optimization (TO), an initial TO iteration run on a coarse mesh (the macro-level) is followed by a TO iteration run on a fine mesh (meso-level) at each of the cells defined by the elements of the macro-level. In structural applications, the boundary tractions applied on each cell of the meso-level are evaluated from the FE stress field of the macro-level. Geometrical continuity between adjacent cells is required in structural applications for a proper load transference between cells. This geometrical continuity cannot be obtained if different traction distributions are applied on the shared faces of adjacent cells. Hence, this geometrical continuity cannot be achieved considering the FE stress field, obtained at the macro-level, since tractions acting on conforming element faces that equilibrate with an internal stress field do not usually maintain the element in equilibrium, and neither are they codiffusive with adjacent elements. Thus, for 2-level TO, we need to postprocess the FE stress field of the macro level to obtain a stress field that provides both, the traction continuity between adjacent cells and the equilibrated tractions at each cell. Hence, we would need a statically admissible stress field.

In this work, and in the framework of the Cartesian grid FEM (cgFEM) [1], we revisit the use of two techniques aiming at evaluating statically admissible stress fields, previously developed in the traditional context of discretization error bounding/estimation. On the one hand, we will consider the process based on the use of graphs showing the interactions between neighbour elements and Maxwell force diagrams [2] used by Ladevèze in the Constitutive Relation Error method. On the other hand, from the context of the Recovery-based error estimators developed by Zienkiewicz, we consider an extension of the Superconvergent Patch Recovery (SPR) technique, the SPR-C technique [1], that uses constrain equations to ensure the satisfaction of the internal and boundary equilibrium equations at patch level. This work analyses the behaviour of these two techniques in 2-level TO.

Key Words: Mesh adaptation, Automatic simulation, Mesh convergence, Ship resistance

Mesh generation is a bottleneck for the current industrial use of CFD, due to its dependence on expert user knowledge and its unpredictable cost, since iterative modification of the meshes may be needed to correctly resolve flow features. Adaptive mesh refinement is a natural solution to these problems. However, mesh adaptation is only acceptable in an industrial context if it can be performed automatically, with little or no user intervention, and if it is robust enough to produce reliable solutions for a large range of test cases.

This paper studies the use of adaptive refinement for the industrial simulation of free-surface water flows. We ensure the reliability of the simulation results by two means. First, the computational setup is automated; physics-based arguments are used to derive guidelines to automatically set the simulation parameters correctly for each simulation, independent of the flow conditions and the geometry [2]. With these parameters, adaptive meshing produces grids that are suitable for capturing each flow.

Furthermore, the metric-based refinement criteria that we use make it easy to produce series of coarse to fine meshes, which can be combined with classical numerical uncertainty estimation procedures [1]. It is shown that the grid convergence obtained is remarkably smooth for unstructured meshes, which implies that the estimated uncertainty bounds are sharp and accurate.

The procedure is demonstrated for the resistance evaluation of ships. A first test case is used to fine-tune the simulation guidelines, which are then applied unchanged to three other ships, ranging from a destroyer to a supertanker. In all cases, the simulation results are good, which proves the generality of the approach. Thus, the mesh adaptation and uncertainty estimation procedure appears powerful and reliable enough for routine use in industry.

Manufactured Solutions for the Method-of-Moments Implementation of the Electric-Field Integral Equation

Brian A. Freno[1*], Neil R. Matula[1], and William A. Johnson[1]

[1] Sandia National Laboratories, Albuquerque, NM, bafreno@sandia.gov

Key Words: Method of Moments, Electric-Field Integral Equation, Code Verification, Manufactured Solutions

Though the method-of-moments implementation of the electric-field integral equation plays an important role in computational electromagnetics, it provides many code-verification challenges due to the different sources of numerical error. In this talk, we provide an approach through which we can apply the method of manufactured solutions to isolate and verify the solution-discretization error. We accomplish this by manufacturing both the surface current and the Green's function. Because the arising equations are poorly conditioned, we reformulate them as a set of constraints for an optimization problem that selects the solution closest to the manufactured solution. We demonstrate the effectiveness of this approach for cases with and without coding errors.

Considering epistemic uncertainty in optical marker based joint angle calculation during human gait

Eduard S. Scheiterer[1*], Simon Heinrich [1], Sigrid Leyendecker [1]
Chair of Applied Dynamics, University of Erlangen-Nuremberg

[1] Institute of Applied Dynamics, Friedrich-Alexander-Universität Erlangen-Nürnberg, Immerwahrstrasse 1, D-91058 Erlangen, Germany, www.ltd.tf.uni-erlangen.de

Key Words: Epistemic uncertainty, Uncertainty modelling, Uncertainty propagation, Soft tissue artifacts, Human gait, Joint angle calculation

Joint angles during human gait are commonly computed from data measured via optical marker based motion capture [1]. For this, markers are placed on the human body and their position is tracked with cameras. Based on the measured positions paired with the correlation of the placement of markers relative to the person's physiology, the joint angles and segment positions can be calculated and evaluated. This process has multiple sources for uncertainty. The measurement of the marker positions as well as their position on the body is affected by uncertainty. Furthermore, due to the relative motion between bones and skin, soft tissue artefacts (STAs) further increase the uncertainty.

In this work, we examine the different causes for uncertainty in the measurement and calculations and propagate it forward, using an epistemic (fuzzy) uncertainty model and α-level optimisation [2, 3]. For each marker, we assume that it's true position is within a sphere around the measured position, whose radius is modelled by a convex fuzzy number. This means the radius can vary within an interval and each value within this interval is assigned a membership value, based on the membership function. The resulting envelopes of the joint angles are then calculated with α-level optimisation, allowing for efficient propagation of the uncertain marker position and to calculate the uncertain joint angles. This enables the analysis of joint angle values with respect to the uncertain input parameter. Different joint angles during gait are examined. The results are discussed with respect to uncertainty modelling and its propagation through the joint angle calculation.

Data-Driven Computational Homogenization of Polymorphic Uncertain Material Properties

Selina Zschocke*, Ferenc Leichsenring, Wolfgang Graf and Michael Kaliske

Institute for Structural Analysis, Technische Universität Dresden, 01062 Dresden, Germany
{selina.zschocke; ferenc.leichsenring; wolfgang.graf; michael.kaliske}@tu-dresden.de

Key Words: Data-Driven Mechanics, Numerical Homogenization, Polymorphic Uncertainty, Data Science, Nearest Neighbor search

The macroscopic behavior of composite materials (e.g. steel or carbon reinforced concrete) is strongly dependent on the mesoscopic heterogeneities. Based on numerical homogenization methods, which are premised on the concept of scale separation, the mechanical behavior of the mesoscale is considered within the structural analysis of the homogeneous macroscopic replacement continuum. The heterogeneous mesoscopic material behavior is characterized by a representative volume element (RVE) with uncertain properties. The realistic modelling of structures requires the consideration of aleatoric and epistemic uncertainty. Generalized polymorphic uncertainty models (p-box, fuzzy probability based randomness with bunch parameter description) are utilized in order to take variability, imprecision, inaccuracy and incompleteness of material data into account. The concept of data-driven computational mechanics [1] enables material model free finite element analyses of solids directly based on stress-strain data sets. The key idea is to assign a state which fulfills equilibrium and compatibility constraints and leads to a minimum of the penalized objective function to every integration point. Thus, the data-driven computation scheme incorporates methods for solving nearest neighbor searches (e.g. k-d tree, ball tree).

A data base characterizing the macroscopic material behavior is derived by solving the boundary value problem of the displacement-driven RVE for varying deterministic boundary conditions and quantifying the polymorphic uncertainty of the corresponding stresses resulting from the uncertain mesoscopic material parameters. A computationally efficient approach for the consideration of data sets containing uncertain stress-strain states within data-driven computation based on information reduction measurements and efficient nearest neighbor search algorithms will be developed. Due to the generalization, the approach is applicable to various aleatoric, epistemic and polymorphic uncertainty models. In addition, different phase space sampling strategies are adapted to the data-driven solver and compared. The workflow and characteristics of the developed methods are demonstrated by structural examples with polymorphic uncertain mesoscopic material properties quantified by p-boxes.

Key Words: Additive Manufacturing, Uncertainty Quantification, Homogenization, Surrogate Models

For a period of time now, additive manufacturing has been a widespread method in a huge variety of engineering applications. Thereby its nearly limitless design freedom has enabled the practice of trial and error approaches in many fields like bio-engineering or civil-engineering, see for instance [1]. However one aspect that has only recently been investigated is the error introduced in the designs due to the manufacturing process. In this context small-scale variations of the material properties (e.g., density fluctuations) and mesoscopic geometric deviations can often be considered as main sources of uncertainty. Indeed the variability in certain mechanical properties of additively manufactured slender elastic rods is significant, see for instance [2]. Quantifying the effect of such deviations on different mechanical properties of slender elastic rods numerical techniques based on finite element methods for 3D solids combined with Monte-Carlo methods are very well known. Unfortunately such methods usually exhibit extremely high computational cost and often turn out to be impractical in the ordinary usage. This is a special limiting factor as besides uncertainties of aleatoric type (following a well-characterized probability distribution) some errors introduced in the printing process are more difficult to quantify and thus fall in the epistemic category where for example only bounds on probabilities can be established (e.g., due to difficulties in imaging the printed objects using computer tomography). In order to quantify the impact of random deviations in a more efficient way simplified and at the same time accurate surrogate models were derived in the present work using dimension reduction and recently developed mathematical methods in quantitative homogenization leading to a marked reduction in computational effort.

Multifidelity Moving Particles via Multiplicative Information Fusion

Jonas Kaupp[1]*, **Carsten Proppe**[1]

[1] Karlsruhe Institute of Technology, {jonas.kaupp, proppe}@kit.edu

Key Words: Moving Particles Method, Information Fusion, Multifidelity, Multivariate Expectation Maximization

In structural reliability analysis the Monte Carlo method (MC) is often used to compute the Probability of Failure (PoF) since analytical solutions are not available. More often than not, the model to be evaluated has a demanding computational cost which makes MC infeasible, due to the high number of samples needed to describe the rare event. With regard to polymorphic uncertainties, the demand increases even further since the PoF's upper and lower bound are computed in a double loop at additional cost [1].

The moving particles method offers significant improvements over plain MC and the number of evaluations is reduced drastically. Here, a small number of samples (particles) is created by MC and then moved into the failure domain by applying Markov Chain Monte Carlo. This leads to a Poisson process whose parameter is linked to the PoF. [2]
To further increase the efficiency, a multilevel version has been introduced recently which combines multiple models of different fidelity via additive information fusion [3].

In a first step to efficent sampling methods for polymorphic untertainties, a new approach is proposed which focuses on aleatoric uncertainties only and uses multiplicative information fusion. Therefore, Expectation Maximization is applied to estimate the Poisson parameter of the high fidelity model. This is achieved in two ways: On the one hand the parameters of a multivariate Poisson distribution [4] are estimated using all models at once, adapted for decreasing samples per fidelity level. On the other hand the models are combined pairwise leading to a step by step solution with a bivariate Poisson distribution estimation in each step. Both versions are tested on an example and afterwards compared with regard to relative error and computational time.

Polymorphic Uncertain Dependency Structures in Multivariate Fuzzy Probability-based Random Variables with Fuzzy Probability-based Copula

F. Niklas Schietzold, Jonas Pallien, Wolfgang Graf, Michael Kaliske

Institute for Structural Analysis, Technische Universität Dresden, 01062 Dresden, Germany,
{niklas.schietzold, jonas.pallien, wolfgang.graf, michael.kaliske}@tu-dresden.de,
tu-dresden.de/isd

Key Words: Uncertainty Quantification, Polymorphic Uncertainty, Dependency Structure, Copula

Copulas are commonly applied to characterize and incorporate dependency structures of multivariate random variables in stochastic uncertainty quantification. For the modeling of copulas, e.g. based on measurement data of the multivariate random variable, copula-parameter estimation methods are required.

In the context of polymorphic uncertainty, on the one hand, aleatoric uncertainty characteristics, commonly based on stochastic uncertainty models and, on the other hand, epistemic uncertainty characteristics, e.g. based on fuzzy or interval uncertainty models, are distinguished and both uncertainty characteristics are considered in combined uncertainty models. Multivariate fuzzy probability-based random variables are investigated as polymorphic uncertainty model, combining the uncertainty characteristics by fuzzy-parametrization of probability functions and, according to [2], fuzzy-parametrized dependency structures.

Two novel approaches are presented to model polymorphic uncertainties in dependency structures based on copulas. The approaches are extending present methods of copula-parameter estimation and both are resulting in fuzzy-parametrized copula models, accordingly denoted as fuzzy probability-based copulas.

In the first approach, dependency structures in multivariate random variables are investigated. In [1], methods for interval-valued copula-parameter estimation are proposed, which are characterized by confidence interval estimators. Based on this, an estimator for fuzzy-parameterized copulas is developed. In the second approach, fuzzy-parametrized marginal probability functions are investigated. An additional fuzzy analysis is introduced to estimate the fuzzy copula-parameters. The developed method enables the estimation of copulas as dependency structure of the polymorphic uncertain multivariate variable.

Novel data based estimator methods are developed for both approaches. Therefore, the applicability of the approaches is shown by numerical examples, where uncertainty quantification is performed for a structural problem of a timber construction, based on measurement data of sensitive system parameters.

Reliability-Based Design Optimization under Polymorphic Uncertainties: Application to Locally Laser-Hardened Car Components

Niklas Miska[1*] **and Daniel Balzani**[1]

[1] Ruhr-Universität Bochum, Chair of Continuum Mechanics, Universitätsstr. 150, 44801 Bochum, Germany, {niklas.miska, daniel.balzani}@rub.de, lkm.rub.de

Key Words: reliability-based design optimization, optimal uncertainty quantification, polymorphic uncertainties, local laser-hardening

To ensure the safety of engineering structures under the influence of polymorphic uncertainties, optimal designs can be obtained from reliability-based design optimizations (RBDO). Therein, the computation of the mathematically sharpest (upper) bound on the probability of failure (PoF) is a crucial task, since the computed bound on the PoF is compared to a specified threshold to evaluate the safety of a design candidate. In this context, no uncertified assumptions in terms of probability density functions on the uncertain input quantities should be made to avoid faulty results from the optimization. Under this premise, the extended Optimal Uncertainty Quantification (OUQ) is a suitable framework for the uncertainty quantification, cf. [3] for the original approach and [2] for its extension to polymorphic uncertainties. The key feature is the ability to incorporate information on moments of epistemic quantities without an assumption on the type of an underlying probability density function while still enabling the inclusion of probability densities for description of aleatory uncertainties. Thereby, uncertified assumptions on the data are avoided and the safety of the design is maintained. In this contribution, the integration of the extended OUQ framework in an RBDO-context is presented. For that matter, the production process and crash behavior of a car front bumper under the influence of polymorphic uncertainties including uncertain sheet metal properties resulting from microstructure variation [1] are numerically evaluated. Therein, the arrangement of locally laser-hardened zones in the sheet metal is optimized in order to maximize the dissipated energy of the front bumper in a simple crash scenario. Since individual computations of each design candidate in terms of finite elements are costly, a surrogate model is constructed, which is then used in the RBDO itself for efficiency reasons.

Key Words: *ASME V&V 10, uncertainty quantification, smeared crack model, finite element method, reinforced concrete*

In the design of reinforced concrete (RC) structures and the development of construction methods, the current mainstream is the use of experiments. However, this method requires a lot of preparation and expense, and it is difficult to prepare a full-scale specimen. On the other hand, numerical analysis for RC structures can reduce the number of experiments currently required and enable efficient design of structures and development of construction methods.

In this paper, an attempt is made to apply the American Society of Mechanical Engineers (ASME) standard ASME V&V 10 as a method for verification and validation (V&V) of computational models for RC structures, following the ASME procedures for computational verification of computational models and quantification of uncertainty of computational results. The reality of interest is an experiment conducted by Kurumatani et al. in which three RC beam specimens of the same specifications were subjected to flexural failure in five different organizations. The computational model used is a finite element method model with a smeared cracking model developed by Morikawa et al. The computational model is validated by probabilistic analysis considering the uncertainty of the computational model and input parameters. Finally, the prospects of V&V for actual structures are discussed.

Key Words: Random field, Manifold, Two-stage, geodesic distance, Isomap

Random fields are widely used to characterize spatial variablity. However, the common simulation methods are not suitable for manifold due to its complex correlation structure. This study introduces a two-stage method to simulate random fields over manifold. At the first stage, the manifold is transformed into a Euclidean domain by dimension reduction algorithm, then over the Euclidean domain the random field is generated by common existing methods at the second stage. The final random field over manifold is obtained by mapping the random field over Euclidean domain back to the manifold. The key of the two-stage method is the transformation at the first stage, where the correlation structure, which is evaluated by geodesic distance, needs to be preserved. Therefore, any dimension reduction algorithm preserving geodesic distance and common random field simulation method can be coupled into the two-stage method. In this study, we adopt the Isometric mapping (Isomap) with accurate geodesic distance as the dimension reduction algorithm and stochastic harmonic function representation as the common random field simulation. Several examples with random fields over manifold are demonstrated the applicability of the two-stage method.

Key Words: *Verification and Validation, Uncertainty, Reinforced Concrete, Damage Model*

An example of the verification and validation, based on ASME VV-10, for analysing reinforced concrete beams is introduced. The finite element method with non-linear material constitutive laws of concrete and steel is used for the computational model. A damage model based on fracture mechanics of concrete [1] is applied to the analysis of crack generation and propagation in concrete. The quantification of uncertainty about material properties of concrete is also performed in the validation of the computational model.

We first show our computational model [1], used in the verification and validation, for the non-linear analysis of reinforced concrete. The model is based on the finite element method with non-linear material constitutive laws. The modified von-Mises damage model is applied to concrete, and the standard von-Mises plasticity model is applied to steel. Finite element meshes of reinforced concrete beam reflecting the geometry of deformed bars are prepared in 3D.

An example of the verification is second presented. A model based on Euler- Bernoulli beam theory with material non-linearity is used for the verification, and the results are compared to the numerical results obtained from the 3D finite element analysis. From these results we confirm that the load-displacement responses conform to the reference solution of beam theory without the dependence of mesh-size.

We finally show a validation example along with the uncertainty quantification. The variation of material properties in concrete is regarded as the uncertainty in both the simulation and experiment in this study. A series of numerical result obtained from Monte Carlo simulation is compared to a series of experimental results obtained for quantifying the uncertainty of reinforced concrete beams. Good agreements are found between the numerical and experimental results, implying that the computational model is validated for the intended use.

Application of Non-Linear Stochastic Finite Element Method based on Multi-Element Non-Intrusive Spectral Projection Method to Stochastic Elasto-Plastic Problems

Hidenori Nakagawa[1*]

[1] Department of General Education (mathematics),
National Institute of Technology(KOSEN), Oyama College,
771 Nakakuki, Oyama City, Tochigi Prefecture 323-0806, JAPAN

Key Words: *Intrusive Spectral Stochastic Finite Element Method, elasto-plastic problem, Non-Intrusive Spectral Projection, Multi-Element Polynomial Chaos*

In this talk, I will summarize the recent activities focused on the application of the intrusive Spectral Stochastic Finite Element Method (intrusive SSFEM) [1] to probabilistic elasto-plastic solid mechanics. Compared to Monte Carlo simulations, which require thousands or tens of thousands of calculations with varying parameter values, the intrusive SSFEM is very attractive because, depending on how it is used, all the necessary probability moments can be obtained in one calculation. The objective of this research is to develop the intrusive SSFEM that can be applied to solve probabilistic elasto-plastic solid mechanics problems. In general, however, the following two problems are obstacles to this goal. (1) the problem of the stress return mapping algorithm in a probability space, and (2) the problem of the very complex process of constructing stochastic matrix equations by applying polynomial chaos expansion (PC exp.) to the tangential stiffness and internal force stochastic matrices. The problem (1) implies that it is difficult to find the exact probability distribution of the yield function that is updated by the return mapping. And finding a stochastic stress field that accurately reflects that probability distribution is the bottleneck. The next 2) is the problem that existing non-linear FEM programs cannot be used as-is because all random variables such as displacements, strains, stresses, and stiffness matrices need to be decomposed using perturbation method or spectral expansions method when constructing the tool. In order to solve the problems (1) and (2), I developed a method called NISP-SSFEM, which is a combination of the non-intrusive spectral projection method (NISP method) and the intrusive SSFEM. NISP-SSFEM is a hybrid method to overcome the problems (1) and (2), where the NISP method is used to update the stress in a probability space and calculate the stochastic stiffness matrix and stochastic internal force matrix of the element, and the intrusive SSFEM is used to solve the global stiffness stochastic matrix. Then, a powerful method developed by Wan and Karniadakis[2], multi-element PC exp., is incorporated into NISP-SSFEM to solve the problem of instability caused by the setting of the number of numerical integration points in stochastic projection. In this presentation, I will introduce the multi-element NISP-SSFEM and conduct numerical experiments to evaluate this method by comparing the results with those of Monte Carlo simulations.

Key Words: *CFRP, Laminate, Damage, Strength, Multiscale, Homogenization*

Carbon fiber-reinforced plastic (CFRP) laminates are materials manufactured by stacking prepregs (laminae) made of resins reinforced with carbon fibers. They have excellent characteristics such as light weight, high specific rigidity and strength, and they are used as structural members in a wide range of industrial fields such as aerospace, automotive, and energy industries. For CFRP laminates, it is known that damages in the micro-scale can lead to macro-scale failure. Therefore, it is very important to analyze the damage initiation and damage propagation behavior in CFRP structural members.

An effective method for structural analysis of CFRP laminates is the two-scale analysis method based on a homogenization theory [1, 2]. This method is able to simultaneously analyze the micro-behavior inside the material and the macro-behavior of the entire structure. The method therefore can precisely analyze the damage/strength of CFRP structural members. However, computational costs of the method generally become quite high.

In this study, we develop a decoupled multiscale damage/strength analysis method for CFRP laminates that provides high efficiency by analyzing micro and macro damage behaviors separately. For this, the Hoffman criterion is introduced into unit cell analysis, and macroscopic behavior and strength of a unidirectional CFRP (lamina) are obtained through coupled multiscale analysis based on the homogenization theory. Then, macroscopic constitutive equations that reproduce the obtained macroscopic behavior and strength are developed and incorporated into commercial finite element analysis software. Using the developed method, damage/strength analysis of CFRP laminates is performed, showing that the method can efficiently analyze damage/strength behaivor of CFRP laminates.

Key Words: *Bone biomechanics, Collagen, Image-based analysis, Zooming FEM, Arbitrary load*

In the field of bone biomechanics, micro-CT image-based analyses have been widely used including the direct modelling of porous trabecular bone. Recently, a new imaging apparatus, second harmonic generation (SHG) technique, has been developed that provides us with nanoscopic information of collagen. When it is applied to the bone, the osteon is visible, and many histological studies have been reported so far. However, as far as the authors know, no report is found on the SHG image-based finite element analysis except our previous report[1]. A novel biomechanics simulation of osteon that is consisted of collagen lamella surrounding blood vessel is expected to give new insight into the study on osseointegration.

The purpose of this study is to analyse the strain in collagen fibres in osteon near the oral implant under the loading condition applied to the implant. The oral implant can be modelled by the micro-CT images for a cadaver. To connect the macroscopic implant and nanoscopic osteon, a traditional zooming finite element modelling was used. The resolution of micro-CT images in this study is 90 μm, and that of SHG images is 0.83 μm, which is accurate enough to model 300 μm square region covering an osteon. The voxel finite elements were used with the same size with the resolution. To bridge the macroscopic and nanoscopic finite element models, a mesoscopic model with 9 μm mesh size was used. The zooming analyses were basically done by customized commercial software VOXELCON (Quint Corp., Tokyo, Japan) and controlled by in-house python code.

In the linear elastic finite element analysis, to consider arbitrary loading condition for two oral implants, the displacements under unit loading conditions were analysed first and stored in the database. In this report, we compared the strain distributions obtained under different loading conditions.

Key Words: *Biomechanics, Finite element method, Computer-aided engineering, Lumbar kyphosis.*

The number of degenerative spine disease patients and the portion of lumbar kyphosis are growing. However, biomechanical researches on kyphosis and its treatment are scarce. In this study, the characteristic effects on kyphosis and the influence of material properties of treatment device were investigated in the view of biomechanical behaviours. The finite element method and statistical analysis were adopted for the study. Fourteen patient-specific finite element models were constructed from patients. To investigate the biomechanical influence of material properties of pedicle screw fixation system rod and bone graft cage, different material properties of rod and cage were incorporated in the finite element models. Three materials were adopted for connecting rods to analyse the influence of material properties. For loading conditions in finite element analysis, the vertical load of 400N and moments of 7.5Nm were applied for muscle force and 4 representative spine motions. From the biomechanical point of view, five parameters, intradiscal pressure(IDP), range of motion(ROM), anterior disc height(ADH), and posterior disc height(PDH), von-Mises stress of bone graft were analysed statistically to clarify the characteristic effects on kyphosis and influences of material property of connecting rod. The parameters were compared between the normal and patient subjects and different material properties of connecting rod. The ADH of kyphosis patients shown significant decrease compared to those of normal subjects. The PDH of L3-L4 in patients shown significant decrease. Statistically, the ROM and IDP of patients were decreased significantly. The von-Mises stress of bone graft was the maximum in patients treated with connecting rod using PEEK. The IDP of the adjacent segment was minimum when PEEK was used for connecting rod. The ROM of subjects was maximum when PEEK was used for connecting rod. The discussed results in this study will be important for the research and treatment of lumbar kyphosis.

Gaussian Process Regression Surrogate Modeling with Transfer Learning for Low Computational Cost Structural Reliability Analysis

Taisei Saida[1*], Mayuko Nishio[2]

[1] University of Tsukuba, 1-1-1 Tennodai, Tsukuba 305-8573, saida.taisei.tj@alumni.tsukuba.ac.jp

Key Words: *Surrogate Model, Transfer Learning, ARD Kernel, Gaussian Process Regression*

Monte Carlo simulation is often adopted for the structural reliability analysis of civil structures that considers the parameter uncertainties, such as uncertainties of structural properties and input loads in the structural analysis. However, as the uncertain parameters become higher dimensional, the number of samples required for probability convergence increases, which increases the computational cost. To reduce the computational cost, the use of surrogate model was shown to be effective in many previous studies. However, most of these models are trained only for the target task. The surrogate model trained for the specific task cannot contribute to the reduction of the number of training data in constructing the surrogate models for other tasks.
In this study, we present a Transfer learned Gaussian Process Regression Surrogate Model (TF-GPRSM) for structural reliability analysis. Transfer learning has recently attracted much attention in the field of machine learning, where the knowledge gained from a model built for one task can be used to build a model for another task. There are a few previous studies that use the transfer learning for the surrogate modelling. For instance, Tian et al [1] used the transfer learning in the deep neural network in the idea of Variable Fidelity Surrogate Model (VFSM). It was shown that the constructed surrogate model could reduce the computational cost of analysing a fine-mesh FE model. In this study, we aim to reduce the computational cost by using the transfer learning to build the surrogate model for the structural analysis in the reliability analysis. Here, the ARD (Automatic Relevance Determination) kernel is used for the Gaussian process regression. By using the ARD, the contribution of each uncertain parameter to the output response can be determined, and those contributions can be used to evaluate the similarity between the original task and the purpose task in the transfer learning. The TF-GPRSM was evaluated for two verification cases. One is the case for the seismic performance evaluation of a bridge pier structure considering the variation of earthquake load. Here, the TF-GPRSM was applied to the surrogate modelling of the nonlinear time-history analysis of a lumped-mass model of the seismic isolated bridge pier. The inputs of the surrogate model were structural property uncertainties and the outputs were the maximum displacements of the seismic isolation bearing and the pier for the evaluation. A pre-built model with one earthquake load was transfer trained to a surrogate model with another earthquake load. The other case was the live load capacity analysis of a steel plate-girder bridge considering the uncertainties of damage conditions using the FE model. In this surrogate model, the inputs were structural properties including the parameters to represent corrosion damages, and the output was the maximum Mises stress at the steel girders. A surrogate model was built beforehand in the undamaged state, and the information from that model was used to build a surrogate model using transfer learning for the model after damage. In both cases, the models with and without the transfer learning were compared by verifying the accuracy and the cumulative distributions of the outputs for the structural reliability analysis. As a result, it was shown that the TF-GPRSM could predict the outputs with higher accuracies, and the number of training data required to obtain the same regression accuracies could be significantly reduced.

High Quantile Estimation for Transpiration Cooling

Ella Steins[1*] **and Michael Herty**[2]

[1] RWTH Aachen, Schinkelstr. 2, 52056 Aachen (Germany), steins@aices.rwth-aachen.de
[2] RWTH Aachen, Templergraben 55, 52056 Aachen (Germany), herty@igpm.rwth-aachen.de

Key Words: Error Estimation, Quantile Estimation, Surrogate Modeling, Uncertainty Quantification, Transpiration Cooling

Transpiration cooling is a promising cooling technique aiming to enable safe operation in applications as e.g. rocket combustion chambers, where the material will not withhold the temperatures by itself. Incorporating parameteric uncertainties into the model leads to stochastic outputs of the system, e.g. the temperature is a random variable. In the area of quantile estimation, reliable methods are explored that efficiently evaluate high quantiles for the purpose of risk assessment, reliability and decision analysis [1].

In this talk, a novel approach is introduced that identifies the unknown quantile of the hot gas temperature using an empirical distribution system [2] which statistical properties are extracted by generalized Polynomial Chaos (gPC) expansions. The method is tested on a transpiration cooling model which consists of an one-dimensional model for the flow through the porous medium and a two-dimensional Reynolds-averaged Navier-Stokes model for the hot gas flow in a rocket combustion chamber, where the two domains exchange boundary conditions at the interface [3].

An error analysis of the suggested method is proposed which allows assessing the necessary accuracy of the gPC meta-model. Another advantage lies in the closed form expression of the quantile which makes directly integrating the risk assessment into an optimization context suitable. Additionally, an analysis of the numerical results shows the decreased computational expense due to meta-model techniques and various contributions of the method to risk assessment for transpiration cooling in the bigger picture of rocket combustion chambers.

Key Words: *Filament Winding, CFRP, Hydrogen Storage Vessel, Homogenization.*

Recently, fuel cell vehicles (FCVs) have been attracting attention due to their low enviromental impact. FCVs need high-pressure hydrogen storage vessels (hydrogen tanks), and carbon fiber-reinforced plastics (CFRP) are applied to the tanks because of their lightweight and high strength.

The filament winding (FW) method is generally used to manufacture CFRP hydrogen tanks. In this method, fiber bundles are wound in the hoop direction and helical direction to cover the curved surfaces of hydrogen tanks, and the stiffness and strength are controlled by the way of winding. Therefore, it is important to analyze the effects of fiber bundle orientation angles and winding misalignment on the mechanical behavior of CFRP manufactured by the FW method (FW-CFRP).

The mathematical homogenization method, which can analyze macroscopic and microscopic properties of heterogeneous materials, is one of the most effective methods for such analysis. In fact, the homogenization method has been developed into a form applicable to time-dependent deformation problems [1], and elastic-viscoplastic analysis of textile composites with consideration of laminate misalignment has been performed [2]. However, the homogenization analysis method for FW-CFRP has not been established yet.

In this study, elastic-viscoplastic behavior of FW-CFRP for hydrogen tanks is analyzed based on the homogenization method. For this purpose, three-scale elastic-viscoplastic homogenization method for FW-CFRP is proposed to consider macro/meso/micro behaviors of FW-CFRP simultaneously. Then, a unit cell modeling method for FW-CFRP with various fiber bundle orientation angles and winding misalignment is established.

This presentation is based on results obtained from a project (JPNP20003) commissioned by the New Energy and Industrial Technology Development Organization of Japan (NEDO).

Key Words: *Computational biomechanics, Oral implant surgery, Trabecular bone, Morphology, Homogenization analysis*

The oral implant is now often used in dental treatment, but accidental cases still happen due to the lack of skill and experience of surgen, -by giving damage to nerve system in mandibular canal or to blood vessel after perforating lingual cortical bone during drilling jaw bone in the implant surgery. With this background, in order to contribute to the dental education, the authors have developed a drilling force sensing device [1] together with a stochastic finite element modelling method to calculate the drilling force considering inter-individual differences [2]. The stochasic computational method employed the first-order perturbation based stochastic homogenization method and uncertainty modelling method in micro-CT image processing, and a correction factor was calibrated by many experimentally obtained data for spine in others' published papers [3].

In the above-mentioned privious studies, it was assumed that the accidental case happens if the drilling direction was originally wrong. On the other hand, this study studied on the untintentional misorientation during drilling, even if the original directdion was correct, due to the nature of the microsocpic morphology in the trabecular bone region. By analyzing a 4 mm cubic representative volume element at the tip of the drill by the asymptotic homogenization method, sudden change in the orthotropic characteristics due to the micro-architecture has been found. Assuming this can cause the unintentional shift of the drilling direction, we compared the drilling forces between two cases with and without misorientation. They were also implemented in the force sensing device. In the virtual experience of two cases, the difference in force was clearly detected.

In this study, the bone volume fraction was compared with the predicted drilling force, which could explain partially the drilling force. However, the morphology analysis by the homogenization method could predict the possibility of misorientation.

Key Words: *Computational biomechanics, Implant stability, Uncertainty modelling, Bone-screw interface, Laser pulse, transient response analysis*

In the orthopaedic treatment using implant for acetabular cup [1] or spine [2], the stability of the screw must be assured during the surgery. A torque meter has been used, but a new non-contact type device using laser resonance frequency analysis has advantages similarly to Osstell [3] that is available for smaller sized dental implant than orthopaedic implant. Supported by AMED (Contract number: 20hm0102077h001, 2020-2023), a prototype apparatus has been developed and applied to polyurethane forms simulating human trabecular bone. The measured insertion torque and pull-out force had a strong correlation. However, when the peak frequency was compared with them, it was hard to identify insertion torque and pull-out force from the peak frequency. This was because the peak frequency showed variability for a certain insertion torque as well as a certain pull-out force. Therefore, in the clinical use for living patients, larger variability will be included in the measured data. This motivated us to study on the uncertainty factors and perform probabilistic simulation.

The transient response was analysed for a cubic model consisting of cortical bone surface layer and trabecular bone region under laser pulse excitation considering three main uncertainty factors. The first one is the thickness of the cortical bone layer. The second is the size and the mechanical properties of the bone-screw interface. The third factor may lie in the laser pulse applied by surgeon. Concerning the thickness of the cortical bone layer and the radius of bone-screw interface, 3 geometrical random parameters were defined. To define the physical random parameters, the trabecular bone in the bone-screw interface region was subdivided into 4 sections, and totally 5 parameters were defined including the cortical bone. For the modelling of laser pulse excitation, two angles and two positions were considered as the uncertainty parameters.

To reduce the computational cost for the transient response analysis by finite element method, the eigenvalue analyses were carried out for 256 cases to evaluate the influence of geometrical and physical random parameters on the eigenvalues. The combination of random parameters was narrowed down to 10. Next, the transient response analyses were performed by adding 6 loading conditions, and obtained the probable variability in the peak frequency. Note that 10-node tetrahedral quadratic element and COMSOL Multiphysics ver.5.6 were used for this study.

The metal additive manufacturing (AM) or 3D printing is becoming a matter of interest as a new manufacturing technique for light-weight or topology optimized components as well as patient-dependent medical devices. One of the problems in AM is the higher possibility of defects, geometrical imperfection and the variability in material properties. Another difficulty lies in the determination of the building direction and support structure. The support structure is consisted of porous micro-architecture, which includes some design parameters. The process simulation by finite element method (FEM) will be of great help to the design of support structure from macroscopic standpoint. However, the porous micro-architecture is not considered at this moment. For instance, the CAD data of the porous micro-architecture tells us that the mechanical properties such as the Young's modulus and the coefficient of heat conduction are orthotropic, but the current existing commercial process simulation tools assume the isotropic material model for the support structure, as far as the authors know.

A preliminary experimental study of ours told us the occurrence of cracks in the support structure during the manufacturing process was strongly dependent on the geometrical design parameter for the micro-architecture. This fact motivated us to investigate the microstructures by micro-CT, partially based on our previous study on the additive manufacturing of lattice components [1].

Many defects and the variability in strut widths were observed. 6 geometrical parameters to express the discontinuities of struts were defined and statistically measured using micro-CT images. Also, the distribution of strut widths was measured statistically. Next, 21 probabilistic microstructure models were generated for the homogenization analysis by FEM to calculate the expected values of the macroscopic mechanical properties and the coefficient of heat conduction as the equivalent orthotropic model. A commercial software VOXELCON (Quint Corp., Tokyo, Japan) was used for the homogenization analyses. The outcome of this study including both statistically measured data and the numerically predicted homogenized properties will contribute to more accurate process simulation for additive manufacturing.

Key Words: *Additive manufacturing, Building direction, Geometrical accuracy, Probabilistic finite element modelling*

The additive manufacturing (AM) or 3D printing technology has been attracting attention in both industrial and medical fields. One of the disadvantages over conventional manufacturing methods such as milling and casting is the higher possibility of microscopic defects and macroscopic distortion of the products. The authors have studied on the geometrical accuracy or imperfection [1] and proposed a probabilistic finite element analysis based on the statistically measured database of geometrical parameters [2].

Another difficulty in AM lies in the determination of building direction and support structure. To achieve good geometrical accuracy, for instance when the product includes circular hole or cylinder part, the choice of building direction is very limited [3]. The authors have found the correlation between the distortion of a circular hole in a flat plate and the building direction in the case of selective laser melting (SLM) of polyamid-12, PA2200 [4]. This study revealed that the proposed methodology to describe the correlation between specific geometrical parameters for distorted circular hole and the building direction holds also for aluminum alloy (Al-Si10-Mg). The constructed database enabled us to predict the mechanical behavior by finite element analyses of a product with a circular hole in a probabilistic way before manufacturing. Also the influence of the geometrical imperfection on the mechanical behavior of the product and that of the variability in material properties are quantitatively compared.

Finally, this paper proposed a design scheme to achieve a perfect circular hole by SLM of aluminum alloy for arbitrary building direction. To this end, the building direction can be determined without any limitation due to the circular hole.

Key Words: *DEM, Particle size distribution, Granular flow, Segregation*

The discrete element method [1] is well recognised as a powerful numerical tool of granular flow simulations. In DEM simulations, however, monodisperse granular models have been widely employed to reduce computation costs while the particle size distribution is one of the important factors controlling the flow characteristics. As a result, the effects of the particle size distribution on granular flow simulations have not been sufficiently studied.

The objectives of this study are to quantify the contribution of the particle size distribution on granular flows and to discuss the mechanism of its effect. A series of DEM granular flow simulation with different particle size distributions were conducted and analysed to investigate a relation between the particle size distribution and flow behaviour. A commercial software, which can solve contact problems of polyhedral objects with the help of the concept of the common plane [2], is employed for efficient numerical simulations. The obtained results clearly indicate that the run-out distance strongly depends on the number of particle sizes and is underestimated in the conditions employed by the monodisperse granular model. The longest run-out distance was recorded by the bidisperse granular model, whereas a constant value was achieved when the polydisperse granular models were employed.

Because particle size segregation was observed during the flow, a series of vibration simulations was also performed to estimate the degree of size segregation. It was shown that each granular model has its own inherent degree of size segregation. From the results of the presented granular flow simulations and vibration simulations, it is reasonable to conclude that the run-out distance has a strong correlation with the degree of size segregation.

Some simulation models have been proposed to predict the time evolution in the deformation of ceramics during the sintering process. Most of them link the thermal history and the sintering shrinkage by so-called “sintering stress” [1], but we would like to obtain the thermal deformation directly from the thermal history. In addition, since the temperature gradients occur inside the structure during heating, it is better to employ a unified model independently on the temperature histories to represent the thermal deformations.

We propose a simple strategy for the sintering simulation with Master Sintering Curve (MSC) [2], which considers microscopic thermodynamics from a macroscopic perspective [3]. In this simulation models, the deformation gradient is multiplicatively decomposed into thermal and mechanical component, and they are further divided into reversible and irreversible component. Assuming that the mechanical and thermal deformations are independent, each deformation component is determined by referring the experimental results of the time evolution in the deformation with/without uniaxial compression loads. The thermal and mechanical reversible deformations are represented by the commonly accepted models, namely thermal expansion and Hencky model [4]. MSC is employed for the thermal irreversible deformation (sintering deformation). It shows a density evolution from any temperature histories and it is easily obtained by sintering experiments. For the mechanical irreversible deformation, the viscoplasticity model [4] is used to represent the creep deformation during the sintering process.

The sintering simulation is performed by installing the model with User Programmable Feature (UPF) into ANSYS thermal–structural analysis. The simulations are validated by comparing with experiments on the time evolution in the deformation. Using this simulation, we would clarify the effects on the total deformations and the stresses of the temperature distribution during the sintering process and the internal heterogeneity.

Key Words: *CFRP, Damage, Strength, Variability, Multiscale, Homogenization*

Carbon fiber-reinforced plastic (CFRP) laminates are important materials especcialy in aerospace and automotive industries because they have high specific strength and stiffness. Failure of structural members made of CFRP laminates is caused by damages in the micro-scale such as matrix cracking and fiber breakage. It is therefore necessary to analyze macroscopic and microscopic damage behaviors of CFRP laminates simultaneously.

For such multiscale analysis, the two-scale analysis method [1] based on a homogenization theory is one of the most useful methods. Using the two-scale analysis method, the macroscopic and microscopic behaviors of CFRP laminates can be accurately analyzed at the same time. Therefore, this research group has developed a two-scale analysis method applicable to damage propagation and strength analysis of CFRP laminates [2]. In this analysis, however, all fibers were considered to have the same tensile strength, and it was not possible to take into account the effects of fiber strength variability obserbed in actual CFRP laminates.

In this study, a two-scale damage propagation analysis method is used to analyze the damage propagation/strength of CFRP laminates considering variability of fiber strength. The Weibull failure criterion is applied to carbon fibers, while the Hoffman rule is used for resins as a damage criterion. Damage propagation and strength of CFRP laminates under uniaxial tension are analyzed with and without considering the fiber strength variability. By comparing both results, effects of the fiber strength variability on the damage propagation/strength of CFRP laminates are investigated. It is confirmed that the fiber fracture occurs almost simultaneously when the variability of fiber strength is not taken into account, whereas it occurs gradually when the variability of fiber strength is considered.

Failure simulations of reinforced concrete members using Rigid-Body-Spring Model (RBSM) [1][2][3] are carried out as a case study for validation including uncertainty quantification of simulation based on ASME V&V guidelines. The experiment of interest is a flexural shear loading test of a reinforced concrete beam, in which 15 specimens were tested under same conditions. The validity of the simulation model is confirmed by comparing the mean and variation of the response values. The results of the study show that the method considering uncertainty quantification is more costly but more explicit in assessing the accuracy of the model compared to traditional validation methods.

Key Words: *Molecular simulation, transport coefficients, uncertainty quantification, statistics*

Molecular-dynamics (MD) simulation is a standard tool in the toolkit of a modern computational mechanician and is used to compute all kinds of properties of science and engineering interest. Despite the ubiquitous use of MD simulations, a task as nominally simple as computing an error bar to place on a measurement can be laden with subtleties. As MD simulation continues to grow in popularity, as advances in hardware and software enable unprecedentedly large and long MD simulations, and as data-driven techniques increasingly demand large datasets produced using this technique, it is critical that the molecular simulation community prioritizes rigorous statistical quantification of uncertainties associated with MD simulations.

In this talk, we present results on a simple yet illustrative vignette that demonstrates the power of a rigorous statistical approach, namely, computing the (self-) diffusion coefficient in a variety of fluid and soft-matter systems, ranging from the ideal to the (fairly) realistic. In each case, we show that commonplace techniques for estimating standard errors in diffusivity measurements (used essentially universally throughout the literature), frequently generate overconfident estimates of this transport quantity. In each case, we identify the core statistical assumptions that plague the standard approach, leading to this overconfidence. We conclude by presenting a simple scheme, inspired by a time-series analysis technique initially developed by econometricians, that enables accurate quantification of uncertainty in diffusion for fluids and soft-matter systems.

Finite Element Analysis at Pin Joints of Modular Bridge under Uniaxial Tensile Loads

Yu Koike[1*], Yuki Chikahiro[2], Masatoshi Nakazawa[3], Ichiro Ario[4]

[1*] Shinshu University, 380-8553, 21w3008b@shinshu-u.ac.jp

[4] Hiroshima University, 739-8527, mario@hiroshima-u.ac.jp

Key Words: *Modular Bridge, Bailey Bridge, Pin Joint, Joint Strength*

Modular bridges can be constructed in a short time by combining standardized rectangular panels according to the site conditions. They are mainly used as temporary or emergency bridges owing to reduction of the construction time by their pin joints. A Bailey Bridge is a typical modular bridge developed by D. Bailey in 1943 during World War II. Its standard panel consists of a rectangular framed panel (width 3048mm and height 1448mm) with a truss structure. The panel have four pin joints at its corners: two male and female types of the pin joints at the left side and right corners on the panel. The joints are completed by inserting steel pins (diameter 48mm) into the interlocking parts. Most of the studies on the modular bridges focused on the strength and layout of the panels [1, 2], and there was a limited knowledge on the pin joints. Hence this study focused on the pin joint of the Bailey Bridge and clarified the influence of its shape to the joint strength by numerical FE analysis.

Parametric analysis was conducted in order to investigate the effect of pin joint specifications on the strength under uniaxial tension loads. A partial model based on the pint joint of the Bailey Bridge was considered, and eight numerical cases were set up by difference design parameters, that is, the pin diameter, joint shape, and the diameter gap between pin and pin hole at the pin joint. For the pin diameter (3 patterns), the size of the pin in each case was determined by the ratio of the diameter to the distance from the centre of the pin hole to the edge of the pin joint. For the joint geometry (3 patterns), the number of teeth and thickness of the joint in the meshing area were varied. For the diameter gap (1 pattern), the size of the gap was determined according to the limitation of the specifications for highway bridges in Japan.

The pin joint strength under uniaxial tension was affected by yielding preceding either the pin, the area near the pin hole, or the other member. The pin joint of the Bailey Bridge yielded from the pin. As far as in this study, increase of pin joint strength of 18% was observed when the pin diameter was increased by 9mm compared to the Bailey Bridge model. It was also found that the joint performance was degraded by the gap between the pin and the pin hole of the pin joint.

Bridge Modal Measurement Using a Novel Frequency-Free Test Vehicle in Parked State: Theory and Experiment

Zhi Li[1*], Zhilu Wang[1] and Yeong-Bin Yang[1]

[1] Chongqing University, No.174 Shazhengjie, Shapingba,
Chongqing, 400044, China, liz@cqu.edu.cn

Key Words: *bridge modal parameters, test vehicle, frequency-free, design, vehicle scanning method, vehicle-bridge interaction*

Abstract. In the application of the vehicle scanning method for bridges, the two factors of vehicle frequency and pavement roughness cannot be ignored. To tackle these at once, this study proposes the novel idea of designing and using a frequency-free test vehicle in parked *state* to retrieve the dynamic characteristics of the bridge. A single-axle test vehicle is considered frequency-free if its frequency is designed far larger than those of the bridges of interest. The test vehicle will also be free of pavement roughness if it is used in the parked (non-moving) state. Firstly, based on the bridge-vehicle transmissibility, it was theoretically shown to be feasible that a test vehicle can be designed to have a frequency far beyond those of the bridges of concern, while the spectral bridge frequency peaks will also be enhanced. Secondly, lab tests were conducted for the axle-wheel assemblies with inflatable or PU tires under ambient vibration. Of interest is that the axle with PU tires shows a favorable *random*, *small* and *even* spectral distribution with no self frequency up to 20 Hz. The PU tires was then assembled as a part of the test vehicle that is self balanced in entity. Finally, the self-made test vehicle was calibrated on a benchmarked bridge and applied to the Xiamen Bus Rapid Transit system. Taking a three-span girder bridge of the system as an example, it was demonstrated that the modal parameters (frequencies, mode shapes and damping ratios) of the first four modes of the bridge (flexural or torsional) can be well detected by the developed frequency-free test vehicle. Compared with the direct measurement, the proposed technique is *equally accurate*, but *more competitive in efficiency and mobility*.

Detecting Bridge's Frequencies by the Rocking Motion of a Moving Test Vehicle

Hao Xu[1], Y.B. Yang[2]

[1] Chongqing University, Chongqing 400045, China, E-mail address: hxu@cqu.edu.cn
[2] Chongqing University, Chongqing 400045, China, E-mail address: ybyang@cqu.edu.cn

Abstract: A self-designed single-axle vehicle is used to detect the bridge frequencies from its rocking motion, caused by wheels moving over uneven surface. For a single-axle vehicle, in addition to vertical motion which is often investigated in previous studies, it also has rocking motion along the axle of the single-axle vehicle. The single-axle vehicle is modeled as a two-degree-of-freedom (DOF) system, unlike its previous single-DOF version, to include both rocking and vertical motions. For the model adopted, the technique for calculating the responses of the wheels' contact points (CPs) with the bridge are newly derived to eliminate the vertical frequency, and especially rocking frequency of the single-axle vehicle. In the flat road test, the vertical frequency of the test vehicle is identified from the average of the two wheel sensors responses, and rocking frequency from the angular response calculated. From the field test conducted on a two-span girder bridge, it is concluded that: (1) the newly derived procedure for the left and right CP responses of the single-axle vehicle is reliable for scanning the first few bridge frequencies, while removing vehicle's frequencies; (2) the CP responses perform better than the responses of the single-axle test vehicle itself, in that bridge frequencies become more outstanding in the CP responses; (3) rocking motion of the vehicle enables us to better interpret the scanned frequencies; and (4)a temporary parking is beneficial for identification of bridge higher modes in the measurement.

Key Words: *Bridge health monitoring; indirect method; moving load; vehicle-bridge interaction*

Indirect bridge monitoring methods proposed by Yang et al. [1-3] can be used to obtain modal parameters by means of vehicles passing over bridges. The advantage of this type of measurement is that the sensors are not mounted directly onto the bridge, but instead on the moving vehicle. Numerous publications have been devoted to this issue in recent years. The long term monitoring and identification of dynamic characteristics of bridges is important for assessing the condition of civil engineering structures as in the case of early detection of damage. A single-axle vehicle was designed and built for the experimental verification of modal parameters both in laboratory conditions as well as on real suspended footbridges. This paper focuses on an experimental study of the feasibility of detecting the fundamental bridge frequency from the dynamic response of a vehicle passing over the bridge. It was found from both the analytical and experimental studies that the bridge frequency is included in and can be extracted from the vehicle acceleration spectrum. The dynamic response of the vehicle, which in turn serves as a receiver or scanner of the dynamic properties of the bridge based on simplified measurements is efficient.

Key Words: *Vehicle-bridge interaction, Bridge damage location, Low-frequency vibration.*

Locating damage of bridge structures is an important issue for bridge maintenance. One of the most general methods is using the acceleration of the bridge with double integration to generate the bridge deflection time history. Then the generated deflection would be compared to the deflection of a healthy bridge to detect and locate potential damage. However, it might be hard to get the precise deflection because the noise in structural monitoring and non-zero velocity can result in drifting of deflection through the integration process. Besides, the ideal health condition of a bridge, especially for some old bridges, usually requires bridge-by-bridge model updating which can be rather time-consuming for engineering applications.

This study proposed a direct method to locate potential bridge damage with the acceleration of several moving vehicles based on characteristics of the vehicle-bridge interaction system. Low-pass filtered vehicle acceleration was utilized for damage location with several slow-moving vehicles. The function of vehicle acceleration was derived from equations of the vehicle-bridge interaction system and the elementary beam theory. The function was proved to be a sum of a quartic function, which is related to the macroscopic elastic deformation of the bridge, and the unknown road roughness. Therefore multiple vehicles, whose mass was different, were utilized to eliminate the interfere from road roughness. Then the damage location can be determined by comparing the monitored vehicle vibration acceleration and the theoretical quartic function. Finite element simulation and experiments were proposed for validation with simply supported beams.

Superiorities of the proposed method over the integration are 1) the direct processing of vehicle acceleration can avoid potential interference from noise with integration, and 2) the model updating procedure can be omitted. The theoretical function would be used to check the damage location where the property of the cross-section should be abnormal and perform a clear difference from the theoretical functional curve. This method was supposed to be time-efficient and could be widely used in engineering applications.

Identification of track/bridge frequencies and track modulus by a instrumented moving test vehicle

Kang Shi*, Y.B. Yang, Zhi-Lu Wang, Hao Xu

School of Civil Engineering, Chongqing University, Chongqing 400045, China,
shikang@cqu.edu.cn

Key Words: *contact point; dual-beam model; track modulus; moving vehicle; vehicle-track-bridge model; vehicle scanning method (VSM)*

A theory is presented for retrieving the track/bridge frequencies and track modulus from an instrumented vehicle moving over a dual-beam model to simulate the track-bridge system. The dual beams are connected by uniform spring-dashpot units to simulate the effects of sleepers and ballast, etc. Based on the dual-beam model, the response of the vehicle is firstly derived in closed form, along with that for the vehicle-track contact point. The dual frequencies solved relate to the track and bridge frequencies. Compared with the vehicle spectrum, the contact-point (CP) spectrum is superior in that it is free of the vehicle and driving frequencies. Using the first "plus" frequency of the dual-beam system, the track modulus can be computed by a simple formula. The proposed technique is numerically validated against the key parameters involved. It is concluded that: (1) the first "plus" frequency can be retrieved from the contact-point spectrum as an outstanding peak; (2) track irregularity has an adverse, but tolerable, effect on retrieval of track modulus; (3) as a trade-off between efficiency and accuracy, the vehicle is suggested to move at a moderate speed; and (4) the proposed technique may be affected by track damping, but remains good for tracks with infinite length.

Key Words: *non-uniform beam; three-mass vehicle; vehicle-bridge interaction; pitching effect; pavement irregularity*

In the analysis of a vehicle-bridge interaction system, the bridge is often treated as the uniform beam for simplicity. As such, the present study proposes a non-uniform vehicle-bridge interaction system by incorporating a three-mass vehicle model in a non-uniform bridge. It is assumed that non-uniform beam elements are of constant width and varying depth. For clarity, both mass and stiffness matrices are re-formulated to comply with the finite element sign convention. In this study, the vehicle scanning method is first adopted to obtain the non-uniform bridge frequencies as the reference. Then, the parametric study is conducted to investigate the influences of associated parameters on the identification of bridge frequencies, including vehicle damping, bridge damping, and pavement irregularity. With the three-mass vehicle model, the desired accuracy subject to pavement irregularity can be reached.

Key Words: *Anisotropic rods, large deformations, multi-stability, discontinuities.*

Anisotropic rods with irregular shapes, arbitrary distribution of material properties and orientation, and kinks and creases, are common in engineering applications including deployable grid shells, collapsible origami and kirigami rings, morphable robots, and stretchable electronics. In this contribution we present a computational framework that can be used for the modeling of anisotropic rods with arbitrary and discontinuous mechanical and geometrical properties undergoing large deformations. These elements are subjected to states of self-stress produced by inelastic strain. Arbitrary and discontinuous mechanical and geometrical properties of the rod are described by a unique continuous and differentiable function defined over its entire length. This function is obtained by combining a series of Heaviside functions that are successively asymptotically approximated by continuous and arbitrarily differentiable functions. The mathematical description of the anisotropic rods consists of a set of differential equations that describe the elastic behaviour of the rod and a set of boundary conditions imposed at its two ends. We solve the resulting two-point boundary value problem by conducting numerical continuation with AUTO 07P to detect and track various bifurcations and folds [1].
We employ the presented framework to study the folding and multi-stable behaviours of elastic slender rods and polygonal frames having discontinuous orientation of the longitudinal axis (i.e. kinks and creases), arbitrary distribution of inelastic curvature, material parameters, and cross section orientation and size. The presented numerical results demonstrate the efficiency and convenience of this novel framework in unveiling the very rich bifurcations and stable branches that characterize the behaviours of these anisotropic rod elements. Comparisons with experimental results obtained from tabletop models are used to validate our numerical predictions.

Key Words: *Form Finding, Wire-and-Arc Additive Manufacturing, Funicular Analysis*

Among different Additive Manufacturing (AM) processes, Wire-and-Arc Additive Manufacturing (WAAM) results particularly suitable for applications in structural engineering. The WAAM process, which consists of off-the-shelf welding equipment mounted on top of a numerically controlled robotic arm, allows realizing large-scale structural elements up to few meters, with limited constraints in terms of forms and shapes. The WAAM technique employing "dot-by-dot" printed stainless steel rods is herein considered, see in particular investigations in [1].

Gridshells take their strength from their double curvature, being constructed from members that mainly undergo axial forces [2]. A numerical approach based on funicular analysis, see e.g. [3], is proposed to cope with the design of spatial truss networks fabricated by "dot-by-dot" WAAM. The equilibrium of funicular networks can be conveniently handled through the force density method, i.e. writing the problem in terms of the ratio of force to length in each branch of the network. As investigated in the literature for the case of vertical loads, independent sets of branches can be detected for networks with fixed plan geometry [4].

In this contribution, following [5], the minimization of the horizontal thrusts in networks with fixed plan geometry is stated both in terms of any independent subset of the force densities and in terms of the height of the restrained nodes. Local enforcements are formulated to prescribe lower and upper bounds for the vertical coordinates of the nodes, and to control the force densities in the branches. This allows also for a straightforward control of the length and maximum force magnitude in each branch. Constraints are such that sequential convex programming can be conveniently exploited to handle grids with general topology and boundary conditions.

Preliminary numerical simulations are shown concerning the optimal design of grid shells with minimum thrusts, under the combined effect of different sets of the above prescriptions. The ongoing research is mainly devoted towards endowing the design formulation with buckling constraints.

Key Words: *Computing Methods, Finite element method, shells, Kirchhoff-Love, Mindlin–Reissner.*

Finite Element Method is a numerical tool for solving partial differential equations in Engineering and Science. In solid mechanics, structural models such as shells, bars and others are developed to simplify the complexity of 3D-simulations. Shells are one of the most important models in solid mechanics since many structures in engineering may be associated with it. It may be adaptable to finite element usage, but some particularities must be watched. For instance, if not treated properly, it is known that very thin structures may have inconsistent results regarding rigidity (see [3]) (locking phenomena) and consequently results may be untrustworthy. In view of this, the study of this type of simulations (shells models in FEA) is fundamental in present times.

The current project aims to study and develop a new simple shell finite element based on hybrid shear rigid/flexible model (Kirchhoff-Love / Mindlin–Reissner) for reliable and efficient simulation of thin nonlinear structures. This new shell triangular element has been tested with 6 nodes and does not use Lagrange multipliers or penalty methods to guarantee displacement C^1 continuity between adjacent elements (as required by Kirchhoff-Love models) or for canceling the drilling rotation (as required in some Mindlin–Reissner models. See [2]). The DOF's are the displacements u at the six nodes and the incremental rotation parameter φ_Δ at mid-side nodes (parameter φ_Δ is properly explained in [5]). The incremental rotation parameters α_Δ (incremental Rodrigues's parameters) and consequently incremental rotation tensor Q at the mid-side nodes are internal degrees of freedom that are computed at element level by solving a simple set of equations. The displacements u are interpolated by quadratic polynomials from the nodal values as usual.

The present work may be interpreted as a continuation of previous studies developed by the group of study from Professor P. M. Pimenta and more references may be found in [1], [2], [4] and [6]. The current model is still under development and results are going to be presented in forthcoming work.

Key Words: *Arch, Damaging, Structural design, Structural mechanics, Damaged Arch Structures, Variable Curvature, Tapered Cross-section*

Arch structure is a widely used and important structure type all over the World. Due to its beautiful form and large spanning capacity, arch structure is widely used in bridges, tunnels and other buildings. Especially in recent decades, the large span space arch structure has a stage of development. The defects of arch structure, such as connection, material, fatigue, stress concentration and welding, will directly affect the safety of long-span structure. The study of the evolution of the damage in structures is a topic of interest since the antiquity. A well-done structural design should always account for the evolution of the damage in time, in particular if it can bring to a change in the static behaviour of the structure itself under different loading conditions [1-3].

In this paper a model for the calculation of localized damaged in arch structures is presented. In particular, using an analytical solution for the computation of the displacements filed and the consequent internal actions of very general arch shapes with variable curvature and tapered cross-section, the damage is modelled by localized depletion of the cross-sectional properties (inertia) in the different points along the arch axis. In particular, the depleted parameters are the cross-section and the bending stiffness of the arch. Finally, the model is applied to the study different configurations of the damage (localization of plastic hinges or different pattern of defects) and to consider the evolution of the damage in time.

Key Words: *Self-stressed Structures, Tensegrity, Graphic Statics, Reciprocal Diagrams*

Graphic statics is a compelling geometry-based approach to the conceptual design of structures in static equilibrium. It is based on two interrelated constructs, the form and the force diagrams, the first representing the geometry of a pin-jointed framework in static equilibrium and the second indicating the equilibrium of forces within the structure [1]. The relationship between these two diagrams allows simultaneous control of both the form and the forces within a given structure. In this way, it is possible to transform one of the diagrams and evaluate the resulting modification of the other. In recent years, generalized methods for the construction and transformation of vector-based 3D force diagrams of 3D self-stressed [2] and externally loaded pin-jointed frameworks in static equilibrium [3] have been introduced.

In the particular case that the form diagram of a self-stressed pin-jointed framework has an underlying planar graph, its corresponding force diagram is reciprocal and can be regarded itself as a self-stressed pin-jointed framework whose force diagram is the initial form diagram [2][3]. In this contribution, we present a new procedure for generating novel self-stressed, topologically symmetric 3D pin-jointed frameworks by manipulating the underlying graph of a given form diagram. The procedure consists of the following steps. For a generic self-stressed 3D pin-jointed framework (single-primal), its underlying graph is first transformed into a topologically symmetric planar graph by duplicating all edges and vertices. Then, the dual graph of this newly generated planar graph is constructed. Considering the nodal equilibrium of the single-primal and conforming to the topology of the dual graph, a 3D force diagram is assembled in which all elements are duplicated (double-dual). This 3D force diagram is itself a self-stressed, topologically symmetric pin-jointed framework. Its corresponding reciprocal diagram is again a self-stressed, topologically symmetric pin-jointed framework (double-primal) in which all the elements are also duplicated. Different transformations of the underlying graph of the single-primal lead to the construction of varying double-primal and double-primal configurations and thus distinct self-stress pin-jointed frameworks. The proposed procedure is exemplified with several case studies, starting from various classical tensegrity structures as single-primal configurations.

Key Words: Bistable Unit, Mechanical Metamaterials, Additive Manufacturing

In this work, we investigate the nonlinear response of mechanical metamaterials assembled from tensegrity-like repeating units. Tensegrity-like structures are frame structures whose geometry and connectivity reproduce those of tensegrity structures, thus conferring to them also a similar mechanical response. Differently from tensegrities, tensegrity-like structures do not have cable members or nodal pin connections, and they are not prestressed, therefore they can be easily fabricated in one piece by additive manufacturing methods. Tensegrity-like units for mechanical metamaterials were proposed in [1], as multistable lattices, and in [2], as failure-resistant lattices, which in both cases were realized by multiphoton lithography techniques. In [3], tensegrity-like units were fabricated by fused deposition modelling and tested in compression, highlighting a nonlinear snapping response. By observing that changes in the geometry of a unit can result in different nonlinear behaviours, such as stiffening, softening, snap-through and bistable responses, here we consider different tensegrity-like units and their assemblies to evaluate the mechanical response of possible nonlinear metamaterial designs.

Nowadays, the need to deal with limited resources together with the new discovered awareness of the human over-exploitation of the environment, has made the optimization a cutting edge topic both in scientific research and in the different professional fields [1, 2, 3, 4].
In this paper, a particular evolutionary optimization algorithm is presented: The Evolution of Distribution Algorithm (EDA). This type of algorithm has been developed to be used in search-based constrained optimization problems which are difficult and time-consuming to be solved by other general algorithms. Being an evolutionary algorithm, the main idea is to generate a population of solutions and evaluate the objective function to each one of them. Then, using the information obtained from the previous generations, the algorithm step-by-step will generate new populations that will tend to the best value of the objective function. In EDA, the population of solutions defines a probability density function (PDF) and, by integration, a cumulative density function (CDF), which is used for the generation of the next generation [1, 2, 3, 4].
In structural design optimization problem, it is very common that the best solution is very close to the constraint function. The main advantage of applying the EDA for constrained optimization problem is that each generation of solutions is obtained starting from a PDF that is defined on the whole domain. This means that, for each generation, the solutions have a probability to be on the unfeasible domain space, maintaining the information about the objective function in the evolution process. In the present research, an original EDA and related self-made code are presented together with a specific application to structural optimization problem, in order to show the effectiveness of the obtained results and to make a comparison with other evolutionary optimization algorithms.

Over the last years, several optimization strategies were conducted to find the optimal shape minimazing internal stress or total weight (volume) of shallow grid shells and vaults [1]. In recent times, this structure typology gained a great importance among researchers and the scientific community for the renowed interest in the form-findind optimization of column-free space solution for large span roofing construnctions [1]. In the present paper, a form-finding of a shollow grid shells was introduced basing on the multy-body rope approach (MRA) for the definitions of vaults with optimized shape and different hole percentage. In order to obtain an experimental validation, a physical model was reproduced at the laboratory scale performing ad hoc measurements to compare the observed respect to the simulated behavior. A 3D printing procedure based on the Fuse Deposition Modeling (FDM) technique in polylactide (PLA) material was used to realize formworks of the cement based blocks of the scaled prototype [2-3]. Several statical and dynamic load configurations are investigated, collecting into a sensitivity analysis the parameters which mainly affect the structural behavior [4,5]. To simulate earthquake ground motion an assigned frequency range as dynamic input to the structure was provided by a shaking table [4]. Statycal and dynamic monitoring of the vault prototype was performed using 2 USB (2 Mpx – 165 Hz) and 4 GO-PRO full HD (8 Megapixel) frame rate 100 fps. DIC measurements were used in order to validate the vibration modes of the vault obtained by the dynamic simulations. Finally, some preliminary considerations of the dynamic response of the model were provided testing the robustness of the form-finding approach when horizontal load are taken into account.

Finite Element Analysis of Load Capacity of Panel Bridge with Multi-Scissors Structure

Kumi Ohno[1*], Yuki Chikahiro[2]

[1] Shinshu University, 380-8553, 18t3008c@shinshu-u.ac.jp

Key Words: *Panel Bridge, Scissors-type Bridge, Multi-Scissors structure*

Panel bridges, such as the Bailey Bridge, are well used as temporary bridges that can be joined and assembled on site from standardized components. However, they made of steel and lack portability. In order to improve a workerbility on-sites of these temporary bridge, a scissors-type bridge is proposed [1]. The scissors-type bridge, which is an application of a deployable mechanism, has the merit that the entire bridge can be expanded and stored by the partial control. Furthermore, the use of lightweight aluminum alloys enables erection by a small number of worker and provides excellent portability. However, the rigidity of the aluminum alloys is low in comparison with the steels. In this study, the multi-scissors panel is applied to the scissors-type bridge (Herein multi-scissors-type bridge) to increase the performance of the bridge keeping the lightweight. Here we clarify the load capacity of the multi-scissors-type bridge with the different panel layouts.

Although the mass of the panels of panel bridge has been reduced in anticipation of manually work, each panel still exceeds more than 200 kg [2]. A panel of the multi-scissors-type through bridge made of aluminum alloys was assumed with a height of 1.0m and width of 2.0m. Numerical FE analysis was performed under the both-end supports conditions with a concentrated load of maximally 100kN increasing linearly in 1 second at the middle of the bridge. The number of layers of the panel was varied from one to five. This numerical analysis was performed with the single panel model and four panel model.

The stiffness of the panels for both the single and four was increased lineally by the number of panel layer of the multi-scissors-type bridge. The stiffness of four panels was 2.2% of that of the single panel. Maximum Von Mises stresses under the loading were found at the pivot near the supports for the single panel and at the pivot near the loading position for the four panel, and both models yielded in these positions. Therefore, the effect of bending moment was increased by the increment of the bridge's span. The bending stress was approximately 80-90% higher than the axial stress at the yield positions for each model. Furthermore, the bending stress decreased with increasing number of layers of the bridge and was inversely related to its mass in the case of the single panel. These results indicated that the bending moment which is dominant sectional force of this bridge can be reduced by multiplexing of the scissors structure.

Key Words: *concrete shell, historic structure, folded beam, hyperbolic paraboloid*

When completed in 1961, the roof of St. Charles Church became the largest unbalanced hyperbolic paraboloid structure in the world and the only shell structure in Spokane, WA [1]. Situated on an 8-acre site on the north side of the city, St. Charles is a modernist structure designed through partnership of Funk, Molander & Johnson and architect William C. James. This asymmetric structure spans over 27.5m (90ft) and utilizes folded edge beams that taper from 1067mm (42in) at the base to a 76.2mm (3in) thickness at the topmost edge using regular strength reinforcing steel and concrete. The novelty of the shell structure serves both architectural and structural design criteria by delivering a large, uninterrupted interior sanctuary space in materially and economically efficient manner.

Having previously completed an initial analysis of the structure [2], now, 60 years later, a complete structural forensic evaluation of the shell has been conducted using full point cloud laser scanning to generate a complete in-situ model. The geometry is analyzed and deflections are compared to original design and construction documents to facilitate repair and maintenance of this architecturally and historically significant structure. A full structural evaluation of the roof and connecting structure has been completed. The forensic survey shows minor shear cracks throughout the shell field and deterioration of the underside of the shell. However, deflection at each tip of the hyperbolic parabola is neglibible compared to the design – highlighting the robust geometric stiffness and apparent resiliency of the prestressing. Results of the current in-situ geometry are compared to the design geometry of original construction documents.

Ongoing work includes detailed CFD modeling to determine accurate wind loads as well as comparison of historical and current design standards.

Key Words: *Gridshell, Form-finding, Conceptual Design, Multi-body Rope Approach D'Alembert Principle, Phyton code,*

Over the past decades, different approaches, physical and geometrical, were implemented to identify the optimal shape, reducing the internal stresses, of grid shells and vaults. As far as their original organic shape is concerned, the design of grid shell structures inspired architects and structural engineers in more than one way [1-5]. Along the history time, the solution of the structural form-finding buried its roots on the activity of scientists and designers. In the present paper, the original approach for the form-finding is proposed by the dynamic numerical simulation of hanging net, subjected to gravity load, over the time domain [4]. In particular, the adopted process for the definition of the structural shape is based on a multi-body rope approach (MRA) with masses connected by inextensible ropes characterized by a certain slack coefficient (*sc*) and by the degree of the constraint conditions [4]. The method, originally presented in [4], is here re-developed and extended employing a self-made code based on the dynamic equilibrium, ensured by the d'Alembert principle, of masses interconnected by rope elements in space-time domain. The equilibrium corresponding the optimized shape to be defined, is obtained through an iterative process in the falling masses connected by a net for the definition of the "catenary surface" coinciding with the best shape of the shell (form minimizing the bending moment). The implementation of the method is realized in Python in an interpreted high-level general-purpose programming language. The adopted design philosophy emphasizes the code readability by other languages with respect to the traditional model realized in Visual Nastran 4D. By the use of this code as well as its object-oriented architecture the MRA Python code will be linked to the Grasshopper environment for the direct visualization of the shapes and their fast-parametrization phase.

Bayesian data-driven learning of industrial light weight structure design optimisation under uncertainty

David Walton[1*], Carol Featherston[1], David Kennedy[1], and Abhishek Kundu[1]

[1] Cardiff University, School of Engineering, Cardiff University, UK, waltondb@cardiff.ac.uk

Key Words: Uncertainty Quantification, Design Under Uncertainty, Data Driven Learning, Aerospce, Dimension Reduction, Gaussian Process Regression, Vector-Valued Functions, Lightweight Structures

Data-driven learning in the context of design under uncertainty is associated with the challenge of creating optimal high-dimensional maps of input parameters to vector-valued output quantities. This work focuses on an approach of compressing multi-output vector data and modelling it within a Bayesian framework. Three models are compared, a brute force learning of all output vectors, learning of reduced dimensioned (compressed) approximation of the vector-valued output, and a compressed model with log standardisation applied. Gaussian process regression with an isotropic squared exponential kernel function is used to learn the maps [2]. Compression is applied using principle component analysis (PCA). Log transformation of the data is applied to reduce bias in the PCA. Both the compression and standardisation introduce uncertainty which is quantified and propagated through the models along with the mixed uncertainty of the vector-valued output.

The data-driven learning is performed with a practical high-dimensional industrial problem aimed at a specifically parametrized aircraft wing configuration. In short, the input is made up of ten parameters over 201 uniformly distributed design of experiment points. The target data are the responses at points along the wing span when it experiences prescribed loading conditions producing a 8556 dimensioned vector-valued output.

It is found that the compressed model is able to reduce computational expense by up to 98% while incurring an increase of 5% in the relative error compared to the brute force and standardised model, where the relative error is of the order $\times 10^{-4}$. The use of an isotropic kernel enables the creation of response surfaces for input parameters of interest while retaining information on the predictive uncertainty at every sampled point in the surface, this is important as this framework lays the foundation for further work into design optimisation under uncertainty [1]. The methods used here are not dependent on demonstration application, and can be applied to any high dimensional machine learning task.

Key Words: *Vibration, Damage detection, Rotational spring, Dynamic stiffness matrix.*

The catastrophic failure of structures has the potential to cause loss of life and incur significant economic loss. To overcome this scenario, the vibrational characteristics of the structure can be used to understand the current and future performance. The use of such vibrational characteristics such as natural frequency to detect damage further overcomes the difficulties of inspection in inaccessible areas of the structure [1, 2].

To model the effect of damage on the natural frequencies of an Euler-Bernoulli beam the exact dynamic stiffness matrix [3] has been formulated for a beam fixed at both ends in which a crack is modelled by a rotational spring. The formulated matrix yields a transcendental eigenvalue problem for which the Newton-Raphson method has been applied to yield the natural frequencies and mode shapes for uncracked and cracked cases. The obtained reductions in natural frequencies of the proposed system, due to presence of the crack, closely match with newly derived analytical solutions for the various locations of the damage.

The use of the Newton-Raphson method enables a high level of computational efficiency to be achieved in solving this forward problem (i.e. the change in natural frequencies due to a crack with a particular location and severity). The accuracy achieved in the forward problem provides a strong basis for solving the inverse problem to determine the location and severity of cracks based on measured changes in the natural frequencies of real structures.

Nonlinear Dynamic Characteristics and Resonant Actuation of Bi-stable Structures

Yuting Liu, *School of Aeronautic Science and Engineering, Beihang University*

Jiaying Zhang, *School of Aeronautic Science and Engineering, Beihang University*

In the fields of morphing aircraft, flow control and energy harvesting, dynamic characteristics of the multi-stable structure provide an idea for realizing change of the structure shape. Nonlinearity and local stability of multi-stable structures provide potential benefits for morphing structures as no energy is required to hold each stable configuration. This paper presents the dynamic characteristics of bi-stable laminate, including the effects of geometric dimensions and boundary conditions. Numerical simulation is used to study the nonlinear dynamic characteristics of each configuration and dynamic response under different excitation levels. A resonance actuation strategy leading to snap-through of bistable structure is investigated, and the realization conditions of single well vibration and cross well vibration are determined.

Keywords – morphing structure, bi-stable composite laminate, nonlinear dynamics, resonant actuation

Postbuckling Optimization of Stiffened Panels via Topological Design

Sheng Chu[1*], Carol Featherston[2], David Kennedy[3] and H. Alicia Kim [4]

Key Words: *Postbuckling Optimization, Stiffened Panels, Topology Optimization*

As one of the primary structural configurations in aircraft, stiffened panels are ubiquitous and play an important role in aerospace due to their high stiffness-to-weight and strength-to-weight ratios. However, their load-carrying capability is strongly influenced by buckling. Many efforts have been made by using optimization techniques to maximize the critical buckling load or minimize the mass with linear buckling constraints. However, it is well known that stiffened panels can carry loads several times higher than the critical buckling load. Therefore, stiffened panels might be able to be designed to work in the postbuckling field beyond the critical buckling load, offering significant potential for further structural weight reductions.

Topology optimization is one of the structural optimization methods with the greatest degree of design freedom. It can help to determine the best possible shapes and material distributions for the prescribed objective by redistributing material. The authors have recently demonstrated the feasibility of applying the level-set-based topology optimization method to simultaneously optimize the size, layout and topology of stiffened panels for linear buckling [1-3]. In this work, this method is extended to consider postbuckling. To the best of the authors' knowledge, this is the first investigation of the postbuckling optimization of stiffened panels via topological design. Specifically, the stiffened panel is discretized into plate elements. The thicknesses of the skin and stiffeners can be optimized. A control mesh is developed to manipulate stiffener layout, and correspondingly the free-form mesh deformation method is utilized to adjust the finite element mesh. The level set method is used to optimize the internal topologies of the stiffeners as well as the number of stiffeners. The iterative Newton-Raphson scheme with load or displacement control is used for finite element analysis, where a small imperfection in the form of the first linear buckling mode is imposed on the finite element model. Different indices, i.e., total reaction force under given displacements, in-plane displacement under given loads and out-of-plane displacement, are considered to assess the postbuckling performance of the stiffened panel. They are respectively optimized with a mass constraint. A semi-analytical sensitivity analysis is performed, and a gradient-based optimizer is used to solve the optimization problem. Numerical examples are used to demonstrate the application of the proposed method. Compared with the initial design, the postbuckling performance of the optimized stiffened panels is improved.

Study on Improvement of Bending Strength of Thin-Walled Structures Composed of Sandwich Panels

Kota Asaumi[1*], Kuniharu Ushijima[2]

[1] Tokyo University of Science, 6-3-1 Niijuku, Katsushika-ku, Tokyo, 125-8585 (4521501@ed.tus.ac.jp)

Key Words: *Sandwich Panel, Lattice, Bending Moment, Critical Angle, FEM*

In recent years, there has been an increasing demand for structures with lightweight and high-strength properties in order to reduce the consumption of raw materials and energy. One such structure is the sandwich panel. Sandwich panels are a type of composite structure consisting of a low-density, lightweight core with a thin faceplate bonded to the surface.

An example of a core used in sandwich panels is the lattice structure. It is a structure in which long and thin beams are arranged in a three-dimensional and periodic manner. In recent years, advances in additive manufacturing technology have made it relatively easy to fabricate lattice structures with fine beams of several hundred micrometers in diameter. Furthermore, the lattice structure has the advantage that the mechanical properties can be adjusted according to the purpose of use by changing the diameter of the beams and the shape of the core, and it is attracting attention as an advanced structure that plays a role in reducing the weight and increasing the strength of structures.

An open-section beam was adopted as the shape of the sandwich panel in this study. Open cross-section beams, such as U-shaped beams, are widely used in automobile bodies and buildings. Chen et al.[1] investigated the bending behavior of open beams in a continuum, including the prediction of the maximum bending moment and the effect of the direction of bending, using numerical simulation analysis with FEM. M.M. Pastor et al. [2] [3] investigated the effect of beam cross-section size on the bending behavior and the maximum bending moment of U-shaped beams in a continuum using experimental and numerical simulation analysis with FEM. However, there is no research report on the bending of open-section beams in sandwich panels.

In this study, the bending collapse behavior of U-shaped sandwich panel filled with lattice has been investigated by using FEM. In particular, the effects of geometric properties of lattice core and faceplate on the maximum bending moment and the critical angle were discussed. The existence of a lattice core could prevent the elastic buckling of the surrounding U-shaped plates, and enhance the maximum bending moment to the fully plastic moment of these plates. Based on numerical investigation, the mode map with relative thickness of the plate and the relative density of the lattice core as parameters was obtained.

The ROM-driven optimization of composite laminated plates for buckling and postbuckling performances

Zheng Li and Ke Liang

School of Aeronautics, Northwestern Polytechnical University, Xian 710072, PR China,
k.liang@nwpu.edu.cn

Key Words: Postbuckling optimization, Reduced-order model, composite laminated plates

Thin-walled composite laminated plates are commonly used as primary components in aeronautic and aerospace structures to bear the in-plane compression loads, benefiting from their high strength-to-weight and stiffness-to-weight ratios. When composite laminated plates under compression are allowed to continuously loaded into the moderately deep postbuckling regime, further weight savings can be achieved. The standard nonlinear finite element(FE) analysis combined with the Newton-Raphson technique and its variants, is the most common method for calculating the postbuckling response; however, the repeated solutions for large-scale FE models in each incremental-iterative step are extremely computationally expensive. Therefore, the standard finite element method is not suitable for the postbuckling optimization process, which requires the evaluation of the equilibrium path for each change in the design variables(e.g. lamination parameters), because a single run is too time consuming with current CPUs.

For this purpose, this work presents an efficient optimization scheme for the design of postbuckling behaviour of composite laminates. The reduced-order modeling method based on the Koiter perturbation theory, is developed to calculate the postbuckling behaviors of the composite laminated plate. The initial postbuckling response is represented by the nonlinear predictor solved by the reduced order model(ROM), while the deformations in the moderately deep postbuckling regime are obtained by applying the corrections under the design load. Five different indices, including the critical buckling load, the initial postbuckling stiffness, the stiffness residual, and the in-plane and out-of-plane deformations under the design load, are depicted to valuate the various postbuckling performances of the compressed plate. These postbuckling indices can be flexibly selected to be either the objective or the nonlinear constraints in the lamination optimization. The optimal algorithms are subsequently adopted to determine the lamination configuration for the most favorable postbuckling performance. The various composite laminated plates with the straight/curved fibers are studied under uniaxial and biaxial compression for different boundary conditions.

A General Higher-Order Shell Theory for incompressible and anisotropic hyperelastic materials using Orthonormal Moving Frame: an application to Arterial Mechanics

A. Arbind*

Department of Mechanical Engineering
Indian Institute of Technology Kharagpur
Kharagpur, West Bengal, India - 721302.
E-mail: *archana.arbind@mech.iitkgp.ac.in*

Key Words: Isotropic soft shell, anisotropic soft shell, analysis of arteries, layered shell structure

This study presents a general higher-order shell theory to analyze the large deformation of single or multi-layered shell structures made of isotropic or anisotropic incompressible hyperelastic materials. The salient feature of this shell is threefold: (i) this shell theory formulation has been done using an orthonormal moving frame (OMF) instead of the classical natural covariant frame, which makes the mathematical formulation relatively simpler even for very complex hyperelastic constitutive relation owing to the orthonormal nature of basis vectors; (ii) General-higher order nature of approximation through-thickness of the shell make it equipped to model the deformation of a thick shell as well as multi-layered shell, and at the same time it also removes thickness stretch associated numerical locking, and (iii) the constitutive relations of incompressible isotropic and anisotropic hyperelastic material, both stretch and invariant based, are considered eying application in the vascular mechanics. The displacement field of the line normal to the shell reference surface is approximated by general Legendre polynomials single layer shell and by Lagrange polynomial for multi-layered shell structure. Subsequently, the kinematics of the shell for orthonormal basis has been derived using the tools of *exterior calculus*. It has been shown by Arbind, Reddy, and Srinivasa in [1] that such a coordinate system makes it possible to represent kinematic quantities, *e.g.,* determinant of the deformation gradient, far more efficiently than the in the classical tensorial representation with covariant basis. This study can be regarded as an extension of [1] for incompressible and anisotropic softshell for more general interpolated shell geometry. Here, for a general shell surface geometry, the finite element formulation of the shell theory is presented, and further, the theory has been applied to large deformation analysis of human arteries, which can be considered as thick layered tubular shell, under internal pressure. The incompressibility constraint has been applied via the penalty method as well as the Lagrange multiplier method. For the post-buckling analysis, nonlinear finite element formulation has also been presented considering the arc-length method. Various numerical examples are presented to verify and validate the formulation presented in this study.

A New Mixed FE-Formulation for Liquid Crystal Elastomer Films

Michael Groß[1*], Francesca Concas[2] and Julian Dietzsch[3]

[1] TU Chemnitz, Reichenhainer Straße 70, D-09126 Chemnitz, michael.gross@mb.tu-chemnitz.de,

[3] julian.dietzsch@mb.tu-chemnitz.de.

Key Words: Anisotropy, Finite Element Method, Variational Principle, Energy-Momentum Scheme.

Liquid crystal elastomers (LCEs) are soft materials, which are capable of large deformations induced by temperature changes and ultraviolet irradiation [1]. Therefore, since many years, these materials are under investigation in experimental researches as actuator materials. LCEs arise from a nematic polymer melt, consisting of long and flexible polymer chains as well as oriented and rigid rod-like molecules, the so-called mesogens, by crosslinking. After this process, the flow ability and the orientation of the mesogens is retained. To date, the alignment of LCEs is primarily achieved in thin films. When the orientational order in the film is lost due to temperature changes or ultraviolet irradiation, the LCE film is capable of length changes of 400 percent.
In order to numerically simulate LCE materials as actuators in multibody system models by using the finite element method, a continuum formulation is necessary, which include in a thermo-viscoelastic material formulation of the polymer chains the orientation effects of the mesogens. This can be performed by introducing a normalized direction vector $\mathbf{n}_t$ as an independent field, and deriving from additional (orientational) balance laws independent differential equations [2]. These differential equations describe the independent rotation of the rigid mesogens connected with the flexible polymer chains. The orientation-dependent stress law of LCEs arises from an anisotropic free energy, comparable with fibre-reinforced materials [3]. But, in contrast to [3], the direction vector of an LCE model has to be independent.
In contrast to [2], we apply a variational principle for deriving a new mixed finite element (FE) formulation, which is based on drilling degrees of freedom for describing the mesogens rotation [4]. This principle leads to an extended set of balance laws which is preserved by an energy-momentum scheme.

Key Words: *Triangular Shell Element, Nonlinear Shell Formulation, Finite Rotations, Large Strains.*

Shells are one of the most important models in solid mechanics since many structures in engineering may be associated with it: metal sheets-based products, slabs, thin-walled pressure vessels, and other objects with one of its dimensions considerably smaller than others. Shell models may be adaptable to finite element usage, but some particularities must be watched it, such as locking behaviours.

This work aims to study and develop a nonlinear formulation for shells models using a special simple triangular shell element, which is a new displacement-based triangular shell element with 6 nodes. Moreover, the shear locking and membrane locking behaviour are not observed at the performance of this new element.

In formulation of shell models, we consider finite strains, large displacements, and rotations. Rotation field is re-parameterized in terms of the Rodrigues rotation vector, resulting in a simpler update of rotational variables. The Reissner-Mindlin kinematical assumption and an initial plane reference configuration for the shell is considered here.

A computational implementation is done with several numerical examples using the new element developed here. Furthermore, a comparison with numerical examples using the well-known element T6-3i [1], a six parameter (3 displacements and 3 rotations) element, is done with the aim to also illustrate the robustness of our formulation.

An objective and path independent geometrically non-linear ReissnerMindlin shell formulation

Alexander Müller[1*], **Manfred Bischoff**[2]

[1] University of Stuttgart, Keplerstraße 7, 70174 Stuttgart, mueller@ibb.uni-stuttgart.de
[2] University of Stuttgart, Keplerstraße 7, 70174 Stuttgart, bischoff@ibb.uni-stuttgart.de

Key Words: shell analysis, large rotations, objectivity, path independence, manifolds, isogeometric analysis, geometric finite elements

Development of geometrically exact, non-linear shell formulations for large rotations has been subject to intensive research for several decades. A lot of progress has been made and many issues are well understood today, but there are also still some open questions. Many existing formulations suffer from singularities due to the non-linear space of the unit sphere. Additionally, some of the existing models proved to be non-objective and exhibit artificial path-dependency. For one-dimensional spatial rod finite elements these problems have been solved by Crisfield and Jelenić [1]. For shell models with Reissner-Mindlin kinematics, however, they seem to persist. We present an efficient, robust, objective, singularity-free and path independent geometrically non-linear Reissner-Mindlin shell formulation for arbitrary ansatz spaces. In particular, this formulation utilizes the ideas on geometric finite elements presented by [2] and [3] for the interpolation on non-linear manifolds. Additionally, we compare three different interpolation schemes that can be found in literature, where two of them are applied for the first time to Reissner-Mindlin shells. Path independency and objectivity of the formulation are verified via a set of numerical examples.

Experimental investigation and mechanical characterisation of cables

Prateek Sharma[1*], André Hildebrandt[2], Alexander Düster, and Stefan Diebels[1]

[1] Saarland University, Campus A4 2, 66123 Saarbrücken, prateek.sharma@uni-saarland.de (https://www.uni-saarland.de/lehrstuhl/diebels.html)
[2] Hamburg University of Technology, Am Schwarzenberg Campus 4 c, 21073 Hamburg, andre.hildebrandt@tuhh.de (https://www.tuhh.de/skf/)

Key Words: *Orthotropic Material, Pure Bending, Reproducibility, Internal Structure*

Cables are long and thin structures that are used not only for electrical but also for structural purposes. With the increasing demand for electro-mobility and with the advances made for industry 4.0, the use of cables in cars, robots, and various other areas has increased in recent times. For such applications, they should be able to sustain the loads applied on them for a certain period of time. This leads to complex cable constructions with various layers of different materials across the cross section. The layers consist of metallic wires, dielectric layers, conducting sheaths, polymer insulations, among other types of materials.

The complex structure and construction lead to anisotropic material behaviour, where the tensile stiffness is much higher than the torsional and bending stiffness. The inner structure of the cable contributes to the coupling of the stiffnesses in all three directions of tensile, torsional, and bending loads. With the application of the bending or torsional loads, the metallic wires can move against each other, which leads to the production of tensile forces. Thus, to determine the behaviour of the cable the coupling of the stiffnesses should be considered during experimental characterisation.

To this end, an experimental setup has been constructed to test the cables under tensile, pure bending and pure torsional tests. To compensate for the tensile forces occurring during the bending and torsion experiments, the two ends of the cable are moved during the load application with the help of linear motors along its axis. The three types of tests were used for characterising a single core and a coaxial cable. Furthermore, coupled loading was also applied to see the effect of pre-torsion on the bending of cables. The experimental results of bending different cable samples were not always reproducible, because of the random orientation of the metallic wires. Moreover, as the cables are cut from different areas of a spool, the already existing curvature also varies from sample to sample. Therefore, an initial loading was applied to condition the samples, which led to an increase in reproducibility. An anisotropic elasto-plastic material model was implemented using the finite element method to simulate the behaviour of cables [1]. The discretisation of the long and thin structure was achieved with high order 3D hexahedral elements. Parameters for the model were identified with the help of tensile and torsion tests and were validated with the bending experiments. Thus, a complete experimental characterisation of cables and its simulation is presented.

Key Words: *Selective Mass Scaling, Hierarchic Formulations, IGA.*

Hierarchic shear deformable Reissner-Mindlin shell formulations possess the advantage of being intrinsically free from transverse shear locking through reparametrization of the kinematic variables, see for instance [1], [2], among others. This reparametrization yields beam, plate and shell formulations with distinct transverse shear degrees of freedom.

The efficiency of explicit dynamic analyses of thin-walled structures is limited by the critical time step size, which depends on the highest frequency of the discretized system. In case of discretizing a thin structure with Reissner-Mindlin type shell elements, the highest transverse shear frequencies limit the critical time step, while being of minor importance for the structural response. Selective mass scaling aims at scaling down the highest frequencies, while ideally keeping the low frequencies unaffected. In most concepts, this comes at the cost of non-diagonal mass matrices. Selective mass scaling was initially invented for thin solid and solid-shell elements, but the extension to the rotational part of standard shell elements is not straightforward. Thus, mostly conventional mass scaling of the rotational inertia is used in commercial explicit codes, as can be seen for instance in [3] in the context of isogeometric shell analysis in LS-DYNA.

In this contribution, we present recent investigations on selective mass scaling with hierarchic isogeometric structural element formulations. Since hierarchic formulations possess distinct transverse shear degrees of freedom, they offer the intrinsic ability for selective mass scaling of the shear frequencies, while keeping the bending dominated frequencies mostly unaffected and retaining the diagonal structure of a lumped mass matrix. We discuss the effects of transverse shear parametrization, locking and mass lumping on the accuracy of results and a feasible time step.

Key Words: Fluid-Structure Interaction, Cosserat Rods, Collision Modeling

Aquatic canopies formed by flexible submerged plants are an essential element in river hydraulics through the flow resistance they provide, their resilience against bed erosion, etc. Knowledge about these processes is usually drawn from experiments. Only recently simulations with deforming blades have been conducted, still with relatively rigid blades [1]. In the present contribution a numerical method is presented which extends the one of [2], [3] towards long, highly flexible blades as they reconfigure, collide, and interact with the surrounding flow. It is composed of the following elements: a Navier-Stokes solver for incompressible flows with Large Eddy subgrid-scale modelling, an Immersed-Boundary-Method (IBM) for coupling, and a Finite-Difference solver according to [4] for geometrically exact Cosserat rods. The IBM is particular in that it incorporates the fluid-structure coupling by a semi-implicit approach, thus yielding very good stability, even with vanishing thickness as well as small or even vanishing mass of the blades. Another challenge arises from the structure-structure coupling via contact and collision. It is treated with a constraint-based method and turned out to provide difficulties of appropriately discretizing these constraints. To cope with these, a number of enhancements over [3] had to be developed. The capabilities of the resulting method are illustrated with first results from a large-scale simulation of 528 flexible blades in a turbulent channel.

Key Words: *Cable Bundle, Material Characterisation, Coupled Loading*

Large capital-investments are being made on cable systems especially in the automotive field. Due to the strong growth in the digitalisation of vehicles, a considerable increase in the number of cables can be seen in them. Cable bundles and harnesses are used for better cable management in these vehicles. Each cable bundle is made up of various cables and each of these cables are complex components consisting of a multi-layer structure made up of various materials. In order to characterise these cable bundles, the prediction of the effective mechanical properties of the system as a whole is focussed on.

Due to their construction, the interaction between the different components in a cable bundle leads to deviation from classical material behaviour [1]. The bending movement induces friction between the cables resulting in non-linearity effects as well as coupling between the bending and torsion load cases [2]. These non-linearity effects are analysed on the basis of the data obtained from the experiments.

For this purpose, a new test rig has been designed and built, allowing the implementation of the decoupled load cases: bending, torsion and uniaxial tension, as well as their superposition on the slender flexible structures. In particular, it is possible to investigate the highly complex effects resulting from the different structure of the various cable systems, which are directly reflected in the different behaviour of the individual systems. Three types of tests are performed, nonlinear pure bending, nonlinear torsion, and bending coupled with torsion. A large number of experiments on different cable systems with a sufficiently high number of samples were performed and the elasto-plastic behaviour of higher bending moments was compared to pure bending. A neural network for modelling cable systems was developed, which is trained with the data from experiments.

Viscoelastic Glass Plates Co-Sagging Simulation Coupled with Air Suction

Zheming Zheng[1*], Steve Burdette[1] and Anurag Jain[1]

[1] Corning Incorporated, Sullivan Park, Corning, NY14831

Key Words: *Fluid-structure interaction, viscoelasticity, glass sagging, air suction*

An axisymmetric fluid-structure interaction (FSI) model, for simulating the circular glass plates viscoelastic co-sagging process with air suction, is developed in the commercial software COMSOL. The two glass plates are modelled as viscoelastic structures which are sagging under gravity at elevated temperatures with their viscosity dependent on the temperature. Generalized Maxwell model of stress relaxation is implemented for simulating the viscoelastic behaviours. The air suction is implemented with a thin film flow based on the Reynolds equation of the lubrication theory. Numerical case studies are performed to understand the fundamentals of the two glass plates interaction with the air film layer and impact of process parameters.

It is discovered that the air suction pressure increases when the viscosity difference between the top and bottom glass plates becomes larger. When the viscosities are the same, the pressure is close to zero. The pressure increases with the top-bottom glass viscosity ratio and reaches a peak value when the viscosity ratio is above 1000. The peak value is equal to the weight of the bottom glass.

Key Words: Fibre Networks, Multi-Scale Modelling, Homogenisation, Constitutive Modelling

Multi-scale mechanical models allow to infer microscopic information from the macroscopic response. Two-scale models of fibre network materials are relevant in many fields of engineering, but also in computational mechanobiology problems, where tissue-scale loads are transfered to the cell scale through a collagenous network to provide the cues for various cellular processes [1]. Discrete network models (DNMs) are a common strategy for two-scale problems. DNMs reveal micro-scale information far beyond real experiments and challenge the macro-micro transitions used by the majority of the common continuum mechanical concepts, but also provide the basis to develop novel approaches.

One piece of information is the distribution of fibre stretch within the network [1, 2, 3]. Based on studying various DNM representative volume elements (RVEs) of generally non-linear elastic fibres, we propose a constitutive relation between this micro-kinematic distribution and the macroscopic deformation imposed via the boundary conditions. Our analysis revealed a strong resemblance of the obtained stretch histograms with the log-normal distribution $\mathcal{L}$. Describing $\mathcal{L}$ in terms of the macroscopic deformation, this novel approach yields excellent agreement with the homogenised stress and energetic response of the DNM RVE, and at the same time preserves the micro-kinematic information on the distribution of stretch, making it a promising tool for efficient computational analysis of fibre network materials.

Finally, we discuss methods to overcome the costly generation of a numerical DNM ground truth needed to parametrise the model, and sketch strategies to obtain the relevant information for model calibration from real experiments.

Key Words: *Inflatable Wings, Dynamic Characteristics, MFC Actuator, Wet Mode*

Inflatable wing is a multi-cavity inflatable structure made of high-strength composite flexible material and filled with high-pressure gas to maintain airfoil. Due to advantages in light weight, convenient collection, rapid expansion and low cost, inflatable wings provide a more flexible technical solution for aircrafts with limited space to launch, such as small and medium-sized UVAs, cruise missiles and gun-launched missiles. The structural dynamic characteristics of inflatable wings are complicated because of the high flexibility and light weight, and traditional methods for rigid wings are no longer applicable. In modal tests for inflatable structures, especially for complex structures with high flexibility like inflatable wings, traditional modal testing technique using hammer or shaker is questionable to excite the global modes of the structure without local overexcitation. The variety of sizes, low mass, and fast time response of the Macro Fiber Composite (MFC) make it an excellent candidate for use in the dynamics and control of inflatable structures. In this paper, a distributed excitation system is proposed based on MFC actuators for modal tests of a flexible lightweight inflatable wing, and the dynamic characteristics of the inflatable wing are analyzed. Firstly, a finite element modelling and modal analysis of an inflatable wing is carried out. Since the inflatable membrane with high flexibility is barely able to endure out-of-plane load, which converts the load into in-plane tension in the form of membrane prestress. And the contribution of added air-mass to the vibration system cannot be ignored. Wet mode considering membrane vibration theory and added air-mass is applied to obtain modal parameters and provide reference for modal tests. Then, a distributed excitation system based on MFC is set up, and an example of simple supported beam is given to verify the feasibility of system. Finally, dynamic characteristics of inflatable wings is analyzed based on MFC excitation system, and the type, number and distribution of MFC are designed to improve the experiment performance. The results show that the distributed excitation system based on MFC is capable to excite global mode of inflatable wings. Besides the spanwise bending and torsional mode, inflatable wings also present chordwise bending mode, which is markedly distinguished from the traditional rigid wings.

A mixed finite-element formulation for axially moving continua

Alexander Humer[1*], **Astrid Pechstein**[1] **and Michael Krommer**[1]

[1] Institute of Technical Mechanics, Johannes Kepler University Linz, Altenberger Str. 69, 4040 Linz, Austria, {alexander.humer, astrid.pechstein, michael.krommer}@jku.at

Key Words: Axially moving continua, mixed finite elements

We present a novel approach for the analysis of axially moving continua, i.e., structures that are characterized by a translational motion in one of their preferred directions. Axially moving continua occur in many important industrial processes as, e.g., rolling mills, in which material is (more or less) continuously transported through the plant. Challenges in modeling and simulation of axially moving continua are manifold: First and foremost, the underlying translational motion is adverse to a Lagrangian formulation of continuum mechanics, in which physical fields are related to material points of the structure. Diverse variants of *Arbitrary Lagrangian-Eulerian* (ALE) and *mixed Eulerian-Lagrangian formulations* have been proposed to account for the fact that material points located in the domain of interest vary due to the translational motion. Secondly, we typically deal with thin-walled structures that are subjected to large deformations. For this reason, structural theories for beams and shells are often adopted in the computational analysis. On top of that, the material behavior is inelastic in many industrial processes. Non-Lagrangian formulations therefore require transport schemes for internal variables that govern the stress response and constitutive relations need to be translated to structural theories.

We address the challenges of axially moving continua by combining an effective mixed finite-element formulation for three-dimensional continua with a generalization of the *sliding-beam formulation* [1], i.e., a non-material description for sliding structures and axially moving continua. In particular, we use the *tangential-displacement normal-normal-stress* (TDNNS) method by Pechstein and Schöberl [2]. The TDNNS method is based on the idea of relaxed continuity in displacement and stress fields across element faces. TDNNS elements have proven superior performance in problems of thin-walled structures as compared to conventional irreducible formulations, since they do not suffer from shear locking. We apply the coordinate transformation of the sliding beam formulation to the three-dimensional relations of continuum mechanics, on which the TDNNS formulation is based. The proposed approach allows us to effectively analyze complex problems of axially moving continua without resorting to structural theories.

Geometrically Exact Dynamics of Sliding and Rotating Nested Rods for Modeling Concentric Tubes Robots

Federico Renda[1*], Costanza Armanini[1] and Frederic Boyer[2]

[1] Khalifa University, 127788 Abu Dhabi, UAE, {federico.renda, costanza.armanini}@ku.ac.ae

Key Words: Sliding rods, Geometrically-exact methods, Continuum robotics

Continuum robot architectures find wide application in medicine since they can be designed to achieve a high ratio of length to width, making them well suited to minimally invasive interventions. These designs are distinguished by using deformable elongate elements whose shape, theoretically, requires an infinite number of degrees of freedom to model. Concentric Tube Robots (CTRs), a collection of nested millimeters tubes, belong to this category. A general architecture comprises three tubes: a fixed, relatively rigid, straight tube that serves as a guide and two flexible concentric tubes with a pre-designed 3D curved shape. CTRs can be controlled through its proximal end, outside of the patient. The physician regulates the relative sliding and rolling of the tubes, whose elastic interaction determines the overall shape of the system and the iteration force at the end-effector for surgical intervention. The accurate control of the CTR navigation and tissue interaction requires the development of sophisticated mathematical models. Although significant results have been achieved, only quasi-static motion of the tubes' sliding has been considered so far [1].
Here we present a complete dynamic model of the three tubes architecture described above, including the sliding phenomena. To do so, a Cosserat model of the rods' deformation is employed, parametrized using a novel, geometrically-exact, Ritz-like reduction of the beam's strains [2]. In the context of CTRs, it allows selecting the active strains of a general Simo-Reissner beam that satisfy the distributed constraints imposed by the rods' concentricity, eliminating from the equations the complex inter-tubes constraints force. Due to the tubes' sliding, the domain of the overlapping sections comprising the CTRs "grows" or "shrinks" as a function of the insertion parameters. Once this additional motion is included in the geometrically-exact kinematics of the Cosserat rod, the d'Alembert's principle can be applied to obtain the equations of motion in the usual Lagrangian form, suitable for control. In the static setting, this procedure allowed calculating the insertion forces required for the equilibrium for the first time [3].

Key Words: Finite Element Analysis, Mixed Eulerian Lagrangian Description, Material Generation

We present a mixed Eulerian-Lagrangean approach used for simulating the strip run in rolling mills. The simulation tool is intended to be finally used for optimizing parameters of attached software controllers before they are implemented at the real plant, an intention which imposes two more or less contrary requirements concerning the final product: On the one hand it should be highly accurate to allow finding near optimal and reliable controller settings for real life application. On the other hand – since a large number of single simulations will have to be run in order to find optima in a multidimensional parameter space – it should be particularly fast. A standard type approach (such as using standard 3D Finite Elements undergoing 3D contact analysis at the roll gap) would miss to exploit specific problem characteristics and thereby be lacking performance.

A more modular approach is presented, which is particularly adapted to the underlying problem and has evolved throughout the last decade of co-operation between Primetals Technologies Germany, Johannes Kepler University Linz, and Linz Center of Mechatronics GmbH on this topic.

Non-material kinematic modelling in roll forming of steel sections

Emin Kocbay[1*], **Yury Vetyukov**[1]

[1] TU Wien, Getreidemarkt 9, A-1060 Vienna, Austria., Emin.Kocbay@tuwien.ac.at

Key Words: roll forming, mixed kinematic modelling, axially moving continua, finite element analysis

Roll forming is a manufacturing process which is classified among the cold forming processes [1]. Here, an initially flat metal sheet is continuously fed through several forming passes. Each forming pass consists of a pair of contoured rolls which contribute incrementally to the total bending deformation. The final cross section shape is obtained by irreversible plastic bending deformation, membrane strains remain small. Furthermore, no significant deformations in thickness direction occur during this process.

Lagrangian finite element formulations are traditional in structural mechanics. This becomes, however, inefficient for axially moving continua, as material particles keep entering and leaving the control domain, as it is the case in roll forming. Numerically induced oscillations are inevitable because of the spatially localized contact forces acting at moving finite elements. Moreover, no mesh refinement near the contact locations is possible. Using the mixed Eulerian-Lagrangian description, we restrict the attention to the active domain of interest. The issues regarding the numerical oscillations and mesh refinement are no longer relevant, as material particles flow across the mesh. For this sake the nonlinear structural equations need to be transformed to a different set of coordinates, namely an Eulerian one in the direction of the movement and Lagrangian coordinates for the transverse and out-of-plane directions [2, 3].

For an alternative attempt to treat the roll forming process using ALE kinematic formulation with the help of the non-material 3D continuum elements we refer to [1]. In the present contribution, we make use of the shell model of the metal sheet, which shall be computationally more efficient. Moreover, the plastic deformations are treated both, on the level of continuum mechanics featuring an integration over the through-the-thickness element of the shell as well as on the structural mechanics level, which is based upon a novel problem-oriented plasticity model for a shell [4].

Sticking and sliding of an endless elastic strip on a moving rough surface

Yury Vetyukov[1*]

[1] TU Wien, Getreidemarkt 9, A-1060 Vienna, Austria. yury.vetyukov@tuwien.ac.at

Key Words: axially moving continua, non-material finite element analysis, frictional transport

Axially moving deformable structures play a central role in various technical solutions like belt drives, rolling mills, winding of coils, etc. Inertia and elasticity of the moving structure, geometric and material nonlinearities as well as contact phenomena altogether result into non-trivial and sometimes counter-intuitive response of such structures to geometric imperfections or external actions. Nowadays, growing attention is paid to dynamical systems, in which the time evolution of the deformed state of an axially moving structure is possible even quasi-statically at slow motion because of nonlinear contact interactions. Examples are the elastic-plastic bending of a metal strip in a roll forming machine [1], motion of sheet metal between the roll stands of a hot rolling mill [2] or the elastic deformation of a steel belt owing to the dry friction in the moving contact pairs of a steel belt drive [3].

The last example of a frictional transport problem motivates the study of the motion of an elastic strip travelling on a horizontally moving rough plane. The lateral misalignment of the guideways at the entry to the control domain and at the exit from it enforces the deformation of the strip and makes sliding inevitable, at least in the part of the domain. An analytical quasi-stationary solution featuring infinitely many self-similar segments of sliding followed by a zone of sticking contact was obtained under the assumption of Bernoulli-Euler beam model of the strip in [4]. In the present contribution we release some of assumptions of the analytical study and consider refined models of the moving strip: the Timoshenko beam model and the two-dimensional plane stress formulation. The mixed Eulerian-Lagrangian kinematic description implemented in form of non-material finite element formulations allows both the transient and the quasi-stationary analysis of the axially moving elastic structure with friction.

Out of Plane Lower Bound Limit Analysis

Peixuan Wang[1*], Gabriele Milani[1]

[1] Department of Architecture, Built Environment and Construction Engineering (ABC), Politecnico di Milano, Piazza Leonardo da Vinci 32, 20133, Milan, Italy, peixuan.wang@polimi.it, gabrile.milani.it

Key Words: *Masonry plates, Failure analysis, Lower Bound Limit Analysis, Linear Programming problem, Homogenization approach.*

Surveys conducted after severe seismic sequences all around the world and fragility curves produced with techniques at territorial level, plus experimental tests show that the most diffused collapses occurring for existing masonry buildings are partial out-of-plane failures of large rigid portions with variable shape, roto-translating and forming a pre-defined kinematic chain, whose shape depends on several concurring factors, such as masonry texture, membrane loads and the interlocking between perpendicular walls.

Compared with the in-plane studies, the experimental research on out-of-plane loaded masonry is less abundant. Limit analysis seems the most suited tool to deal with the determination of the behavior at failure of out-of-plane loaded masonry panels.

A novel Lower Bound Limit Analysis Finite Element model for the study at failure of masonry walls in two-way bending is presented. In the model, a masonry plate is discretized into infinitely resistant hexahedrons and quadrilateral interfaces where all plastic dissipation occurs. Three internal static variables act on interfaces, namely bending moment, out-of-plane Kirchhoff shear and torque. Equilibrium is imposed on hexahedrons, whereas admissibility is enforced exclusively on interfaces between adjoining elements. The admissibility of the internal actions on masonry interfaces is imposed with a strength domain obtained by means of an already existing LB homogenization technique where joints are reduced to interfaces. The resultant Linear Programming (LP) problem - which allows to estimate collapse loads and distribution of internal actions at collapse - is characterized by a number of variables and constraints relatively limited, which requires a very limited computational burden to be solved through standard interior point LP software. Failure mechanisms are obtained solving the dual LP problem.

The procedure proposed is validated against two existing experimental data sets, namely three series of walls with slender perpendicular walls connected on vertical edges and tested at the University of Adelaide (Australia) [1] and four series of solid (one) and perforated (three) panels tested at the University of Plymouth (UK) [2][3]. A high accuracy of the model proposed in the prediction of the load carrying capacity, failure mechanism and distribution of internal actions at collapse has been found.

[3] Politecnico di Milano, Piazza L. da Vinci 32, 20133 Milan, Italy, elsa.garavaglia@polimi.it

Key Words: *Historical Heritage, Seismic Vulnerability Assessment, Fragility Curves Application,*

The assessment of the seismic vulnerability of built heritage is still an open issue. Regarding this topic, in recent years many researchers have worked in the development of refined numerical models to simulate the behaviour of different building typologies subjected to seismic action. To be reliable, these models require in-depth knowledge of the building object of study.

In many countries, such as Italy, where the widespread historical heritage is widely present, there is the need to define quick, but reliable, evaluation procedures, which allow, in advance, to assess the vulnerability of the historical heritage of an entire area using databases already present without necessarily proceeding with detailed investigations on each building. This procedure has already been adopted in some case studies to compute a vulnerability index [1] or a safety factor for the structures examined [2].

Based on procedures in the literature, the authors have developed a forecasting methodology focused on the construction of fragility curves, safety factor vs PGA and vulnerability index, which allows to formulate hypotheses on the probable behavior of a specific type of building, to any similar actions and the probable expected damage. In the view of proceeding to the safety of a small historic village in an area with a high seismic propensity, this procedure could be useful for prioritizing interventions in probabilistic terms.

Key Words: *Masonry, Non-smooth contact dynamics, Distinct Element Method, Concrete Damage Plasticity*

The dynamics of historical masonry buildings is one of the most difficult tasks to be investigated in structural engineering, since these kinds of structures are commonly heterogeneous, with complex geometry, and with unknown quality of the connections between different structural parts, in particular walls and floors, that often play a crucial role. However, understanding the dynamical behaviour is crucial for a reliable seismic vulnerability assessment, which became more and more important due to recent catastrophic earthquakes (Umbria-Marche 1997–1998, Abruzzo 2009, Emilia-Romagna 2012, Marche-Lazio-Umbria-Abruzzo 2016).
In this work, the nonlinear dynamics of a medieval tower located in Accumoli, a village in central Italy, recently damaged by earthquakes is investigated. Generally, the mechanical response of masonry towers is commonly investigated by finite element methods [1], often including very sophisticated constitutive laws considering post-elastic behaviours and damage. These methods, while being very appealing, do not focus on the possible non-smooth nature of the dynamic response, which can come sliding and impacting between different blocks, and situation that is common just before and during the collapse. For this reason, in the present paper, the dynamics of the tower, schematized as a set of rigid blocks, is investigated by means of a distinct element code that implements the Non-Smooth Contact Dynamics method (NSCD) [2].
The main goal is to determine the weakness zones of the structure during seismic events, and the possible collapse mechanisms.
Harmonic oscillations applied to the basement of the tower are considered first, and a systematic parametric study is done, aimed at correlating the tower vulnerability to the amplitude and frequency of the excitation. In addition, numerical analyses are performed to see the effects of the friction coefficient and of the block's geometry on the dynamics, and on the collapse modes.
Then, the study of the tower stability against recorded seismic excitations is addressed. Attention is paid to the occurrence of out-of-plane torsional overturning mechanisms, and some comparisons of the damage obtained with the present approach and with other numerical models, like continuous finite element approach, are reported.

Unbonded Fiber Reinforced Elastomeric Isolators (UFREIs) made of high damping natural rubber blends

Gaetano Pianese[1*], Gabriele Milani[1] and Antonio Formisano[2]

[1] Department of Architecture, Built Environment & Construction Engineering (A., B., C.), Politecnico di Milano, Piazza Leonardo da Vinci 32, 20133 Milan, Italy

Key Words: *Seismic isolation, Unbonded fiber reinforced elastomeric isolator (UFREI), High Damping Rubber, Finite Element analysis, nonlinear dynamic analysis.*

In the last four decades, some commercial base isolators have been introduced to protect buildings from vibration and earthquakes. Typically, they are constituted by several alternating layers of rubber pads and steel interposed by two continuous pads, having the role of limiting vertical deformability. At the same time, they exhibit good deformation capacity in the horizontal direction when subjected to a seismic load. A very effective seismic isolator shall satisfy the following functions: good performance under all service loads, vertical and horizontal; provide enough horizontal flexibility to reach the target natural period for the isolated structure; recentering capability after the ground motion, so that no residual horizontal displacement can downgrade the serviceability of the structure; provide an adequate level of energy dissipation (damping) to control the displacement that could damage other structural members. Steel-reinforced elastomeric isolators (SREIs) is the most used method of seismic isolation. Since these devices are generally too expensive due to the need to introduce thick steel plates for their supports and the high energy consumed for the manufacturing process, they are not suitable for ordinary residential buildings, especially in developing countries. Compared with SREIs, fiber-reinforced elastomeric isolators (FREIs) have considerably lower weight and can be manufactured through cold vulcanization [1][2]. They could be installed between the structure in elevation and the foundation without any bonding or fastening in the so called unbonded application (UFREI), reducing costs hugely [3][4][5][6]. Furthermore, without steel supports, the shear load is transferred through the friction generated between the isolator and the structure surfaces, improving the dissipation energy of the devices. The main feature of such a UFREIs is the large deformability thanks to the roll-over deformation and the favorably lower lateral stiffness compared to the bonded isolator [7]. In this paper, a series of experimental tests and numerical analyses have been performed to investigate the seismic behavior of UFREIs made of high damping rubbers (HDR) combined with glass fiber reinforcement. In particular, two HDR have been considered. The first one consists of a Natural Rubber and Bromobutyl (NR-BIIR) blend. Instead, the second one is constituted of a NR and Ethylene Propylene Diene Monomer (NR-EPDM) blend. Results obtained from FE cyclic shear tests analysis and nonlinear time history analyses of structural application have shown that the devices are suitable to isolate low-rise masonry buildings properly.

Key Words: *adaptive structures, slabs, integrated actuators, Multi-axial load transfer*

In previous researches it has been shown that 33 % to 44 % of the mass in residential and office buildings and up to 50 % in high-rise buildings is attributable to floor slabs [1, 2]. Floor slabs typically take loading through bending. Such a load-transfer mechanism is not efficient, since the material in the proximity of the neutral plane is practically unloaded thus resulting in a poor utilization rate. Since bending stiffness is significantly lower than axial stiffness in a slab, typically deflection limits under out-of-plane loading govern the design of floor slabs. This causes significant oversizing. In addition, structures are typically oversized since they are designed to take extreme loading events, which in practice occur only for a small part of the service time. The on-going climate crisis, the expected world population growth and associated resource scarcity, call for new methods and solutions to build material-efficient structures with low embedded greenhouse gas emissions [3]. Employing adaptive structures could provide solutions. By integrating structures with components such as sensors, actuators and control units – stress and deformation caused by changing loads can be reduced actively, which enables significant material savings [4, 5]. Previous work carried out at the University of Stuttgart within the Collaborative Research Center 1244 has demonstrated that it is possible to compensate deflections by integrating fluidic actuators in beam structures subjected to bending [6]. However, it is not obvious how to transfer actuation strategies employed in beams to floor slabs due to multi-axial behaviour. In this work fluidic actuators are strategically integrated into floor slabs to employ multi-axial force transfer to counteract the effect of out-of-plane loading. The research also addresses the choice of an optimal distribution and layout of the actuators. Numerical simulations of different actuation strategies, such as uniaxial and biaxial actuation have been carried to derive influence fields. The relationship between principal moments and the influence of actuation is quantified numerically. Examples are provided to show how influence fields can be employed to select suitable actuation strategies. Results show that displacements can be efficiently compensated through a combination of uniaxial and biaxial actuation.

Key Words: Building automation; optimal control; adaptive structures

The growing world population and the increasing urbanization worldwide leads to continuous growth in the global construction activity. The building sector is responsible for about 35% of global green house gas emissions and more than 50% of resource consumption. Therefore, integrating innovative technologies into buildings is an important step towards achieving the climate and environmental policy goals, such as the Paris climate protection agreement.

The concept of adaptivity offers a way of reducing the material consumption by half. However, the mass reduction leads to multiple challenges such as increased susceptibility to static loads, e.g. snow, and oscillations resulting from dynamic disturbances as wind and earthquakes [1]. Adaptive buildings comprise sensors, control units and actuators and are able to actively counteract external disturbances. Furthermore, the active control strategy needs to take into account component failure in order to maintain the high safety standards of the construction sector.

The world's first adaptive high-rise building is built at the University of Stuttgart, Germany. The state of the building is measured by strain gauges and an optical measurement system, identifying the nodal displacement. Hydraulic cylinders, integrated into the structural elements, are able to actuate the structure in order to counteract static and dynamic disturbances.

A control law for compensation of static loads under consideration of the limited actuator forces is presented in [2] and validated using simulations and a scale model of the adaptive high-rise structure. Furthermore, our research group developed multiple control strategies for vibration damping, including linear quadratic controllers [3, 4, 5] and a model predictive controller. Experimental validation of the proposed control approaches is important but yet to be done. In this work, we will present some early validation results.

Key Words: *adaptivity, lightweight construction, beams, slabs, integrated actuators, simulation*

A high demand for living and working space as well as the corresponding infrastructure, caused by a growing population and increasing prosperity worldwide, leads to an increased consumption of mineral resources. This is accompanied by a high usage of grey energy and a high output of greenhouse gas emissions. For example, the cement production is responsible for up to 10 % of global anthropogenic CO_2 emissions [1]. In addition, the design of conventional building structures must be based on relatively high loads or load combinations that rarely or even never occur. Thus, today's conventional structures are oversized for most of their lifetime.
Adaptive structures represent a promising approach for mass and resource savings. Through the interaction of actuators, sensors and control units, the structure can adapt to the external loads to reduce stresses and deformations. As a result, material input can be reduced. [2]
In order to respond to all possible load cases, the structural element has to be manipulated locally. For structural elements subjected to bending loads, it is advantageous to integrate actuators into their cross-section to optimize the load transfer and thus achieve material savings. Fluidic actuators are a suitable solution due to their high energy density. However, they must be designed for this application. This is part of the subproject ‘C02’ of the Collaborative Research Centre 1244. The functional capability has been demonstrated for beams made of concrete in various simulations and on functional samples [3]. Therefore, actuators were integrated into the compressive zone of the beam. By applying forces in the longitudinal direction of the beam, a moment is generated that counteracts the bending moment caused by the external load. The effective range of the generated moment is limited, since the force is directly short-circuited via the concrete surrounding the actuator. For actuators in slabs, new challenges arise due to the multi-axial load transfer. In particular, the aim is to achieve the largest possible effective range of the applied moment in order to reduce the number of integrated actuators required. One approach is to optimize the geometry of the force-introducing surfaces inside the structural element.
This contribution presents a study about the correlations of the geometric parameters. Here, numerical simulations are used to determine these correlations. Based on the results, an analytical approach is formulated that describes the impact and area of influence of the intra-structural force application. Thus, the geometric and mechanical interface between the structural element and the integrated actuator can be pre-dimensioned. A first step towards the design of an adaptive element with integrated actuators subjected to bending is hereby possible.

Fault Diagnosis for Adaptive Structures

Jonas Stiefelmaier*[1], Michael Böhm[1], Oliver Sawodny[1], and Cristina Tarín[1]

[1] Institute for System Dynamics, University of Stuttgart, 70563 Stuttgart, Germany,
{jonas.stiefelmaier, michael.boehm, oliver.sawodny, cristina.tarin-sauer}@isys.uni-stuttgart.de

Key Words: fault diagnosis, adaptive structures

Adaptive buildings can dynamically adapt to changing external loads using integrated actuators, and thereby significantly reduce the resource consumption and the emissions in the course of the building's construction [1]. Given the large number of sensors and actuators in such an adaptive building, in combination with its long lifetime, failure of one or more of those components is likely. This is generally referred to as a fault, and comprises different types of failures ranging from a bias in a sensor's measurements or the force provided by an actuator, to the total unresponsiveness of the component. As adaptive buildings are operated in a closed control loop, such faults directly affect the control inputs, i.e. the forces applied to the building by the actuators, and can thereby compromise the building's functionality and safety. A reliable fault diagnosis system that detects and classifies faults promptly and reliably is a prerequisite for initiating suitable countermeasures in case of a fault, and is therefore essential for any adaptive building.

For both purely model-based and hybrid model-/data-based approaches, simulation studies considering an adaptive high-rise building revealed a detection and classification of such faults with high accuracy [2], [3]. Lacking a suitable experimental platform, however, these methods could not be validated on a real-world adaptive structure until now.
Using a recently constructed demonstrator building, an adaptive high-rise truss structure of 36 meters in height located on the campus of the University of Stuttgart, we now provide such an experimental validation. In order to successfully transfer the methods for fault diagnosis from simulation to a real-world setting, model errors are a major challenge and can cause a significant drop in performance. Previous simulation studies did not consider model errors exceeding simple parametric errors in a linear state space model, which are not representative for the model errors encountered in real-world conditions. In that context, we investigate the suitability of different methods for fault diagnosis by evaluating their performance in a real-world setting.

Formulation of actuation units for stress-free control of deformations in statically indeterminate adaptive structures using actuation influence matrices

Simon Steffen[1*], Lucio Blandini[1] and Werner Sobek[1]

[1] Institute for Lightweight Structures and Conceptual Design (ILEK), Pfaffenwaldring 14, 70569 Stuttgart, Germany, {firstname.lastname}@ilek.uni-stuttgart.de, www.ilek.uni-stuttgart.de

Key Words: *Adaptive structures, influence matrices, actuation units, stress-free*

The construction sector contributes considerably to material resource depletion and it is responsible for a large share of global emissions. Given the growing world population and related demand for new built environments, new approaches are needed to significantly reduce the environmental impact of the construction sector. One proposed solution are adaptive load-bearing structures [1,2]. Actuators, sensors and control units are strategically integrated to manipulate deflections and stress under loading, which results in significant material and emission savings. Current research is looking into actuation strategies, optimal actuator placements as well as structural topologies that result in material- and emission-efficient adaptive structures. A useful method for analysing the capabilities of adaptation of spatial trusses and frames are actuation influence matrices [3]. These matrices contain quantitative information on how nodal deformations, normal and shear forces or bending moments can be influenced through actuation for a given structural topology – independently from a specific control objective (inherent adaptivity). A row gives the influence of actuation of each element on the selected structural response e.g., the corresponding displacement or element force. A column gives the influence of actuation of the corresponding element on the structural state e.g. the state of normal forces or nodal deformations. The rank of an actuation influence matrix is thus equal to the number of linearly independent states that can be induced through actuation. Forces, moments and displacements resulting from actuation can be computed by multiplying the individual columns with an actuation input load.

Combining multiple columns of an actuation influence matrix allows for the formulation of so called actuation units [4]. These actuation units can be employed to model physical actuators spanning over multiple elements or to predefine a specific relation in which multiple elements are to be actuated (constraint equation). For example, to guarantee stress-free control of deformations in statically indeterminate structures. A method is derived to formulate actuation units for stress-free deformation control showing that its general applicability can be assessed from the rank of the actuation influence matrices.

Key Words: *Morphing wing, adaptive structure, load alleviation, multidisciplinary optimization*

Morphing wings are currently of high research interest in the field of adaptive structures. They promise to increase the efficiency and mission adaptability of future aircraft. By replacing discrete high-lift and control surfaces, the aerodynamic efficiency can be improved. Furthermore, by adapting the wing to its optimal shape for each flight condition, fuel consumption over the whole flight mission can be reduced. Despite the promising benefits of morphing wings, significant increases of the wing mass have to be expected. Moreover, the energy required for active shape deformation reduces the net reduction of fuel needed. Therefore, lightweight design of morphing aircraft wings becomes even more important than for conventional wings. On the other hand, morphing wings themselves offer potential for weight reduction if they are used for load alleviation. In consequence, design loads can potentially be decreased, resulting in reduced structural masses. This motivates the necessity of enhancing active morphing wings with load alleviation potentials.

In order to obtain preliminary design suggestions for morphing wings, the multidisciplinary characteristics, arising from the combination of structural, aerodynamic, kinematic and actuation aspects, have to be taken into account. For this purpose, the authors recently presented an optimization framework for optimizing active morphing wing sections with the aim of reduced drag over a certain flight mission and low structural mass [1]. The internal layout of the morphing wing sections is defined by a truss structure [1]. Based on the resulting design proposals for active morphing wing sections, the present work investigates the potential of combining the active morphing wing sections with a passive deformation behaviour in order to reduce loads arising from increased angles of attack, as it is typical during gust. Therefore, target-oriented stiffness reductions of individual components of the active truss structure are optimized using Evolutionary Algorithms and a loosely coupled fluid-structure interaction approach. Target is the reduction of the lift increment by passive deformation of the aerofoil section for increased angles of attack.

The optimization approach presented allows to conduct first preliminary feasibility studies that can build the basis for future morphing wing concepts combining drag reduction and load alleviation. It is shown that the investigated concept enables feasible deformations of the aerofoil contour in order to reduce undesired lift increments.

State Estimation for Adaptive Structures

Amelie Zeller*[1], Michael Böhm[1], Oliver Sawodny[1] and Cristina Tarín[1]

[1] Institute for System Dynamics, University of Stuttgart, 70563 Stuttgart, Germany,
{amelie.zeller, michael.boehm, oliver.sawodny, cristina.tarin-sauer}@isys.uni-stuttgart.de

Key Words: state estimation, adaptive structures

The construction sector causes a significant part of the global resource consumption (material, embodied energy, waste, emissions). A rising living standard and a growing world population aggravate this problem. In order to reduce the resource consumption in the construction sector, ultra-lightweight structures are helpful. Ultra-lightweight structures can be realized through the concept of adaptive structures [1]. Adaptive structures refers to structures equipped with sensors, actuators and control units. Although ultra-lightweight structures may be more susceptible to static deformation and vibration caused by loads or disturbances such as wind, snow or earth quakes. In contrast to conventional (passive) structures, adaptive structures can handle them by actively counteracting them.

For an adaptive structure to actively and effectively counteract disturbances, a control concept is required, the design of which is one of the challenges in developing adaptive structures. The main components of the control concept are a controller, a state estimator and a fault diagnosis block. The state estimator uses the sensor measurements and a dynamic model of the structure to compute the structure's state, which consists of all nodal displacements and velocities. The state is then used by the controller to compute a control signal for the actuators and by the fault diagnosis block to detect and isolate faults of sensors or actuators. Usually, the static deformation and vibration of a structure is initially caused by immeasurable, external disturbances. However, if these disturbances are unknown to the state estimator, they can lead to a significant estimation error. That motivates to develop disturbance estimation concepts, too. Within our research group, sensor placement and model-based state estimation methods have been successfully applied to and adaptive high-rise building in simulations [2, 3, 4]. In that context, we investigate simulatively methods for state and also disturbance estimation for example adaptive structures.

Vibration control of simply supported beam bridges equipped with an underdeck adaptive tensioning system

Arka P. Reksowardojo[1]*, Gennaro Senatore[1], Manfred Bischoff[2], Lucio Blandini[1]

[1]Institute for Lightweight Structures and Conceptual Design (ILEK), University of Stuttgart, Germany

Key Words: *Adaptive structures, bridge engineering, vibration control*

External post-tensioning is an effective solution to improve the structural performance of beam bridges [1]. The tension force from the external cables is applied eccentrically to the neutral axis by means of deviators. The resulting system of forces induces a bending moment that counteracts the effect of the external load. However, typical external post-tensioning systems are effective under one scenario which is usually the permanent load. This work investigates the application of an external adaptive tensioning (EAT) system to the design and control of high-speed railway (HSR) bridges. The design of HSR bridges is challenging because strict criteria for safety and comfort must be met, which typically results in oversizing. Train loading can often cause a significant dynamic response. The sudden entry of a high-speed train is similar to an impact load and the excitation frequency caused by the regular spacing of the train wheels can induce resonance. The EAT system comprises under-deck cables deviated by variable-length compressive struts that act as intermediate supports. The structural system behaves as an underdeck cable-stayed bridge [2] where each cable end is fixed to the corresponding end of the beam nearby the support. However, linear actuators are employed to adjust the length of the struts, which changes the tension in the cables allowing to manipulate the bending moment as the load changes. Previous work has shown that similar external adaptive tensioning systems are effective to reduce the response of beams under quasi-static [3, 4] as well as dynamic loading [5]. A sensitivity analysis is carried out on simply supported steel-composite beam bridges to identify limitations from design best practice. Typical dimensions are considered by varying the span from 15 m to 45 m while keeping the depth to 2.4 m. Full time-history analysis shows that vertical acceleration limits cannot be met for most medium- and long-span configurations. A comparison is carried out with identical bridges equipped with an EAT system comprising a single actuator. The vertical response is reduced through the actuator length adjustments that are computed by a state-feedback controller based on the Linear Quadratic Regulator. Results show that vibration control through the EAT system enables vertical acceleration limits for medium-span HSR bridges to be met. The cyclic stress intensity range is significantly reduced demonstrating the potential for fatigue-life extension.

Key Words: Structural Health Monitoring, Damage Detection, Optimal Experimental Design, Optimal Sensor Placement, Digital Twin, Structural Dynamics

Identification and monitoring of damage have a growing importance in the maintenance of structures. A robust active sensing framework that integrates model-based inference and optimal sensor placement is proposed. The approach addresses the monitoring problem with a holistic view in which inference from data and data acquisition scenarios are tightly connected. Structural health can be continuously and accurately assessed by solving an alternating sequence of damage estimation and optimal sensor placement problems.

A partial differential equation-constrained formulation for damage estimation is first developed using a conventional model-updating approach with a binary penalization damage parameter. Then, this formulation is linearized around an appropriate nominal damage state to produce an Optimal Experimental Design (OED) problem for desirable sensor locations. The sequential sensing framework is postulated using a variance-minimization approach as follows: given a current candidate damage state associated with the most up-to-date sensor information, find the next sensor location that minimizes the variance in the inferred damage state and update the damage estimator.

The sequential sensing framework is also enhanced by introducing a Modified Error in Constitutive Equations (MECE) functional in the damage estimator. Adding MECE will quasi-convexify the damage estimation problem, making the framework more robust by limiting the damage estimator from being trapped in local minima. This ensures that the sequence of damage estimation problems will converge to the true damage state given arbitrary initial guesses and sufficient sensor information.

Finally, the sequential sensing framework with MECE is demonstrated using numerical and experimental models analogous to digital twins of reactor vessel internals in nuclear power plants. Practical algorithmic heuristics including sensor placement constraints and convergence criteria are explored.

Key Words: *Model Calibration, Bayesian Updating, Verification and Validation, and Li-Ion Battery*

As the commercialization of electric vehicles (EVs) progresses, high reliability of the systems in EVs like battery systems are required. For high reliability of the battery system, information about the health state of the battery system during degradation is essential. When the battery is used repeatedly, the chemical state inside the battery changes. The chemical state changes cause the degradation of battery health sates such as state of health (SOH), mechanical properties (stack pressure and swelling). Such a change in the health state is a cause of failures inside and outside the battery systems. For preventing these failures, the various studies are attempting to model and accurately predict the changes of the battery systems. There are two challenges in the predicting health state using the mathematical models. (1) Batteries of various specifications are used for each EV models, and different batteries have different parameters in the models, and (2) even within the same battery, aleatory uncertainty occurs due to chemical uncertainty. Therefore, in order to accurately predict the health state of the battery system, statistical state information in consideration of the above factors is required.

Model calibration plays an important role in the engineering field as a way to improve the results of Model & Simulation. Various model calibration methods perform the calibration process in consideration of the bias and uncertainty existing in the model or real world. The well-known KOH framework defines the model discrepancy term for the bias between the simulation model and the real data, and updates the bias through this framework. [1] And the recently studied SeCav framework is sequentially performing model calibration and validation using uncertainty quantification and reduction. [2] And the BC-TS technique performs model correction of parameters lacking prior knowledge by using the Takagi-Sugeno fuzzy models rather than the GP in the existing calibration framework. [3] This paper studies the framework of existing model calibration frameworks (1) to check whether the GP, RBF, and fuzzy models adequate for the battery bias model updating generated by different parameters for each battery, and (2) compares whether each framework statistically predicts the aleatory uncertainty of the battery system. The comparison study finds the best modelling techniques and calibration framework for the model prediction of batter systems by using the existing battery model and given data.

Key Words: drill string nonlinear torsional dynamics, stability analysis, bifurcation, Bayesian model selection, parameter estimation

Drill string is a slender structure that rotates to drill rocks in search of oil and gas. Its torsional non-linear dynamics is of particular interest because high oscillations might occur and should be avoided. The self excited mechanism happens due to the non-linear bit-rock interaction. There are different ways to model this interaction which lead to different bifurcation maps. We would like to stablish a methodology to choose the model that most corresponds to the available experimental data [1].

The Bayesian strategy for parameter estimation is convenient for this type of application [2]. The stochastic inverse problem begins with prior information about the probability density model of the parameters that should be identified. Then, experimental data is used to update the probabilistic model with the aid of Bayes formula, if the likelihood function is known. Statistics of the parameters and of the predictive models are obtained.

In this context, the present work proposed to apply the approximate Bayesian computation (ABC) [3], which is likelihood free, for parameter estimation, uncertain quantification and bit-rock interaction model selection. The (i) exponential, (ii) hyperbolic tangent, (iii) combined models are able to represent the non-linear interaction, but the ABC procedure indicates that the combined model yields a higher probability, considering the configuration analysed and the available experimental data.

Key Words: *scientific machine learning, nonlinear dynamics, universal differential equations*

With more and more data and computational capacity becoming available, data-driven modelling of real-life systems is an increasingly popular approach both in the scientific community and industry. At the same time, there is a growing interest towards 'Digital Twins'; accurate, online and adaptable digital counterparts of physical structures which could be used e.g. as a design aid or to help with maintenance decisions at structures already in operation.

Universal differential equations (UDEs) [1] are a promising approach to include measurement data with machine-learnt structures inside differential equations alongside algebraic terms representing mechanistic models. By having a physics-based core, UDE models can incorporate the insight and expertise one has on the behaviour of the modelled structure. However, every physics-based model involves some degree of error compared to measurement data due to the dynamics neglected by the model. The purpose of using machine-learnable structures with the mechanistic model is to compensate the error between the observed and predicted behaviours resulting in not just a qualitatively but also quantitatively accurate model of the physical structure. While pure machine-learnt models could also be used for this task, the UDE model can be expected to require a smaller training dataset, more lightweight machine-learnt structures and, as a result, smaller computational effort as the physics-based part already stores information about the behaviour of the observed system.

Most of the studies on UDEs however focus on identifying a well-fitting model with a constant set of system parameters while it is often also interesting to investigate the system's response to varying parameters, e.g., to allow for parameter-uncertainty, or to incorporate the change of external conditions. Our study focuses on nonlinear dynamical systems and learning measured bifurcation diagrams using the UDE models leading to inherently varying-parameter problems.

Using the examples of aeroelastic flutter and a forced nonlinear oscillator [2] we assess the efficiency of the UDE modelling approach using neural networks [1] and Gaussian processes [3] as the machine-learnt part of the model. We demonstrate that the modelling approach has a great potential in delivering accurate models of nonlinear dynamical systems whereas we also report on the challenges encountered during the training procedure, such as overfitting and finding local minima of the objective function and discuss the potential ways of avoiding these issues.

Key Words: *Virtual Testing, Parameter Estimation, Multibody Model, Kalman Filter*

Within the context of wind turbine component design, there is an interest to develop novel, advanced virtual test approaches using Digital Twins of both components and test bench setups. More specifically, virtual testing of novel pitch ball bearing designs is of interest, as these typically require large scale test setups.

In this work, the use of a Smart Virtual Sensing (SVS) Digital Twin [1] is proposed to estimate pitch ball bearing parameters, as well the overall system states and inputs. A multibody model of a pitch bearing test setup, including a parametrized analytical ball bearing model representing the pitch ball bearing, is combined with a Kalman Filter. A multibody formulation typically yields a set of Differential Algebraic Equations (DAEs) due to the presence of kinematic equality constraints. Recently, several approaches have been proposed in literature to combine these DAEs with a Kalman Filter ([1], [2] and references therein) for combined state and input estimation by relaxing the constraint definition leading to a set of non-linear Ordinary Differential Equations (ODEs). Rodriguez et al. [3] have recently presented an approach for multibody model parameter estimation. While these approaches cover equality constraints in different approximated ways, they do not in general consider inequality constraints. It is shown in this work that these approaches can lead to unstable behaviour of the Kalman Filter for bearing parameter estimation, as these parameters represent physical quantities, which in general have to be bounded (e.g. non-negative values) via inequality constraints. Without these constraints, the estimated parameter values can be out of bound and lead to unstable behaviour.

This work therefore further proposes an active set approach to enforce inequality constraints, stabilizing the Kalman Filter and allowing for robust bearing parameter estimation. The proposed approach is validated numerically and the necessity of including the inequality constraints to stabilize the Kalman Filter is highlighted.

Key Words: nonlinear dynamics, parameter identification, model selection, reinforcement learning, ABC, decision under uncertainty

This paper proposes an extension of a recent developed methodology for model selection and parameter identification [1] which combines (i) reinforcement learning (RL) for model selection through a Thompson-like sampling with (ii) approximate Bayesian computation (ABC) for parameter identification and uncertainty quantification. Motivated by the digital twin framework where a system (physical twin) evolves over time, we consider three new features. (1) The worst model is not discarded because it might be useful in the future, as the system evolves. (2) The algorithm detects a change in the system by monitoring the models' acceptance; a significant drop in acceptance indicates a change. (3) If the system changes the algorithm is reset: new parameter ranges are computed and the Beta distribution of the Thompson sampling is restarted, as well as the rewards. Data are obtained from an experimental test rig which is a non-linear oscillator composed of a clamped beam with a tip mass, magnets and a coil. The amplitude of the dynamical system is obtained sweeping the amplitude of excitation; the control-based continuation strategy is used for this purpose [2]. The evolution of the system with time is emulated varying the distance between the tip mass and the coil. Three Duffing-like models are used: (a) cubic, (b) fifth-order and (c) seventh-order. Different cases are considered to test the new algorithm which seems promising for the analysed application and can be extended to others, for instance related to digital twin where a physical system is changing over time. The proposed RL-ABC strategy should be further tested in different systems to verify its extent.

Robust State-Input Estimation for Differential Algebraic Equations and Application to Multibody Systems

Tommaso Tamarozzi[1], Pavel Jiránek[1] and Daniel De Gregoriis[1*]

[1] Siemens Digital Industries Software, Interleuvenlaan 68, 3001 Leuven, Belgium,
tommaso.tamarozzi@siemens.com, pavel.jiranek@siemens.com,
daniel.de_gregoriis@siemens.com

Key Words: *Kalman Filter, Multibody Model, State Estimation, Input Estimation, Digital Twin*

Digital Twins (DT) allow to accelerate the development of new products and enable new insights throughout the different product lifecycle stages. Smart virtual sensors based on DTs are capable of estimating quantities that cannot be easily measured, such as the full system states (and related quantities like strain and stress fields) and unknown inputs. Using a Kalman Filter approach [1], such a Digital Twin can be created by combining data coming from physical sensors with the asset's numerical model.

For complex mechanical systems composed of interconnected bodies and experiencing large motions and small deformations, a multibody formulation is commonly employed. The resulting equations of motion allow to efficiently express the kinematic constraints (i.e. connections) between the different components (i.e. bodies) using algebraic equations in combination with Lagrange multipliers. This yields a system of Differential Algebraic Equations (DAEs). Different approaches have been presented in literature to combine these DAEs (i.e. the multibody model) with a Kalman Filter ([2]-[4] and references therein). These approaches mainly differ in their handling of the algebraic constraint equations. They typically require using a specific multibody formulation and/or allow constraint violation (i.e. soft constraint enforcement). This tends to limit their use to either special cases or requires problem-specific tuning that can be detrimental for the application as a Digital Twin.

This work therefore presents a robust, general Kalman Filter-based state-input approach that allows to directly enforce the kinematic constraints exactly. More specifically, the estimated state is enforced to lie on the manifold described by the constraint equations and therefore meet the equality constraints exactly. This allows to generate a robust and smart virtual sensor using the Digital Twin of complex mechanical systems. The proposed methodology is numerically validated using closed and open kinematic chain multibody models.

Stochastic Physics-based Model Updating for Fatigue Crack Detection in Riveted Lap Joints Using Lamb Waves

Wongon Kim[1*] and Byeng D. Youn[2]

[1] Seoul National University, 08826, Seoul, Korea, bethesome@snu.ac.kr
[2] Seoul National University, 08826, Seoul, Korea; OnePredict Inc., 06160, Seoul, Korea, bdyoun@snu.ac.kr

Key Words: *Digital Twin, Lamb Wave Propagation, Fatigue Crack Estimation, Physics-based Model*

The mechanical joints (e.g., lap joint, weld, bolt, pin, etc.) are vulnerable to fatigue because of stress concentration and various internal flaws. Various digital twin strategies were used to support engineering decisions for system operation to prevent catastrophic system failure by fatigue damage in mechanical joints. The digital twin is a computational model that simulates the operating engineering system in the real world to support engineering decisions. The digital twin is a virtual model representing physical entities such as engineering products, components, and systems. The virtual model can be categorized into 1) data-driven, 2) physics-based, and 3) hybrid approach. The digital twin needs to be updated or analyzed using the observed response from the physical system to represent the current state/condition of the system. The PZT(lead zirconate titanate)-induced lamb wave is a suitable observed quantity for digital twin estimating crack detection in a mechanical joint. The PZT sensor is an active sensor in a fixed position, acquiring the repeatable signal without nonstationary noise. In a previous study, various data-driven approaches were proposed to estimate fatigue damage detection using PZT-induced lamb wave signal. He et al. (2013) proposed a data-driven approach to estimate crack length using Lamb waves in riveted lap joints based on the feature extraction and regression methods [1]. Pandey et al. (2022) proposed a deep-learning approach for damage detection using a 1-D convolutional neural network [2]. However, data-driven require many lamb wave signals measured in different crack lengths and geometry and suffer from low accuracy in noisy conditions. On the other hand, the physics-based approach is less dependent on data and is physically interpretable.

In this study, the stochastic physics-based model updating is proposed for fatigue crack estimation in riveted lap joints using lamb waves. The proposed approach is based on two techniques; (i) deterministic model calibration and (ii) stochastic model updating. In deterministic model calibration, physical properties of the medium, such as wave speed and decaying rate, are estimated using the observed signal. The k-Wave MATLAB Toolbox was utilized to simulate the lamb-wave propagation in the lap joint [3]. In stochastic model updating procedures, the possible crack growth path is sampled based on the probability of crack direction to consider uncertain crack propagation paths. The probability of the stochastic process is calibrated using Monter-Carlo simulation and the simplex method. The validity of the proposed method is demonstrated using an observed lamb wave in the fatigue test of the lap joint specimen. The results conclude that the proposed digital twin approach can accurately estimate fatigue crack growth state in lap joints.

The Comparison of Sensor Optimisation Strategies for Structural Health Monitoring Using Machine Learning

Tingna Wang, Keith Worden, Robert J. Barthorpe and David J. Wagg

Dynamics Research Group, University of Sheffield, Mappin Street, Sheffield, United Kingdom, S1 3JD
Email: twang71@sheffield.ac.uk

Key Words: Sensor Placement Optimisation, Supervised Learning, Unsupervised Learning, Time-series Data, Correlation Coefficient

Machine learning algorithms have been widely used to monitor the health of structures. The application of sensor placement optimisation (SPO) can be conducive to acquiring the most valuable data for constructing an effective damage identification model. There are two basic methods of machine learning, including supervised learning and unsupervised learning. The main difference between the two methods is whether to use labels of different structural health states. Therefore, different SPO approaches should be developed to improve the performance of structural health monitoring (SHM) systems based on these two machine learning methods.

In this paper, two SPO strategies with a linear correlation coefficient as the optimisation objective are proposed and compared using features extracted from time-series data. The critical difference between these two developed strategies is in whether the labels of different health states of a structure are involved in the optimisation process or not. A case study that uses the experimental data collected from tests on a glider wing demonstrates the characteristics of both strategies. The results show that the optimal sensor placement obtained by the first approach without considering the labels has better performance in detecting the occurrence of the damage on unexpected areas. However, if only the predictable damage cases of interest are focused on, the second optimisation approach that considers the state labels should be adopted.

Key Words: Isogeometric analysis, random roughness, coefficient of friction, frictional contact

In this paper, frictional contact problems of elastic bodies with random roughness are addressed using the Isogeometric analysis computational framework. To model the randomly rough surfaces, a new method is proposed consisting of a collocation-based Karhunen-Loeve random field modelling method and Non-uniform Rational B-spline (NURBS) interpolation method. The frictional contact problems are solved using a mortar-based contact algorithm. The local and global coefficients of friction (COF) are compared under the conditions of varying interfacial properties and external loads. The mean value and standard deviation of the global-to-local COF ratios of each scenario are obtained through Monte-Carlo simulations. Both quasi-static and dynamic contact problems are under investigation. It is found that the correlation length and Root Mean Square of the random contacting surfaces and the magnitude of the external loads impact significantly the development of global-to-local COF ratios with different rules.

TRANSFER LEARNING TO LEVERAGE DIGITAL TWINS IN DRILL STRING DYNAMICS

Thiago G Ritto[1*], Keith Worden[2], David Wagg[2], Fernando A Rochinha[1] and Paul Gardner[2]

[1] Universidade Federal do Rio de Janeiro, Cidade Universitária – Ilha do Fundão 21945-970, Rio de Janeiro, Brazil, tritto@mecanica.ufrj.br, faro@mecanica.ufrj.br

[2] University of Sheffield, Mappin Street, Sheffield S1 3JD, United Kingdom, k.worden@sheffield.ac.uk, david.wagg@sheffield.ac.uk,p.gardner@sheffield.ac.uk

Key Words: digital twin, transfer learning, drill string torsional dynamics, localised friction, deviated wells

Digital twins seek to replicate a physical structure in a digital domain [1]. For a digital twin to have close correspondence to its physical twin, data are required. However, it is not always possible, or cost-effective, to collect a complete set of data for a structure in all configurations of interest. It is useful to repurpose data to help validate predictions for different configurations and scenarios. This is true in drill-string applications [2], where, for example, the length of the drill may be altered throughout operation. This paper demonstrates how transfer learning, in the form of three domain adaptation methods, — transfer component analysis (TCA) [3], maximum independence domain adaptation (MIDA) and geodesic flow kernel (GFK) — can be used to construct a digital twin for localising torsional friction in deviated wells under structural changes (e.g., when the drill column gets longer). The method uses a physics-based torsional model to train a machine learning classifier that can localise torsional friction for a given drill length, and diameter, where friction localisation labels are known (source). As the length or diameter of the drill are altered in the field, transfer learning is utilised to map the classifier from the labelled (source) scenario onto these unlabelled (target) scenarios. As a result, transfer learning improves the performance of the classifier when applied to the target data, and increases the domain of validity for the classifier. The performance of the classifier, and therefore its suitability to new drill configurations, is estimated by utilising two different distance metrics between the source and a proposed target dataset.

Key Words: Parametric Reduced Order Model (pROM), Ultrasonic Guided Waves (UGW), Structural Health Monitoring (SHM), Damage Detection

Ultrasonic Guided Waves (UGW) bear an enormous potential for application within a Structural Health Monitoring (SHM) context. Advantages of UGW include their potential for detecting small defects, whilst propagating through long distances in thin structures, and the rather low cost of involved sending units (PZT-based). To unwrap the full potential of UGW, fusion of the measured data with models is required. Fused data and models allow for reaching higher levels of SHM – such as localisation or quantification of damage – following Rytter's specified hierarchy [1].

Due to their short period and wavelength, UGW require a fine discretization in time and space when one seeks to simulate the forward problem of wave propagation. This fine discretization leads to computationally expensive simulations. Since solving the inverse problem, which fuses UGW data with the models, necessitates repeated evaluations of the forward problem, the computational costs represent a major bottleneck towards effective use of UGW in SHM [2]. This work tackles this problem by introducing a parametric Reduced Order Model (pROM) for simulating UGW propagating in plates that contain flaws (e.g. cracks).

For efficient use, the pROM needs to be parameterized with respect to different defect configurations and properties, such as the location, shape or size of the defect. To train the pROM, enough information on the response of the system, depending on different parameter sets, is necessary. Due to the multiple parameters that can be involved, especially in the case of multiple flaws, and due to the large cost of the high–fidelity model, a sparse grid in the parameter space and additional knowledge on the systems behaviour needs to be used. To address this, we propose a pROM based on Gaussian Process Regression (GPR). The GPR enables to fit engineering knowledge through the definition of priors, while keeping the amount of high–fidelity training simulations low through active training. The developed framework is verified on simulated case studies.

Structural damage and deterioration of structures forms a primary engineering problem as such process can often cause catastrophic failures. The objective of structural health monitoring (SHM) is to identify anomalies or damages such as cracks, delaminations, etc. in structures. A number of SHM techniques exist for damage detection, such as vibration-based SHM, electromechanical impedance-based SHM, guided wave (GW)-based SHM, etc. The GW-based technique offers a number of advantages because of its high sensitivity to small defects and large area scanning. Damage detection is an inverse problem, in which the damage needs to be detected using the measured input and output signals. The conventional calculus-based search techniques use gradients, which can not handle problems having a finite number of discontinuities or functions with many local maxima or minima. But, genetic algorithms (GAs) can handle such problems without getting locked into a local optimum configuration. Damage detection in the form of an inverse problem can be performed using stochastic and evolutionary optimization methods, such as the GA, which is based on the principles of natural selection and genetic evolution.

In this research, elastic wave propagation emulated by a deep learning-based model is used as a tool for damage detection.The GA employs the deep learning-based simulator for multiple solutions of the forward problem. Our deep learning-based model is found to outperform traditional numerical solvers. Thus allowing low computational cost of damage detection, using GA as an optimization, with good accuracy.

(email: jeong1c@cmich.edu)

Key Words: Inverse problems; seismic input inversion; non-convolutional second-order complex-frequency-shifted perfectly matched layers

A new inverse modeling is investigated for reconstructing seismic input motions propagating into a domain surrounded by a domain reduction method (DRM) boundary from limited seismic measurement data. The non-convolutional second-order complex-frequency-shifted perfectly matched layers (CFS-PML) is employed to truncate a two-dimensional semi-infinite domain of a plane-strain setting, and the DRM is utilized to model seismic input motions coming from the outside domain of the CFS-PML. A partial differential equation (PDE)-constrained optimization method aims at minimizing a misfit between measured motions at sensors on the surface induced by targeted incident waves (or equivalent effective forces on a DRM boundary) and their reconstructed counterparts induced by estimated effective forces.

The numerical results show that the targeted effective forces can be accurately reconstructed. It is observed that the wave responses in a structure and soils in the domain induced by the targeted effective forces are in excellent agreement with those by the reconstructed ones. Therefore, the presented method can help engineers to replay seismic responses of structures and soils from limited seismic measurement data and estimate the impact of earthquake waves on infrastructures.

Lamb wave-based damage identification in bounded structures through an inverse Bayesian process

Abstract

Guided wave test is a promising technique for online monitoring in various industries such as aerospace and wind power. A Bayesian framework based on guided waves for damage identification of three-dimensional joints of arbitrary shape and finite size is presented here for the first time. The hybrid wave and finite element approach is adopted to obtain the scattering coefficients corresponding to different size defects, which can provide the results of different excitation types in a single operation. However, the physics-based Bayesian framework requires numerous calls to the physical model, which will drag the inversion framework into a time-consuming quagmire. In order to increase the efficiency of the proposed scheme, a Kriging surrogate model is used to generate a database containing measured scattering properties. Finally, a numerical model is used to validate the damage identification scheme.

Simulation of wave propagation in remote bonded FBG sensors using the spectral element method

Piotr Fiborek[1], **Rohan Soman**[1], **Pawel Kudela**[1], **and Wieslaw Ostachowicz**[1]

[1] Institute of Fluid Flow Machinery, Polish Academy of Sciences, Fiszera 14 Str., 80-231 Gdansk, Poland

Key Words: Wave propagation, spectral element method, optical fiber, FBG, non-matching mesh, remote bonding

Ultrasonic guided waves (GW) due to their ability to monitor large areas with few sensors, are commonly employed for structural health monitoring (SHM) in aerospace, civil, and mechanical industries. The FBG sensors in the edge filtering setup are re-emerging as a favored technique for GW sensing. The FBG sensors offer embeddability, ability to be multiplexed, small size, and immunity to electric and magentic fields and as such are seen as ideal sensors. To enhance the sensitivity of these sensors, these sensors are deployed in the so-called remote bonding configuration where the optical fiber is bonded to the structure while the FBG sensor is free. This configuration not only enhances the sensitivity but also opens up possibility of self-referencing.

In this setup the GW in the structure is coupled to the fiber and converted into fiber modes. These modes propagate along the fiber and then are sensed at the FBG. The conversion of the plate modes to fiber modes is a phenomenon which is still being studied. The effect of the adhesive layer and the material properties of the adhesive on the coupling are still not known. Furthermore the directional nature of this coupling and its marked difference from the directly bonded configuration needs to be studied in detail. For this detailed study a computationally efficient model which captures the physics of the coupling is necessary.

Hence, in this research we develop a numerical model based on the spectral element method for the modelling of the remote bonded configuration of the FBG. The model comprises four meters long optical fiber bonded to the centre of the plate by the adhesive layer and the piezoelectric disc (PZT) used for wave excitation. All components are modelled by 3D spectral elements, with second-order elements used for the fiber and adhesive layer. Parametric studies were performed for various thicknesses and the Young's modulus values of the adhesive layer, the FBG distance from the bonding fiber to the plate, PZT location and signal excitation frequency.

The model is validated with experimental results and shows that it indeed captures the physics of the coupling and is computationally more efficient than other methods using conventional finite element software.

Critical Velocity and Instability of Inertial Objects Moving Uniformly on Layered Track Models

Zuzana Dimitrovová[1,2*]

[1] Department of Civil Engineering, NOVA School of Science and Technology, NOVA University of Lisbon, Portugal, zdim@fct.unl.pt (https://docentes.fct.unl.pt/zdim)
[2] IDMEC, Instituto Superior Técnico, Universidade de Lisboa, Lisboa, Portugal

Key Words: *Moving Proximate Masses, Mass-Induced Frequency, Semianalytical Solution, Dynamic Interaction, Instability, Contour Integration*

In this contribution, a new form of semianalytical results related to inertial objects that are traversing homogeneous infinite structures, introduced in previous author's work [1], is used to analyze one-, two- and three-layer models of the railway track. The aim of these analyses is determination of the critical velocity of a moving force and of the onset of instability of moving masses or oscillators.

The new form of semianalytical results is related to infinite structures, but in addition to these derivations, equivalent finite models are presented and solved in order to provide easy validation of the results. For such structures, the eigenmode expansion method is used and therefore the natural frequencies and orthogonality conditions must be derived. Furthermore, due to the coupling of modal equations, a rearrangement of the terms involved is introduced to save computational time. All results, both from finite models and from infinite models, are presented as much as possible analytically using dimensionless parameters, and therefore can be used directly for several combinations of input data.

First of all, the possible range of dimensional parameters is identified. Within these ranges, there are significant differences between the models. While for the one- and two- layer models the critical velocities are well-defined and their number is 1 or 3 [1-3], respectively, in the three-layer model their number depends on parameter values and can be 1, 3 or 5. Regarding the onset of instability, there are also significant differences, not only between the models but also between the cases with one or more moving masses or oscillators. For one-layer model, which is in fact the model of an infinite beam on the classical Winkler-Pasternak foundation, instability of one moving mass has regular behavior and occurs always in the supercritical velocity range when damping is present and at the critical velocity in case of no damping. Two moving proximate masses already introduce severe alterations, because in damped case the dynamic interaction can shift the onset of instability deeply into the subcritical velocity range [2]. The other models introduce other irregularities, even for one moving mass [3]. This contribution will summarize all the differences and common features that exist between these models and within the full range of possible parameter combinations.

A Generalized Beam Theory and its Applications in FGM Beam Structures

Stephan Kugler[1]*, Peter A. Fotiu[1] and Justin Murin[2]

Key Words: Generalized Beam Theory, Reference Beam Method, Stress Analysis, Functionally Graded Materials

Classical Beam Theories (CBT) are widely accepted as an efficient model to analyze mechanical properties of slender beam structures. They assume a rigid cross-section and neglect all stress components except axial normal and transverse shear stresses. However, the predictive quality of CBT deteriorates for stout beams and in a dynamic analysis, where in-plane distortions of the cross-section and the accompanied warping deformations become important. In such cases a Generalized Beam Theory (GBT) has to be used for realistic results. This talk discusses novel approaches in GBT [1, 2], where cross-sectional deformations are extracted from a modal analysis of a Reference Beam Problem (RBP). Each mode of the RBP is decomposed into a distortional and an accompanied warping field, and each individual part is then weighted axially within the member analysis by cubic shape functions. The resulting GBT formulation introduces three convergence related parameters, i.e., the number of elements discretizing the cross-section, the number of generalized beam elements and, crucially important, the number of introduced mode couples from the RBP. It is shown by example that the proposed model yields significantly better kinematical results compared to CBT, while the computational effort remains moderate. Additionally, detailed insight is given regarding the evaluation of three-dimensional stress distributions within the cross-section. It has to be noted that the proposed GBT formulation enables the introduction of inhomogeneous Functionally Graded Material (FGM) cross-sections by principle, and no further complexity is established regarding this modern branch of structural mechanics.

Key Words: Micromagnetic Simulations, Finite Element Method, Microstructure

To cope with current issues such as the digitization, climate change and the turnaround in energy policy, new technological innovations will be indispensable. Here, particularly powerful and efficient magnets play a key role. A composition of magnetic grains and a decoupling non-ferromagnetic boundary layer can lead to an improvement in coercivity [1]. This shows the great potential of microstructure optimization. Here, numerical observations can provide support. Micromagnetic simulations are often combined with finite elements to determine the magnetization distribution on very fine scales. The latter are particularly suited for the precise geometrical approximation of very complex microstructures. The correct magnetic material behavior is captured by an enthalpy functional that contains contributions to the magnetostatic-, exchange-, anisotropy- and elastic energy. However, the evolution of the magnetization vectors is described by the Landau-Lifshitz-Gilbert equation. This equation requires the conservation of the magnetization vector length during the simulation. Since this is not fulfilled intrinsically, different methods of conserving the constraint have been developed, such as penalization strategies [2], exponential updates [3] or spherical coordinates [4]. In this contribution the results of finite element based micromagnetic simulations of heterogeneous microstructures are presented. Here, the focus lies especially on the analysis of their magnetic and mechanical material properties, the coupling between those fields and how they can be tuned by an optimal microstructure composition.

ABSTRACT

This paper deals with the active vibration control of the aluminum beam using a piezoelectric actuator. Cantilever beam was excited by one thin piezoelectric film placed near the fix support. [1] The second piezoactuator was placed near the first one and used for active vibration suppresion. The oscillation of the beam's free end was measured using a laser position sensor.

The beam's eigenfrequencies and damping ratios for the first and second bending vibration modes were determined using FEM and verified experimentally. These results were used to design simulation model of the control system with PID Controller.

The excitation actuator was driven by signal generator to produce forced vibration of the system. The control actuator was driven by DAQ device and controlled using LabVIEW software. The excitation and control actuators were powered by high-performance power supplies and linear amplifier modules.

The operation of the designed control system for damping free as well as forced vibration of the cantilever beam is finally evaluated.

Key Words: *Soft Materials, Wang Tiles, Metamaterials, Testing, 3D printing, Open Hardware*

Soft materials and metamaterials explicitly are going to be a key paradigm for industrial applications, as e.g. soft robotics, medicine and/or collaborative technologies, of the 21st century. In this contribution, we discuss the use of the Wang tiling based modular concept in the design, manufacturing, and self-assembly of a soft graded metamaterial for soft-robotic scissors-like gripper, and its testing by means of in-house small scale portable testing frame.

The talk splits into two parts. The first part addresses the tiling concept in its most straightforward installment, the design a soft porous metamaterial with a non-periodic structure and its manufacturing. Here, the emphasis is put on the inherent modularity of the concept and a potential for scalable robot-assisted sample production.

The second part aims at an Open Hardware based high precision mechanical testing frame for experimentation on small-to-medium size soft material samples under the loads up to 50N supported by the contact-less DIC measurement system. The frame has been specifically tailored for testing soft (meta)materials as that discussed in the previous part, namely in horizontal setup to exclude the gravitational forces acting on two-dimensional experimental specimens and causing unwanted out of plane buckling. Despite its primary purpose, it has finally developed into a powerful self-sustained experimentation system that may be used in several ways in different engineering disciplines in both vertical and horizontal setup.

Key Words: *New Finite Element, Functionally Graded Materials, Multiphysical Analysis, Actuator*

Functionally Graded Materials (FGMs) are new types of material where their properties vary spatially according to chosen function to reach such features that are unable to provide using standard materials or composites. Hence, a structure made of FGM can dispose for example with excellent thermal conductivity at one component part together with thermal insulating properties at another component part.
Proposed paper deals with electro-thermo-mechanical analysis of chosen actuator structure made od FGM using new finite element derived specially for this purpose. Rectangular cross-section of individual beams that form the von Mises structure with variation of material properties in longitudinal and lateral direction will be considered. Actuator action, electric voltage and temperature peak and also mechanical stress of the structure will be evaluated. Results from the analysis calculated using our new FGM beam finite elements will be compared to results from conventional FEM analysis where standard finite elements will be used.

Smart materials are a very important building blocks in mechatronic applications [1]. These materials include shape memory materials, magnetorheological, functionally graded, piezoelectric, and other types of modern materials [2] . Their main feature is their possibility to extend the functional usage of a given system, to modify the dynamic behaviour of a given system or to allow a return to the original state of the system under certain conditions.

The paper deals with the development of the finite element method (FEM) model of piezoelectric beam elements, where the piezoelectric layers are located on the outer surfaces of the beam core, which is made of functionally graded material. The created FEM model of piezoelectric beam structure is reduced using the modal truncation method, which is one of model order reduction (MOR) method. The results obtain from reduced state-space model are compared with results obtain from finite element model. MOR state-space model is also used in the design of the linear quadratic regulator (LQR). Created reduced state-space model with feedback with the LQR controller is analysed and compared with the results from FEM model.

Key Words: *Warping Torsion, FGM Beams, Spatially Varying Material Properties*

In this contribution, which is an extension of author's research [1, 2], the influence of the in three directions varying material properties on non-uniform torsion of Functionally Graded Material (FGM) thin-walled beams with open cross-section is originally investigated. The effect of warping and secondary deformations due to the angle of twist is considered. The warping part of the first derivative of the twist angle caused by the bimoment is taken into account as an additional degree of freedom at the beam's finite element nodes. The Reference Beam Method (RBM) [2] is applied for homogenization of the spatially varying material properties in the real beam towards effective longitudinally varying stiffness quantities. The focus of the numerical investigation, with consideration of the warping and Deformation Effect due to the Secondary Torsional Moment (STMDE), lies on elastostatic torsional analyses of straight FGM cantilever beams with open I-profile cross-sections. The influence of the variation of the material properties with respect to three directions on the angle of twist, the bimoment normal and the torsional shear stresses, respectively, is investigated. The obtained results for primary and secondary variables are compared with the ones calculated using very fine meshes of standard solid finite elements. A large influence of the variability of material properties on the deformation as well as on the stress state of the beam with I-cross-section, calculated by the author´s FGM WT beam finite element has been found. The entire real beam with spatially varying material properties is modelled by only one FGM WT beam finite element, thus the proposed algorithm causes only very litle computational effort.

Code-Oriented Floor Acceleration Response Spectra of RC Framed Buildings Accounting for Nonlinear Response of Masonry Infills

Fabio Mazza[1] and Angelo Donnici[2*]

[1] Università della Calabria (Italy), 87036 Rende (CS), fabio.mazza@unical.it

Key Words: *Floor Acceleration Response Spectra, RC Framed Buildings, Masonry Infills, In-Plane and Out-Of-Plane Response, Nonlinear Seismic Analysis.*

Damage surveys that followed the occurrence of strong earthquakes have shown that code provisions may result in wrong estimation of the safety of masonry infills (MIs), which is generally carried out through simplified methods. The types of damage observed for MIs are usually a combination of, or an interaction between, in-plane (IP) and out-of-plane (OOP) mechanisms. The IP drift ratio is generally reduced at the upper storeys of buildings, where the OOP drift ratio increases due to an increase of seismic acceleration. Significant OOP damage may also take place at the lower storeys where the highest values of IP drift ratio are attained. The present work is aimed at identifying the effects of the IP and OOP nonlinear modelling of MIs and their mutual interaction on floor acceleration response spectra. To this end, a spatial one-bay multi-storey shear-type model is considered as equivalent to infilled RC framed buildings, having MIs made with two 12 cm leaves of clay hollow bricks. Additional variability of the following design parameters is considered: number of storeys (three, five and seven); behaviour factor (low, 1.5, medium, 3, and high, 4.5); OOP strength of MIs, with lower and upper bound values corresponding to one- and two-way arching mechanisms, respectively. A recently proposed computer code including a five-element macro-model [1], comprising four diagonal OOP beams and one (horizontal) central IP truss for nonlinear modelling of MIs, is considered for the numerical investigation. The proposed algorithm modifies stiffness and strength values of MIs in the OOP direction on the basis of simultaneous or prior IP damage and vice versa. Moreover, a lumped plasticity model describes the inelastic behaviour of RC frame members. Biaxial spectrum-compatible accelerograms are considered at life-safety limit state provided by the Italian seismic code. A simplified code-oriented formulation for the assessment of floor response spectra of infilled RC framed structures is proposed. Nonstructural maximum acceleration is firstly evaluated by means of vertical and nonstructural amplification factors. Continuous wavelet transforms are used to calibrate parameters that define the resonance region width, accounting for moving resonance due to nonlinearity and higher modes effects. Parabolic and Gaussian curves are considered in order to reproduce pre- and post-resonance regions, respectively. Finally, code-oriented proposal is compared to exact floor spectra of MIs evaluated in the common range of OOP vibration periods (i.e. 0-0.3s).

Mitigation of Seismic Pounding between Adjacent Buildings by means of Isolation and Supplemental Dissipation at the Base

Fabio Mazza[1*] and Rodolfo Labernarda[2*]

[1] Dipartimento di Ingegneria Civile, Università della Calabria (Italy), 87036 Rende (CS), fabio.mazza@unical.it

[2] Dipartimento di Ingegneria Civile, Università della Calabria (Italy), 87036 Rende (CS), rodolfo.labernarda@unical.it

Key Words: *Seismic Pounding, In-Plan Irregular Structures, Near-Fault Site, Single and Double Concave Surface Sliders, Viscous Dampers.*

Double concave surface slider (DCSS) is considered as an effective solution for base-isolation of existing structures located in a near-fault site, because of its capacity to notably increase horizontal displacements that can be accommodated in comparison to a single concave surface slider (SCSS) of identical in-plan dimensions. However, unexpected torsional pounding of in-plan irregular adjacent structures may be induced by variability of frictional force and lateral stiffness of both SCSS and DCSS, depending on the axial load and friction coefficient changes during an earthquake [1]. Effectiveness of supplemental viscous damping at the base is studied in this work with the aim to analyse its effectiveness for limiting base displacement, so avoiding too large seismic gap requirement. To this end, structural pounding between fixed-base and base-isolated L-shaped buildings, placed adjacent to form T- and C-shaped plans, is analysed. A simulated design of the original reinforced concrete (RC) fixed-base framed structure is preliminarily carried out in accordance to a former Italian code, for a medium-risk seismic zone and a typical subsoil class. Then, seismic retrofitting with SCSSs is carried out, in order to attain performance levels imposed by the current Italian code in a high-risk seismic zone and for moderately-soft subsoil, while DCSSs have radius of curvature equal to half the SCSSs and the same friction coefficient. Different in-plan distributions of linear fluid viscous dampers (FVDs) are examined, following damping distribution inversely proportional to the distance between the stiffness centre of the base-isolation system and the plane frame where each FVD is placed. Moreover, the equivalent viscous damping ratio of the supplemental FVDs is taken in the range 10%-20%. Nonlinear modelling of SCSSs and DCSSs considers variable axial load combined with friction coefficient at breakaway and stick-slip and as function of the sliding velocity, axial pressure and rising temperature at the sliding interface. Attention is focused on the pulse-type nature of near-fault earthquakes generally observed in the velocity time-histories but largely overlooked in the acceleration ones. Automated classification algorithms using wavelet analysis are adopted to compile three datasets of seismic input rotated in the range 0°-360°, with a constant step of 15°. Distinction is made between no-pulse and velocity-pulse, the latter further categorized into non-acceleration and acceleration-pulses. Combination of DCSSs and FVDs results the most suitable trade-off between mitigation of maximum response of the isolation system and seismic pounding between adjacent fixed-base and base-isolated structures.

Using transit finite element method to evaluate the Structure-borne noise levels of metro system bridges

Wei-Lun Hsu

Assistant Professor, No.2, Beining Rd. Keelung City 202301 Taiwan (R.O.C),
WLH@mail.ntou.edu.tw

Key Words: *Structure-borne noise, Metro, Vibration, Finite element method*

Taipei is home to a 146-km-long metro system that handled a record number of 1.9 million passengers in a single day in 2020. At present, approximately 56% of the Taipei metro network is composed of bridge structures, and in the following decade, bridge structures are expected to double in length within the Taipei metropolitan area. However, the problems caused by noise and vibration pollution are also on the rise as the Taipei metro expands further using viaducts

The structure-borne noise problem is a coupled problem that involves both noise and vibration. Most metro-related noise studies have focused on high-frequency and low-frequency noise, and structure-borne radiation noise has rarely been studied. For this reason, this study discusses the relationship between the local vibration of bridges and the structure-borne noise. Then, a transit finite element method (FEM) is applied to model the train–track–bridge dynamic interaction problem and evaluate structural vibration.

Three of the most common types of bridges, i.e., double-box pre-stressed concrete (PC) girder, double-box steel girder, and double-U-shaped PC girder are investigated in this study via in situ measurement and 3D transit finite-element analysis. The effects of plate thickness, trackpad stiffness, train speed, and track irregularity on bridge plate vibration are considered in this study. Finally, the proportional evaluation method is proposed and a structure-borne noise influence index is used to determine efficient methods to reduce structure-borne noise.

The conclusions show during the bridge design stage, the best combination of thickness and rail stiffness can be chosen to reduce the local vibration. Each bridge type can modify the rail stiffness to reduce the structure-borne noise index. In the operation stage, the methods of reducing the structure-borne noise would be to change the train speed and grind the rail to make the rail running surface smoother. In the viewpoint of reducing structure-borne noise, the PC box girder is the most commonly recommended bridge type for use in urban areas, and it generates the lowest vibration levels among the three types for each parameter combination.

Key Words: *Microstructure, Data-driven approach, Artificial Intelligence, Surrogate model*

Composites have become the most promising materials of this century applied in a variety of engineering fields including aerospace, automobile, and marine by their merits of high strength, and lightweights. In addition, most composites have heterogeneous characteristics, consisting of two or more different phases such as matrix and inclusions, at the microscale. Therefore, computational homogenization method has been a favourable approach to describe an effective continuum model for heterogeneous composites at the microscopic level. Also, it can be extended for a multilevel finite element method known as the FE^2 method. However, heterogeneous composites with hysteretic nonlinear behavior causes significant computational cost and inevitable many-query simulation due to the complex deformation mechanisms while connecting different scales. From this point of view, the reduced-order model can be an appropriate approach to overcome those significant drawback related to the computational inefficiency [1]. In this study, we propose a surrogate model that can efficiently predict the global and local nonlinear behavior of microstructure by applying a deep learning-based data-driven model reduction method. Herein, variational autoencoder (VAE) can be applied for a model order reduction method based on a deep neural network [2]. It is utilized to handle the quantities of interest on the RVE of microstructure. Moreover, we employed a gated recurrent unit (GRU) to describe the hysteretic relationship between stress and strain [3].

Key Words: Flexible multibody dynamics, Deep neural networks, Stochastic graident descent, Error correction, Real-time simulation

Predicting system responses in real-time have been required in various industries. A deep neural network (DNN) based data-driven modeling have shown the possibility without compromise accuracy for the highly nonlinear systems. In the rigid multibody systems, without solving the equations of motion of the systems, well-trained DNN model can predict the responses in real-time with high accuracy [1].
In this study, we introduce a data-driven metamodeling technique to deal with the multibody systems with flexible bodies. To handle the huge data which are come from the degrees of freedom of the flexible bodies, an efficient two-step training algorithm has been presented [2]. In the first step of the algorithm, a stochastic gradient descent (SGD) step, several coarse data sets are constructed by selecting randomly from the full data. The initialized DNN model is trained sequentially and iteratively with the coarse data sets. When improvement of the model accuracy from the iterative training is not sufficient, it moves on to the error correction step. In the EC step, a DNN model that predicting the error of the DNN model obtained in the final step of the SGD step is trained. The final predictions are calculated as the sum of the prediction of the SGD model and the error predicted by the EC model.
Through the proposed algorithm, it is possible to train a DNN model that uses only a part of the full data to increase the training efficiency and predicts accuracy similar to the trained model using the full data. The performances of the proposed algorithm have been verified using some numerical examples. It is confirmed that the DNN model can obtain the desired responses in real-time.

Key Words: *Convolutional Neural Network, Airfoil, Aerodynamic characteristics, Autoencoder, Proper Orthogonal Decomposition, Signed Distance Function,*

Interest of aerial vehicles such as a small Unmanned Aerial Vehicle(UAV) and Micro Aerial Vehicle(MAV) has risen during the last few decades. Many of these aircrafts use a fixed wing or rotor blade and operate at low Reynolds number regime. For example, *Re* is commonly less than 2×10^5 or 1.5×10^4 for MAVs or Nano Aerial Vehicles(NAVs), respectively. Moreover it can be even lower for insect flight [1]. For the design of the wings or blades of these biomimetic aerial vehicle or a drone for atomospheric planet exploration, the unsteady blade element momentum theory can be employed. Herein, aerodynamic performance of an airfoil at low Reynolds number should be considered [2]. In general, evaluation of aerodynamic performance of airfoil can be performed by mean of Computational Fluid Dynamics(CFD). Recently, studies applying machine learning to reduce the computational cost and time of CFD are being conducted [3]. In this study, a framework based on deep learning technique is proposed, which can predict the aerodynamic performance of airfoil at low Reynolds number regime. The input of the network is the airfoil data represented through Signed distance function(SDF), and the output is the pressure field of airfoil. To improve an efficiency of the proposed framework, three model-order reduction methods, i.e. proper orthogonal decomposition(POD), autoencoder (AE), and variational autoencoder (VAE), are considered to describe the pressure field of the airfoil.

Finite element models of realistic nonlinear structures are characterized by very high dimensionality that renders simulations of the full system infeasible. Mechanical structures are usually characterized by light damping which results in exceedingly long integration times before a steady state is reached. Despite the broad availability of dedicated software packages, the computation and continuation of the steady-state in response to periodic forcing remains a serious computational challenge for full-scale nonlinear finite element models.

The recent theory of Spectral Submanifolds [1] has laid the foundation for a rigorous model reduction of such nonlinear systems, leading to reliable steady-state response predictions within feasible computation times. Further developments [2] have enabled the computation of SSMs and their reduced dynamics by solving the associated invariance equations directly in physical coordinates using only the eigenvectors associated with the master modal subspace. The software implementation of the method has been available in an open-source package, SSMTool [3], making direct SSM computations scalable to realistic, nonlinear finite-element models.

In this talk, we demonstrate recent advances towards the computation of SSMs that enable the treatment of realistic finite-element models using direct as well as non-intrusive/data-driven methods.

Key Words: *Projection-based model-order reduction (PMOR), Proper orthogonal decomposition (POD), Hyper-reduction, Defect-parametric reduced-order model (Dp-ROM)*

For the mechanical and aerospace hardware, e.g., turbine blade, aircraft wing, large-size dynamic simulation which uses huge computational resource and iterative computation will usually be required for their fluid-structure interaction (FSI) and design optimization while considering their nonlinear properties.
In this paper, projection-based model order reduction (PMOR) technique will be suggested and applied to reduce the relevant computational expense.
PMOR is one of the traditionally intrusive approaches to construct a reduced-order representation by directly projecting the full-order representation onto a lower-dimensional subspace or reduced-order basis. The proper orthogonal decomposition (POD) [1] is a representative data-driven method, and it has been a widely used technique under the idea of PMOR. However, its recursive projection process for a nonlinear simulation may incur a significant computational expense. To compensate such computational inefficiency, the POD-based reduced order model (ROM) will be suggested and combined with the hyper-reduction technique [2]. The present hyper reduction includes the discrete empirical interpolation method, Gauss-Newton with approximated tensor, and energy-conserving sampling/weighting. It will allow reconstruction of the nonlinear terms in the reduced dimension, by using smaller number of the sampling points. Furthermore, a defect-parametric reduced-order model (Dp-ROM) [3] based on the modal method [4] will be applied to efficiently address the parametrized shape defects.
The aim of this paper will be to develop various projection-based ROMs and systematically evaluate the resulting ones regarding the prediction capability for the nonlinear formulations accurately and fast. To achieve such goal, numerical examination will be conducted regarding the time-transient analysis for an aircraft propeller and wing which possesses geometrically nonlinear characteristics.

Key Words: *Machine Learning, Convolutional Autoencoder (CAE), Variational Autoencoder (VAE), Fluid-structure Interaction (FSI), Model Order Reduction (MOR)*

In this abstract, an improved machine learning-based model order reduction scheme is presented for the parametric estimation regarding the fluid-structure interaction (FSI) problem. The current scheme consists of the following two stages: spatial and temporal reduction on the computational fluid dynamics (CFD) flow field. The first stage is done by the convolutional autoencoder (CAE) which significantly reduces the number of DOF for the flow-field. The second stage is by the variational autoencoder (VAE) which reduces the number of DOF's in the temporal space.

The current scheme is then applied for a simple FSI situation on a two-dimensional NACA 0012 airfoil. The airfoil of a chord length of 0.156m is subjected to a uniform flow in a standard atmosphere at the incoming flow speed of 1m/s. The airfoil is also subjected to the prescribed plunging motion with the plunging frequency of 10rad/s where the plunging amplitude varies between 0.05 and 0.14m in 10 increments [1]. The full-order model (FOM) snapshots are obtained by Navier-Stokes CFD analysis, OpenFOAM v1912.

From the snapshots, the latent codes for the first stage are constructed for each parameter and time step by using CAE. The latent codes for the first stage contain the temporal and parametric information in a reduced form (spaital information reduced into several codes) and are provided to the second stage. VAE then will reduce the first latent codes and temporal information into the second stage latent codes which will contain only the parametric information. Afterwards, the second latent codes will be interpolated and fed back to the decoders of VAE and CAE in order, while constructing the interpolated flow field.

As a result, the interpolated flow field for the plunging airfoil of 0.095m will be constructed. The average flow field velocity discrepancy is found to be as small as 0.23%, as shown in Fig. 1. For the present approach, the offline stage requires 75.6 hours for ten FOM constructions by using CFD. The training for CAE and VAE requires 29 hours. The online stage, composed of executing the interpolated latent code through the decoders requires smaller than 0.2 hours. The current scheme will become more efficient when more than four interpolated flow fields are to be required for the given range.

Key Words: *Model order reduction, Coupled field problems, Modal vectors, Krylov subspace*

The finite element discretization of coupled partial differential equations leads to complex and very large-scale discretized equations [1]. The time dependent analysis of these large-scale coupled discretized equation is computationally challenging. Generally, the projection-based model order reduction methods are used to get computationally efficient solutions of large-scale dynamical systems. In this work we use a method based on sequential projection which was proposed by Kim et al. [2] for the model order reduction of strongly coupled problems. Thermomechanical coupled systems are considered for the study. First the modified mode superposition method based on modal vectors is used to obtain the reduced order models of thermomechanical systems. In the next part, projection matrix obtained from Krylov subspace technique is used for model order reduction of the thermomechanical coupled systems. The numerical accuracy and computational efficiency of the model order reduction methods is studied for different thermomechanical systems.

Key Words: *Prop-blade, Natural frequency, Fan-plot, Convolutional neural networks*

In this work, a convolution neural network (CNN) was employed to construct a surrogate model to represent the dynamic characteristics of prop-blades, such as fan-plots in terms of natural frequencies, according to the rotational speed of the rotor. A set of key images of the cross-sections of a rotor blade whose outer mold layer (OML) was determined by aerodynamics designers. The cross-sections images were illustrated with individual color pixels according to the spar, skin, and OML, which also expresses the structure of the cross-sections of the blade. After converting color pixels into grayscale images, as input data of the CNN model, 1000 image sets consisting of 10 cross-sections of the rotor blades were adopted. As output data, 1000 fan-plots were prepared. During the training, 93% of the data set was used for the training, and prediction of the fan-plot of the blades was conducted with 7% of the data set. Twenty CNN models were created to find the model with the best performance. To demonstrate the performance of the proposed CNN model, we predicted the dynamics characteristics in terms of the fan-plots on various test data sets. The prediction accuracy was verified in terms of the loss functions and the error of the natural frequencies. The prediction results were in excellent agreement with the test data sets, and the fan-plots were quickly predicted for other rotor blade cross-section images. This confirmed that the proposed CNN model is simple and powerful and can efficiently clarify the relationship between the rotor blade cross-section images and fan-plots of rotor blades.

Key Words: *Damage Detection, eXplainable Artificial Intelligence, Class Activation Map, DIC*

When damage occurs to structures, such as the wing of aircraft and blades of rotorcraft, it is generally initiated in local and spread to the entire structure. To prevent the destruction of the entire structure due to the damage occurring in a local area, it is important to detect and act on damage at an early stage through real-time monitoring of the entire structure [1]. Techniques for detecting structural damage include modal based detection techniques and strain-based detection techniques. However, these techniques can change the dynamic characteristics of a structure by attaching a sensor to the structure and it may require large amount of sensor to increase detecting resolution. To compensate for those shortcomings, research on displacement/strain measurement using a non-contact method, Digital Image Correlation (DIC) [2], has been conducted. DIC is a technique to measure the deformation and displacement of a structure using images before and after the deformation of the structure. In addition, it is relatively straightforward to achieve the real-time monitoring of the structures by using the DIC equipment. In this paper, a method for monitoring the presence or absence of damage and the location of damaged area is developed by using the Class Activation Map (CAM) network, a kind of explainable artificial intelligence technology. To generate training data, the finite element method is used to obtain displacement/strain of a target structure. The developed CAM network can classify the presence or absence of damage by considering the strain fields. Moreover, the relevant result of the CAM network is the CAM image which indicates a damage location of the structure. Finally, the present CAM network for damage detection will be validated by considering the DIC experimental data of tensile specimens.

Key Words: *RESERVED SPIRAL ORIGAMI STRUCTURE, REVERSED TORSION ORIGAMI STRUCTURE, PARTIAL-HEATING TORSION MOLDING METHOD,HALF CUT SEMI ORIGAMI STRUCTURE , LIQUID PRESS FORMING METHOD, POLYGONAL CROSS SECTION SEMI ORIGAMI STRUCTURE*

In the crash collision, the vehicle energy absorbers play an important role in the energy absorbed performance. Current vehicle energy absorbers have two defects during collision, such as only 70 % collapsed in its length and too high initial peak load. It is because present energy absorbed column is the most primitive from the point of Origami structure. We developed the column so called Reversed Spiral Origami Structure; RSO which solves these 2 defects[1]. However, for RSO, the manufacturing cost of hydroforming[2] in the existing technology is too expensive to be applied in real vehicle structure. To address the problems, we have developed a new forming method called "Partial-heating torsion forming method". And we have developed RTO (Reversed Torsion Origami Structure) by this new forming method at a very low cost[3]. We show this RTO also solves the two defects of the present vehicle absorbers by not only simulation but also experiments. This structure is possible to replace conventional energy absorbers and it is expected to be widely used such as not only in automobile structures but also in building ones. By the way, there are 3 types of crash energy absorbing origani structures such as RSO & RTO which have 6 folding lines at each intersection , bellows hold which has 4 folding lines at each intersection and semi origami structures such as , Also it is discussed advantages and disadvantages of these three types of origami structures.

Key Words: *Origami Forming, Incident Wave, Reflective Wave, Optimization*

We have developed a new truss core panel by origami forming to get the higher aspect ratio than that by multi-stage press forming. Our object is to apply the new origami truss core to the train floor. Whether or not this goal can be achieved depends on whether this new origami truss core with a high aspect ratio has excellent sound insulation characteristics especially in low frequency range. Therefore, to estimate accurately the relation between the aspect ratio and the sound insulation performance, we try to develop an effective simulation technology with finite element method (FEM). So far, sound insulation simulations using FEM did not match with theory of the mass law [1]. However, this can be achieved by setting the end of the transmitted side to be a nonreflective boundary for a panel that is supposed to be stiff enough [2].

In this paper, to generalize this method, it is determined theoretically that the sound pressures from the FEM can be separated accurately into the sound pressures of the forward and backward waves from Helmholtz's equation. In addition, the validity of the proposed method is confirmed by evaluating the effect of attaching a sound absorbing material to the plate. Furthermore, application of the proposed method to a flat plate with one core and an examination of whether a high aspect ratio is advantageous for sound insulation are also presented.

In addition, with this method, it is confirmed that the shape to optimize the sound insulation performance under certain conditions canbe calculated because the knowledge that the sound insulation performance in the low frequency range improves in the flat plate with a high aspect ratio vertical core was obtained. As a result, it is expected to improve the sound insulation performance of low frequencies that cannot be compensated with sound absorbing materials.

Key Words: *Origami Forming, Incident Wave, Reflective Wave,Optimization*

Nojima and Saito introduced the term “kirigami honeycomb” in [1] where they use the cross section of the 3D shape to describe the panel and include cuts in the pattern to obtain its 3D structure. Neville et al [2] have studied the mechanical properties of “kirigami-honeycomb” panels to test its feasibility of using shape memory polymers (SMPs) to actuate the folds in open Kirigami-honeycombs. Recently, Caslish and Gershenfeld [3] designed a continuous folding machine to construct the Kirigami patterns obtained by the previous method [1]. However, above approaches [2, 3] also use two curves in the cross section of the shape that limits the representation of shapes with more complex geometries.

In our proposal, the design method is generalized for more complex shapes based on 3 fundamental contributions: 1) the need to represent the shape by 2 curves in the cross section to represent any 3D shape is eliminated, 2) the ”honeycomb cores” are embedded in the 3D shape by means of boolean operations on the 3D shape and 3) an optimal method of assigning folding lines, cutting and gluing areas was developed for the manufacturing of the panel.

Biomimetics, is in essence learning from and mimicking, emulating the strategies, formations, systems, structures and etc. found in native biological systems. Among several strategies in nature, folding which can be observed in biotic and abiotic part have been studied extensively. Folding is not “an adaptation but merely a physical consequence that just emerged at a point in evolution”(Hunter 2015)

Folding is determined by force and material as shown by Kresling (2012), Miura (1997), Yoshimura (1951 changing the structural memory of material by exceeding the yield point. Paper for example, is an excellent medium to understand folding where a crease is a plastic deformation of the sheet, where it has passed the yield point, “effectively re- setting the elastic memory of the paper to a non-zero angle” (Demaine et al., 2009). Understanding the “fold memory of materials/matters” result in many new models in several disciplines like biology, robotics, space structures and many novel solutions in use of shape memory alloys and today in developing 4-D printing for which shape shifting is achieved not only by the material but also by the form.

Architecture like many other fields deeply involves in biomimetic research to find novel solutions in the design problems. Responsiveness which is a broad term employed to explain force-artefact interactions under external forces or internal forces related uses folding as a strategy to optimize the performance through kinetic systems. In this paper, how origami and biomimetics are employed in developing novel solutions in architecture is to be discussed. First recent advances in biomimetics and origami used in architecture is to be scrutinized, then examples developed within this framework through the projects in METU are to be explained showing how thick folding and 4-D printing is used not only as form finding of kinetic surfaces, but also solving mechanisms either for modular or tessellated structures as well as new potentials to develop recursive kinetic formworks.

Key Words: *Space Filling, Control of Plural Eigenfrequencies, INDEX OF GENERALIZED EIGENFREQUENCY*

No solution has been obtained for situations where fruits and vegetables such as strawberries, cells, blood, etc. are damaged or die during transportation. It is presumed that the biggest factor in these situations is that there is a perishable and mortal vibration band. For example, the frequency band that most affects ride comfort of train and car passengers is said to be 4 to 10 Hz. Therefore if there are eigen frequencies of vibration system consisting of seats, floors, and occupants, it is designed to move out of band with resonant frequencies. In this study, we will examine the basic issues for the challenge of moving the resonance frequencies to solve the above-mentioned problems of damage and death of fruits and vegetables and cells. The birth of topology optimization analysis technology was expected because generally speaking, significant movement is difficult to move of resonance frequency with dimensional optimization but realization of topology optimization was not easy. Since the topology optimization was finally developed using the homogenization method in 1988[1], so much research of topology optimization has been done.

Tenek and Hagiwara compared for static problems between using each element thickness as design variables and homogenization and showed that there was no big difference[2]. Now the former is called the density method and the density method is now more commonly used than the one using homogenization. Now since reference [1], the second author Hagiwara also published some papers concerned with topology optimization. Judging based on these experiences, the conventional topology optimization methods cannot be easily applied to the problem of lowering some resonance frequencies and raising some resonance frequencies.

Although this idea can be said in common both for static stiffness problem and for dynamic vibration problem. Therefore, we propose here a new method named "Energy Density Topology Optimization Method" which has been discovered by returning to the origin of vibration where eigen frequency is determined by equivalent stiffness and equivalent mass. And also shown is the origami safe carrier box by this new method.

Key Words: *Metal-ceramic Interpenetrating Phase Composites, Impact Loading, Peridynamics, Finite Element Method, Atomistic Simulations*

Multiphase Ceramic Composites (CCs) are used in several modern industries like aerospace, automotive, nuclear power, or defense. They are used in the situation of expected extreme loads like variable loads or impacts.

The interpenetrating composites (IPCs) is a class of composites that are defined by the technological process. The IPCs consist of a crushable skeleton and a metallic phase introduced into the skeleton under pressure. The resulting material combines the features of the skeleton and the filling metal.

Earlier analyses of the composite systems showed the significance of the interface between the particular phases [1, 2, 3] for the overall performance of the samples and its load-carrying capacity. An attempt to include the mechanical properties based on atomistic simulations is shown.

An analysis of samples of IPC based on SiC ceramic skeleton and an aluminum alloy under impact conditions is performed. The 3D structure of the sample is obtained with CT scans. The numerical model takes into account the properties of the interfaces between the phases. It has been noted that the interface properties are a significant feature of the materials and the resulting numerical model.

[3] University of L'Aquila, Piazzale Pontieri 1, 67100 L'Aquila - Italy, angelo.luongo@univaq.it

Key Words: Thin pipe, beam-like model, buckling, postbuckling

Thin pipes are structural elements which are widely used in technical applications, especially concerning civil, industrial and aerospace engineering. The careful evaluation of their carrying capacity plays a key role in the design process, in particular due to the possible involvement of local effects related, for instance, to flattening or warping of the cross-sections. As a typical example, when pipes are bent over, the concurrent ovalization of the cross-section can induce a softening behavior, referred to as Brazier's effect [1], leading to a limit point in the bending moment-curvature relationship and a sudden failure of the structure.

Recently, a nonlinear beam-like model of thin pipe was proposed in [2, 3], where the classical kinematic descriptors for the rigid cross-section Timoshenko beams were combined to further descriptors, indicating amplitude of ovalization and warping under prescribed shapes. The obtained one-dimensional continuum model turned out to fully catch both nonlinear static and dynamic response of the pipe and, for its simplicity as compared to shell models, it appeared as very convenient to be tackled with perturbation methods.

In this paper, the above mentioned beam-like model is extended to address buckling and post-buckling analysis of thin pipes. For this scope, geometrical stiffness terms are consistently included and consequent evaluation of the critical loads is carried out. Numerical tools are then used to assess the post-buckling behavior, where the effect of cross-section change in shape can be prominent. Comparison with outcomes provided by finite element method commercial software, where the pipe is modelled as assembly of this shells, is carried out.

ABSTRACT

Laminated glass plates consist of two or more thin glass layers and an interlayer made of PVB (polyvinyl butyral). They can easily undergo large deflections since they are very thin therefore they need to be analyzed considering large deflection effects such as developing membrane forces etc. Consequently the equilibrium equations governing their behavior should be based on the large deflection theory.

Vallabhan et al. [1] modeled the laminated glass units and verified the mathematical model by comparing the results with the results of experiments conducted at the Glass Research and Testing Laboratory at Texas Tech University. Asik et al. [2] and Asik [3] made contributions by their research on the true behavior of glass units.

Four of the five equations are used to represent in-plane displacements in x and y directions and the last one for the transverse deflection of a unit. In order to obtain the governing differential equations, total potential energy of a unit is written as the summation of membrane, bending and force potential energies in terms of displacements.

The main difference of this study from previous ones is that employs free boundary conditions on two edges of the plates. For the other two ends the laminated unit is simply supported or fixed (clamped). Also the width of a unit which is not greater than the one-tenth of the length of a unit (which makes the unit a thin plate). Five coupled and partial differential equations obtained through variational principle for lateral and in-plane displacements. The governing differential equations are first discretized by finite difference method and then solved numerically by employing iterative solution procedures to obtain the displacements and stresses.

Accurate and Efficient Quadrilateral Plate Element for Vibration Analysis of Laminated Composite Plates Using a Refined Third-Order Shear Laminated Plate Theory

Qiaorong Guo[1*], Guangyu Shi[2]

[1] Tianjin University, Tianjin 300350, China, guoqiaorong2001@163.com
[2] Tianjin University, Tianjin 300350, China, shi_guangyu@163.com

Key Words: *quadrilateral plate element, laminated composite plates, third-order shear deformation theory, quasi-conforming element technique, higher-mode natural frequencies*

An accurate, efficient and reliable four-noded quadrilateral plate element is developed in the present work for the vibration analysis of laminated composite plates. The element formulation is based on the quasi-conforming element technique (an assumed strain method) using a refined third-order shear deformation laminated plate theory proposed by the second author. The present quadrilateral plate element possesses higher accuracy than the conventional shear flexible plate elements, as it is derived from an assumed linear bending strain field. By using Hamilton's principle, the variational consistent equation of motion in matrix form corresponding to the third-order shear deformation theory is derived. The resulting mass matrices are decomposed into four parts: the usual part, the rotary inertia part similar to that in the first-order shear deformation theory, the part resulting from higher-order displacement and the part resulting from the coupling between the different components of the axial displacement. The higher-order and coupling mass matrices have a significant effect on the frequencies of high mode vibration. The element stiffness matrix and mass matrix of the present quadrilateral plate element are given explicitly and free from shear locking. Consequently, the present quadrilateral plate element is very computationally efficient. The average rotation across the plate cross-section is used in the refined third-order shear deformation laminated plate theory against the rotation at the plate mid-plane used in other higher-order plate theories, which leads to the correct boundary conditions to fix the rotation across the plate thickness. The free vibration examples of circular, square and skew composite plates are computed and discussed by using the present quadrilateral plate element. The effects of different boundary conditions, different aspect ratios and plate thickness are considered in this study. The numerical results show that the present plate element can give the correct results of the higher-mode natural frequencies. These numerical results clearly demonstrate that the quadrilateral laminated plate element presented in this paper is not only efficient but also very accurate.

This research paper presents a geometrical methodology for developing Auxetic metamaterials based on graphic statics. Specifically, it is shown how by employing reciprocal convex Airy stress functions [1] and Minkowski sums [2] it is possible to derive non-standard 2D Auxetic patterns with negative Poisson's ratio. Furthermore, it is discussed how said geometrical construction underpins origami flagstone tessellations [3].

Key Words: Design Optimization, Single-phase Metamaterial, Stress minimization, Impact load

Elastic metamaterials (EMMs), which are architected materials with unique properties due to the presence of bandgaps – frequency ranges in which the wave propagation is attenuated – have drawn attention of researchers to their effectiveness in attenuating waves. Unlike phononic crystals (PnCs), which are periodic structures that exhibit bandgaps due to Bragg scattering, EMMs rely on the use of internal resonators [1]. This type of locally resonant structures have shown promising results for attenuating low-frequency waves as the ones originating from repetitive impact loads [2].

The use of single-phase EMMs has recently been investigated, because their manufacturing requires less complex and low-cost processes. Furthermore, with the trend of circular economy, such EMMs can be manufactured from raw disposal materials or can be easily re-processed for other applications. However, obtaining a low-frequency bandgap by using such single-phase structures requires large masses and thin structures targeting low stiffness, which may result in impractical designs from a mechanical point of view. In order to overcome such limitation, optimization techniques can be used to enhance the mechanical properties of the unit cell by minimizing the stress.

This work investigates the mechanical behavior of a single-phase EMM formed by a cylindrical inclusion connected to the frame by four beams. The aim is to filter energy at specific frequencies of an impact signal. The unit cell shows bandgaps at a low frequencies, which are related to the geometric parameters of the internal resonator. It is observed that the EMM fails mechanically due to high-amplitude loads, especially because of the requirement of thin beams and huge masses to obtain low-frequency bandgaps. The proposed scheme optimizes the geometric parameters so that the stresses are minimal, while keeping the bandgap unaltered. Through such procedure, the metamaterial can be used for vibration suppression and noise control of structures undergoing high amplitude impact loads.

Key Words: *Retrofitted masonry; Homogenization; Linear elasticity; Static and dynamic analyses.*

The unreinforced masonry has been used for constructing a large number of buildings placed in seismic areas worldwide. It is well known that the typical low tensile strength of this material makes existing buildings vulnerable to both in-plane and out-of-plane seismic actions. For this reason, a lot of research studies are devoted to develop and improve retrofitting techniques for enhancing the seismic behaviour of masonry buildings. Among these, an innovative technique that combines the advantages of traditional methods with the use of advanced materials is represented by Steel Fibre Reinforced Mortar (SFRM) coating. This rather new retrofitting method consists of a thin mortar coating, bonded either on one or both sides of masonry elements and reinforced with short fibres. The literature about this topic regards mainly experimental tests (see [1-3]). On the other hand, the specific modelling of SFRM and of its interaction with masonry structures is rather lacking.

In this work, the idea is to replace the fine model of the wall retrofitted by SFRM with an 'equivalent' homogeneous Mindlin–Reissner plate, having unitary thickness and the same stiffness and mass of the nonhomogeneous model. A homogenization procedure is applied to an elementary cell to derive closed-form expressions for the linear elastic constants of bending and twist stiffness, of the out-of-plane shear stiffness and of the membrane stiffness. The stresses of the masonry and SFRM components are also evaluated analytically once the average stress acting on the homogeneous medium is determined. Parametric analyses are carried out to evaluate the influence of the reinforcement system on the equivalent material properties, by varying the thickness and the elastic properties of the SFRM. The accuracy of the theoretical results is assessed by means of comparisons with finite element (FE). Finally, static and dynamic FE analyses are carried out on sample masonry walls, with the aim of comparing the non-homogeneous and homogeneous models. The mechanical performances of the structures are investigated according to the effectiveness of the SFRM.

Nonlinear electro-mechanical dynamics of a piezo-composite beam rotor system

Jaroslaw Latalski[1*], **Marcin Kowalczuk and Jerzy Warminski**

[1] Lublin University of Technology, Nadbystrzycka St 36, 20-618 Lublin, Poland, j.latalski@pollub.pl

Key Words: active composite beam, piezoceramic material, rotor, nonlinear constitutive behaviour

A system consisting of the active composite beam clamped to the rotating hub is considered. A combined shearwise bending and twist deformation of the blade as resulting from directional properties of a composite substrate (core) is considered and relevant kinematic relations are formulated within geometrically linear framework [1]. To match the experimental results published in literature [2] and to enhance the generality of the proposed formulation a nonlinear constitutive behaviour of the piezoceramic material layer is assumed. Finally, nonlinear inertia effects related to the system rotation are taken into account.

The mathematical model of the system is formulated by means of the extended Hamilton's principle. Since the piezoceramic layers exhibit nonlinear material properties the relevant component of the potential energy is calculated as a volumetric integral of the electric enthalpy density function. The derived system of three integro-partial differential equations represents the electro-mechanical behaviour of the system. In particular, the beam dynamics is represented by a generalized displacement coordinate and an output voltage coordinate; the behaviour of the rigid hub is given by its rotation angle coordinate. The state equations are discretized by the Galerkin's method and next solved around the first resonance zone for the system excited by periodic torque supplied to the hub. The obtained response curves reveal strong softening behaviour resulting from nonlinear constitutive properties of the active piezoceramics. Moreover, additional unstable solutions have been identified out of the resonance zones. It's observed the magnitude of the softening effect and width of unstable zones decreases while the mean rotor angular velocity is increased.

A series of further numerical simulations is performed to examine the impact of torque excitation amplitude, torque mean value, hub inertia and electrical load resistance on system behaviour. Next, the performance of the system with parallel or in-series connected transducers is discussed and both configurations are compared in terms of energy harvesting efficiency. Finally, the impact of composite reinforcing fibres orientation/laminate configuration represented by various bending/torsional coupling ratios on system dynamics is studied.

Key Words: meta-cell, compound nonlinear restoring force, slow invariant manifold, fast/slow dynamics

Metamaterials are systems designed to exhibit some properties which can not be found in nature [1]. One special type of metamaterials is the mass-in-mass system, which can present interesting properties such as equivalent negative mass and stiffness. The studied system, a mass-in-mass unit cell, possesses a nonlinear restoring forcing term, $F(\alpha)$, which depends on the relative displacement of the two masses m_1 and m_2. In this work, several types of nonlinearities (unique and compound), presenting smooth or nonsmooth restoring forcing functions, are considered. System variables are complexified [2] and the resulting dynamics is treated via a time multiple scale method. It will be shown that systems with compound nonlinearity may present some characteristics which differ from systems with classical nonlinearities. Moreover, the frequency responses of the system can present isola, which should be taken into account carefully for control aspects.

Key Words: *Lattice, Sandwich Panels, Thermal Buckling, Critical Buckling Temperature, Global and Local Buckling, FEM*

In recent years, the development of spacecraft for re-entry into the atmosphere has been revived due to the acceleration of private-sector space development. During re-entry, the spacecraft is subjected to an extremely high thermal load, which may lead to thermal buckling of the spacecraft. It is important to correctly estimate the buckling temperature of mechanical structures that are subjected to thermal loads, because this phenomenon can lead to serious accidents due to performance degradation and damage.

Over the decades, many studies [1, 2] have been reported on the thermal buckling of flat plates, composite plates, and sandwich structures, which are commonly used in airframe structures. For example, Chen et al. derived a theoretical equation for the critical buckling temperature of a lattice sandwich panel with a pyramidal core in the deformation mode where the panel buckles as a whole, with the core homogenized [3]. However, the buckling behaviour depends on not only the macroscopic mechanical properties but also the micro-architecture of the panel, so it is inadequate to estimate the buckling temperature from the homogenization method only.

In this study, the finite element analysis was conducted on the composite panel with lattice core by modelling the exact micro-architecture. In particular, the effects of geometric properties such as core height, core length, and number of cells were investigated. As a result, it was confirmed that there are mainly two types of thermal buckling modes for sandwich panels: global and local buckling modes, and that the global buckling mode is affected by the number of cells in the panel. The global buckling temperature can be estimated with good accuracy by multiplying the analytical equation derived from the conventional homogenization method by a correction factor including the effect of the number of cells. On the other hand, the local buckling temperature can be estimated by considering the buckling behaviour of a small plate surrounded by the cells and supported by four corners. The analytical equations for the global and local buckling temperatures presented in this study can be used to quantify the design of lattice sandwich panels.

Key Words: non-linear meta-materials, mass-in-mass cells, fast/slow dynamics

Meta-materials are developed to present unusual non natural responses against external or internal actions. In the vibro-acoustics domain, mass-in-mass systems are one type of meta-materials which are developed for vibro-acoustic applications. For this purpose, the following L-periodic chain is composed of non linear cubic mass-in-mass cells which are coupled linearly. Forcing is applied on the whole chain with spatial sinusoidal weighting derived from the dispersion equation.
The discrete form of system equations is transferred to continuous domain. Then, the study is conducted using multiple scale methods [1] in order to analytically determine the dynamical behaviors of the chain. The dispersion equation is obtained by considering the linearized associated system. Complex variable of Manevitch are introduced to simplify the understanding of fast and slow system dynamics [2]. Fast dynamics leads to detection of the slow invariant manifold and its stable zones. Slow dynamics leads to detection of singular and equilibrium points, allowing to establish bifurcation points and the frequency responses. The analytical work is verified by numerical simulations on the discrete periodic initial chain. For each cell, its seen that equilibrium points, as functions of deriving frequency, can be located in the main branch of the frequency response or on isola, either in stable or unstable zone of the slow invariant manifold. Moreover, depending on the property of the point, the system can present periodic or non-periodic responses. The development provides necessary tools for designing such a chain for localization of the vibratory energy inside some zones of a targeted mode.

Spectral design and nonlinear dispersion properties of a mechanical metamaterial with local inertia amplifiers

Valeria Settimi[1*], Marco Lepidi[2] and Andrea Bacigalupo[2]

[1] DICEA - Polytechnic University of Marche, Ancona, Italy, v.settimi@staff.univpm.it
[2] DICCA - University of Genoa, Italy, Marco.Lepidi@unige.it, Andrea.Bacigalupo@unige.it

Key Words: Pantographic Metamaterials, Wave Propagation, Spectral Design, Nonlinear Dynamics

Architected metamaterials yielding superior dynamic performances can be conceived by realizing local mechanisms of inertia amplification in the periodic microstructure [1]. A periodic cellular waveguide characterized by an intracellular pantograph mechanism is considered as minimal physical system simulating an inertially amplified metamaterial [2]. A discrete tetra-atomic model is formulated to describe the undamped free dynamics of the cell microstructure. The ensuing ordinary differential equations of motion feature quadratic and cubic inertial nonlinearities, induced by the axial indeformability of the pantograph arms connecting the principal massive atoms with the secondary massive atoms, serving as inertial amplifiers. First, the linearized model is investigated to analytically design the metamaterial spectral properties. To this aim, the band structure of the complex-valued dispersion spectrum is determined analytically, and a spectral design problem is stated and solved by inverting the functions expressing parametrically the boundaries separating attenuation (stop) and propagation (pass) bands in the frequency spectrum. Upon demonstrating the existence of feasible design solutions, the analysis provides complete definition of the physically realizable band structures in the frequency domain and alternative criteria to design iso-band structured metamaterials [3]. Moving to the nonlinear model, dispersion properties governing the free undamped propagation of harmonic Bloch waves are investigated in absence of internal resonances. The multiple scale method up to the third order is adopted to analytically determine the nonlinear functions relating dispersion properties and oscillation amplitude of the propagating acoustic and optical waves. Specifically, the nonlinear wavefrequencies and waveforms are determined as analytical closed-form functions of the parameters, quadratically depending on the oscillation amplitudes. Validation of the analytical outcomes, performed by directly integrating the nonlinear equations of wave motion for different initial conditions, confirms the goodness of the asymptotic approach.

Key Words: Targeted energy transfer, time-dependent nonlinear rigidity, control, meta-cell

We consider a system composed of a linear oscillator which is linearly coupled to a nonlinear oscillator with a time-dependent nonlinear stiffness. We study the energy exchange between two oscillators for vibration control [1]. For this we detect the fast and slow dynamics of the system [2] in order to find out its fixed points and different possible regimes, i.e. periodic or non periodic ones [3]. Thus, the behaviour of the system can be predict. This study permits to reveal the Slow Invariant Manifold (SIM) of the system and its singular and equilibrium points. We spot that the geometry of the SIM of the system with variable rigidity is different from the one with constant nonlinear rigidity. The non classical geometry of the SIM and atypical positioning of system singularities (ranging from continuous to closed form curves on the SIM depending on the system parameters) creates energy channelling between two particles which depend on the phase of the system. Our developments permit to design the energy channelling (and so tunning system parameters) between two oscillators (or particles). The system under studying can be seen as a time dependent nonlinear "meta-cell".

Compliant Folding Hinge Structure using Radial Slit Pattern

Munkyun Lee[1*] and Tomohiro Tachi[2]

[1] The University of Tokyo, 153-8902, tokyo2021lmk@g.ecc.u-tokyo.ac.jp
[2] The University of Tokyo, 153-8902, tachi@idea.c.u-tokyo.ac.jp

Key Words: *Origami, Thick Origami, Compliant Mechanism, Hinge, Slit Pattern*

Origami models are often idealized by discrete folding of zero-thickness sheets; however, the sheet thickness and the elastic limit of the material cannot be ignored in engineering practice. Existing studies realize the folding deformation of origami structures in the elastic range of the material by replacing the crease lines with a wide deformation zone with slit patterns on it [1, 2]. However, this approach based on a compliant hinge has several limitations. Namely, the wide hinge cannot maintain the center of rotation between panels during the folding motion, so it is difficult to accurately deploy the origami structure with interior vertices where multiple crease lines meet. In addition, the play caused by the width of the deformation zone increases the degree of freedom of the origami structure, leading to the instability of the folded structure.

To solve these issues, we design a new hinge structure based on composing parallelly connected compliant spherical joints through the use of the theory of flexure joints [3, 4]. Specifically, we create a spherical joint by radially placing the Lamina Emergent Torsion (LET) joint [5, 6]. Then, we arrange multiple spherical joints in a straight line to create a fixed axis, which acts as the hinge.

The proposed hinge structure is evaluated through an experiment and simulation. The experiments show that the center of rotation is maintained up to a wider range of fold angles when compared to the general LET joint. Then, we verified that the shape of the hinges in the experiment and the simulation match well. By conducting optimization based on the genetic algorithm in the simulation model, we obtained patterns that minimize the maximal curvature of the hinge.

Since the proposed hinge structures can be manufactured from a single plate material through 2-axis CNC cutting or laser cutting, the whole origami structures using the hinge can also be manufactured from a single plate. Potential application of this hinge structure includes kinematic facade, foldable displays, and deployable solar panels.

Key Words: *Electromagnetic damper, Semi-active Control, Shaking Table Test.*

A near-fault (NF) ground motion can induce considerable base displacement and structural acceleration in a seismic isolation system. In order to improve this problem, adding viscous dampers in isolated systems in NF regions has been recommended by researchers. However, a high damping ratio can induce high structural acceleration of a seismic isolation system when subject to far-field ground motions.

In this study, a novel semi-active electromagnetic seismic isolation system (SA-EMSIS) was developed. The SA-EMSIS consists of a passive EMSIS [1] and an electrical resistance controllable module. The EMSIS is composed of an EM damper, sliding platform, and a pair of springs. The EM damper is composed of a DC motor, gearbox, and rack and pinon mechanism. The semi-active control algorithm can be achieved by adjusting the external resistance of the circuit in real time via the resistance control module. By combining the seismic early warning technology in the future, the SA-EMSIS can perform adaptive EM damping coefficient under different types of excitations. In this stage, a prototype of the SA-EMSIS was designed and manufactured. The relationship between the equivalent EM damping ratio and the corresponding total electrical resistance of the circuit was identified via sine-sweep test. Semi-active control algorithms were also tested to investigate the controllability of the electrical resistance controllable module.

Key Words: Mechanical Properties, Structural Analysis, Flattering, Pure bending, FEM

A net-shaped structure is recognized as a component of truss structure and a lot of researches have been reported. For example, there are lightweight roof structures in structural engineering and cylindrical structures such as stents and McKibben actuator in the mechanical field.

On the other hand, the cross-sectional flattening in pure bending of cylinders has been investigated by many researchers[1, 2, 3, 4]. The circular tubes have also been used in many kinds of machines and structures as a structural part.

According to their previous studies, it is found that there are mainly two factors that dominate the collapse of cylinders subjected pure bending loading. Chen has investigated the elastoplastic pure bending collapse of cylindrical tubes using the non-linear finite element analysis. In his study, the flattening velocity parameter v_b is introduced to evaluate the flattening response of tubes. Also, based on his numerical investigation, he proposes a theoretical model for predicting the bending moment-curvature relationship.

In this paper, the elastic bending collapse of net-shaped circular tubes subjected to statically pure bending is studied by using finite element method (FEM). Comparison with equivalent shell structures, net-shaped circular tubes are more flexible and slow down the bending collapse. In net-shaped circular tubes, the slope of the flat line is $v_b = 2$, but the intercept is different depending on the density. Thus,increasing the density, the flat line brings near to the shell's. From the proposed flat line, it is possible to predict the response of the bending moment to bending curvature regardless of the micro-architecture of the net.

Key Words: Bistability, Piezoelectric actuation, Shape-morphing, Adaptive structures

For decades, numerous efforts have been made to design structures against buckling and instabilities, which often lead to their catastrophic failure. By contrast, recent studies have shown that harnessing mechanical instabilities can provide structures with new features as negative stiffness and energy dissipation [1]. Domes are shell structures that can exhibit up to two stable states, mostly depending on geometric and material parameters [2]. Apart from its basis state, a dome can be subjected to snap-through buckling and remain stable in this state indefinitely over time in absence of external loadings, being then considered as bistable. Recently, studies showed that bistability of domes may be used for shape morphing of sheets [3] and mechanical programmability [4].
The present work exploits snap-through buckling in dome-patterned structures to design novel responsive surfaces whereby the local topography is triggered by bistability and is reversed using an external electric field. The mechanical dome-like systems are designed with the help of finite element (FE) simulations, and are then realized via 3D printing for testing under electro-mechanical loading.

Key Words: *Heat transfer, Pressure drop, Porous structure, Finite element method*

Over the decades, due to the rapid development of engineering, a large number of high-load electronic devices have been developed, and rapid the increase in processing speed and computational load has led to a high heat generation density. To remove heat from the equipment efficiently, many kinds of cooling devices such as have been proposed. One of the candidates of the cooling device is equipped with air impinging jets. Many studies on the heat transfer characteristics of air impinging jets using flat surfaces have been conducted by many researchers [1]. On the other hand, heat transfer characteristics using porous materials have also been actively studied in recent years due to their ability to provide a large surface area even in a low volume, and their application to heat sinks with various cooling methods has been investigated[2].
Recently, the development of laser processing technology has led to the rapid spread of metal 3D printers, which are expected to be applied in various fields as they are capable of modeling structures with fine and complex shapes with diameters of several hundred micrometers. The lattice structure with the length of micrometres can be fabricated by a 3D printer, and is expected to make it easier to predict the heat transfer characteristics.
The number of reports on heat transfer experiments using heat sinks formed by 3D printers is gradually increasing[3], but there are few verification examples of the application to jet flow models.
In this study, a BCC structure is selected for investigation, and its heat transferring response of the BCC heat sink were investigated using the finite element method. Here, the BCC lattice is located on a heating block, and coolant air is blowing from the top surface through the impinging jet. In particular, the effects of fin height and heat transfer characteristics on the heat sink with BCC structure were also investigated. It was confirmed that the heat sink with BCC structure can possesses superior heat conduction and heat transferring capacity to the coolant under the slower flow speed.

Key Words: *Tristability, Composite, Cross-Shape, MFC Actuators, Snap-through*

Morphing multistable structures are highly attractive for advanced shape-changing applications due to their low weights, excellent mechanical properties, and large deformation capabilities. Multistable composite structures have at least two stable configurations; each configuration represents a different geometry and can withstand significant changes in its shape without a continuous power supply [1]. Aim of the paper is to develop a tristable cross-shaped structure, consisting of unsymmetric laminates actuated using Macro Fibre Composite (MFC) actuators. With the advancements in flexible piezoelectric materials, actuation with MFC actuators is proved as a faster and efficient method to change the shapes of multistable laminates [2]. The cross-shaped tristable laminates find potential applications in solar tracking models and energy harvesters. The critical snap-through voltages required to change the shapes are investigated using commercially available finite element package. Use of planar MFC actuators to snap the bistable laminate from one equilibrium shape to another is demonstrated. MFC actuators are bonded on both sides of the four legs to trigger multiple snap-through events. The third stable equilibrium configuration is a transition state which occurs in the snap process from the first to second equilibrium configurations. The snap processes, including the first–third–second and second–third–first, between the different stable equilibrium configurations of tristable cross-shaped unsymmetric laminates are investigated. An attempt is made to address the possible design difficulties arising from the additional stiffness contribution by MFC layers on the naturally cured equilibrium shapes of cross-shaped tristable laminates. Suitable potential applications using the designed self-resetting active tristable cross-shaped laminate are proposed.

Key Words: *Origami, Bioinspired, Kinematic Analysis, Spatial Linkages, Robotics*

Worm-like robots have received great attention due to their ability to navigate through limited space and crawl over uneven surfaces. The living organisms like earthworms, usually consist of several continuous body segments to achieve peristaltic movements [1]. To mimic such behaviours, roboticists have adopted various approaches to design versatile worm-like robots. For instance, soft materials have been used to achieve radial and longitudinal expansion on body segments, and thus a retrograde peristaltic wave is produced [2]. Origami also offers a simplified way to design metameric segmentation capable of locomotion through length variation and body rotation [3].

While resembling worms in many ways, a millipede is not a worm but an arthropod whose body segments are covered by stiff outer skins. When sensing danger, it curls into a spiral, which is a self-defensive mechanism and protects it against predators [4]. Inspired by this specific organism, our research is to develop an origami-based concept for a robot that replicates peristaltic and curling motions similar to those of a millipede.

The proposed mechanism is made with a chain of interlinked modules, mimicking the segments in a millipede. In contrast with the usual origami approach where zero-thickness sheet materials are used, our module is an assembly of deformation free facets with uniform and finite thickness, connected along their upper or lower edges by creases and thus forming an origami pattern of thick panels. Kinematically, a module includes two types of Bricard linkages. Since it has been known that the finite thicknesses of origami facets can reduce the overall degrees of freedom (DoF) [5], our module has only one DoF with kinematic bifurcations. Moreover, the module is specially designed so any numbers of modules can be linked while the single mobility feature is preserved.

This works focuses on the kinematic aspect of a millipede robot. A detailed analysis of the origami mechanism is to be presented, where the curling and peristaltic motions are quantified kinematically. The motion paths are given, with bifurcation configurations identified for motion switch. In addition to the two typical millipede movements, three more configurations of the origami, i.e., a wave, a bench, and a heart, are displayed, bringing the potential for locomotion mode change and opening up additional design space with targeted applications. Our concept is validated by both kinematic simulations and physical models. The work paves way for the realisation of millipede-like robots in the future with actuation and control components integrated.

Mechanics of Morphable Architected Materials

Damiano Pasini and Ruizhe Ma

McGill University, 817 Sherbrooke Street West, Montreal, damiano.pasini@mcgill.ca

Key Words: *Origami, Kirigami, Morphing, Reconfigurability, Temperature Stimulus*

Materials capable of transforming their shape in response to an external stimulus hold promise for application in multiple sectors, from aerospace, robotics, to mechanical and civil engineering. In this talk, I will present a set of reconfigurable metamaterials developed in my group that leverage their mechanics to morph in response to either an applied force or to a change in environmental temperature. On the first front, I will present a class of reprogrammable cellular origami that can not only rigidly fold but also lock into several stiff states that are load bearing in multiple directions. On the second front, I will show examples of temperature-induced morphing, such as a multimaterial truss that can reversibly adapt its structure without forgoing structural capacity, and a class of transformable smart metamaterials that undergo topological changes and giant thermal expansion.

Multi-stable structures induced by pneumatically inflated pouches with laid-in origami paper pattern

Key Words: *Instructions, Multiphysics Problems, Industrial Applications, Covid-19*

When a surface bounded by an inextensible frame shrinks, it buckles and forms a saddle shape. Such a surface can be realized by pleating a sheet of paper [1] or by pre-stretching membrane and attaching it to a 3D printed frame [2]. In particular, the system provides a multi-stable structure when the boundary frame is polygonal [1].

Inspired by the concept of pouch motors [3], we introduce a novel method for providing multi-stable surfaces by pneumatically inflating these surfaces along the patterned frame. We fabricate the structure from two layers of nylon film with heat adhesive layers and the patterned sheets of paper in between. When the structure is heated, the films fuse except for the paper covered part which forms a pouch of desired pattern. We show how the inflation of pouches induces multi-stability by comparing it with prestressed membranes and origami systems.

We applied various geometric patterns inspired by origami to our pouch-based system to produce switchable surfaces. We also show the behaviors of cellular structures obtained by stacking such surface structures.

Key Words: *Origami, Metamaterials, Mechanics, Large deformation, Poisson's ratio*

Origami-based structures have gained interest in recent years due to their potential to develop lattice materials, called metamaterials, whose mechanics are primarily driven by the unit cell geometry. The folding deformations of typical origami metamaterials result in stretch-dependent Poisson's ratio, and therefore in a Poisson function with significant variability across finite deformation. This limits their applicability as the desired response is retained only for a narrow strain range. To overcome this limitation, a class of composite origami metamaterials that exhibit nearly a constant Poisson function, specifically in the range of -0.5 to 1.2 over a finite stretch of up to 3.0 with a minimum of 1.1, is presented. Drawing idea from the recently proposed Morph pattern, the composite system is built as a compatible combination of two sets of cells exhibiting contrasting Poisson effects. The number and dimensions of the cells are optimized for a stretch-independent Poisson function. The effects of various strain measures in defining the Poisson function are also discussed. The results from the study are validated using a bar-and-hinge-based numerical framework capable of simulating the finite deformation behavior of the proposed designs.

Key Words: *Sound absorption, Porous structure, Homogenization method, 3D printer*

In recent years, due to environmental regulations and industrial development, there has been a growing interest in noise problems and their reduction, and the demand for components used for soundproofing has increased. Currently, porous materials such as glass wool and urethane are widely used, and research on foam materials using metallic materials has already been conducted [1].

In general, in order to improve the sound absorption performance of porous materials, we can make the pores inside the material as small as possible and increase the tortuosity of the air passing through the pores to dissipate the acoustic energy as heat loss.

On the other hand, the rapid development of laser processing technology in recent years has led to the widespread use of powder metal 3D printers, and their active use in manufacturing has been increasing. Since metal 3D printers directly use CAD data for manufacturing, it is relatively easy to fabricate micro-lattice structures consisting of minute beams with diameters of several hundred micrometers.

One of our co-authors [2] investigated the sound absorption characteristics of a lattice structure that can be fabricated by a powder-bed metal 3D printer by numerical analysis and sound absorption experiments using acoustic tubes. The structure is composed of body cantered cubic (BCC) structure with partially closed surface which can be manufactured by the printer. The numerical analysis is based on the homogenization method which takes into account the multiphysics occurring in poroelastic media including elastic deformation in the solid phase, compressive viscous fluid flow and the pressure and temperature distribution in the fluid phase, which has already proposed by Yamamoto et al. [3].

In this study, the sound absorption capacities of another type of porous structure with partially closed walls have been investigated by using the same numerical approach. The structure is based on the octahedral lattice cell with partially closed surface, and has great potential to absorb sound sufficiently as well as possessing high structural stiffness. Based on the numerical analysis, the effects of micro-architecture on the sound absorption capacity as well as the contribution of the dissipated energy are discussed.

Two-dimensional analytical solution for multi-segmented Al/ steel-composite panel-An Aerospace Application

Poonam Kumari[1*], Viwek Kumar[1]

[1] Department of Mechanical Engineering, Indian Institute of Technology Guwahati, Guwahati 781039, India, kpmech@iitg.ac.in, singh.viwek@gmail.com

Key Words: *composites, 2D exact, panel, dissimilar material*

Abstract:

E-vehicles and light weight structural parts in automotive and aerospace industry has led to design and development of new structures where traditional materials aluminium/steel are joined with composite laminated materials. This approach has led the engineers/researchers to reduce weight and ultimately save fuel consumption and reduce carbon footprints.
Moreover, prosthetic limbs are also designed to have varying material along the length for better suitability. The above problems cannot be analysed using functionally graded theories/concepts. In theory, material properties vary linearly, exponentially, or power-law-like along x-values but for the above cases, material property does not follow a particular variation. Further even, it is not always practical to produce or manufacture components having very smooth variations along the length.
Number of research articles are reported on the development of joining techniques for the dissimilar materials [1,2]. Bending, free vibration and buckling analysis is also needed for theses case [3]. At the joining or interface point, local inplane and transverse stresses may rise sharply and may cause debonding and failure of structures. One dimensional analysis based on classical assumption or higher order can not accurately predict the stress behaviour at theses places.
In this paper, an attempt is made to develop the 2D analytical solution for multi-segmented Al/ steel- composite panel under transverse loading. Extended Kantorovich method is used for developing governing equations. Continuity of displacement and stresses are satisfied at interface of each segment. Two segmented panels having aluminium/steel and Gr/Ep equal and unequal segment are considered. The deflection and stresses are compared with the finite element solution and found in good agreement.

Key Words: Anti-plane wave, Anisotropy, The method of fundamental solutions

In recent years, anisotropic materials such as fiber-reinforced plastics (FRP) have been increasingly applied to civil engineering structures. Anisotropic materials have different mechanical properties depending on the direction, and wave propagation in anisotropic materials is known to be more complicated than that in isotropic materials [1]. Therefore, numerical simulation of wave propagation and scattering in anisotropic elastic materials play an important role in not only understanding their characteristics but also developing nondestructive evaluation techniques.

The method of fundamental solutions (MFS) is a numerical technique of mesh-free type for solving partial differential equations [2]. The MFS uses fundamental solutions as a basis function, and the source points of the fundamental solutions are located in the complementary domain of analysis one. The MFS requires fewer unknowns than the finite difference method (FDM) and the finite element method (FEM), because it does not require mesh generation of domains and boundaries. In addition, numerical implementation of the MFS is easier than that of the boundary element method (BEM), because the MFS can avoid the singular integration over the boundary. On the other hand, there are few applications of the MFS to wave problems in anisotropic elastic materials.

In this study, we apply the MFS to anti-plane wave scattering of anisotropic elastic materials. Numerical results computed by the proposed MFS are compared with those of the conventional BEM for the validation of the proposed method. Afterwards, we discuss the relationship between the source point location and computational accuracy.

Key Words: Time-domain BEM, Deep learning, Inverse scattering, Ultrasonic non-destructive evaluation, Defect shape reconstruction

The inverse scattering analysis that reconstructs the defect shape using the scattered waveforms from a defect obtained by an ultrasonic array transducer has been performed for a long time. In general, the inverse scattering techniques based on the Born, Kirchhoff approximations [1], and time-reversal approach are known as relatively time consuming methods. On the other hand, the machine-learning is attracting a lot of attention in many engineering fields. In particular, the deep learning (CNN: Convolutional Neural Network), which is an extension of the neural network (NN), has become a basic technology for creating an artificial intelligence (AI). In the field of the ultrasonic nondestructive evaluation (UT), the inspectors have to make a judgement whether test materials have a defect or not using scattered waveforms from a defect. This operation requires a great deal of skill of UT inspectors and the UT accuracy depends on the inspector skill.

To overcome this difficulty, in this study, a deep learning is utilized to detect a defect in 2-D isotropic solids. The images required for the present deep-learning with the convolutional neural network (CNN) are numerically prepared using the convolution quadrature time-domain boundary element method (CQBEM) [2] for simplicity. The CQBEM is known as a suitable numerical approach for wave analysis and can produce high precision solutions better than the classical time-domain boundary element method (BEM). In the CQBEM analysis, scattered waveforms by a defect at some receiver points are artificially produced. These waveforms as a function of the time are transformed into the color mapped image data. These color mapped image data are given for input data as the CNN. As numerical examples, some defect position and scale detection problems are solved by using the created deep learning model. The results for how the created deep learning model determines the defect position and scale may be useful for future practical application of this method.

Detection of Bi-Material Plate Debonding by Guided SH Waves Scattering with BEM

Supawat Wongthongsiri[1*] and Sohichi Hirose[2]

[1] Tokyo Institute of Technology, wongthongsiri.s.aa@m.titech.ac.jp
[2] Tokyo Institute of Technology, hirose.s.aa@m.titech.ac.jp

Key Words: *Guided SH waves, Scattering, Debonding, Boundary Element Method*

This research aims to investigate the guided shear horizontal (SH) waves scattering phenomena used in the non-destructive inspection for detection of interface debonding in bi-material plate structures. A boundary element method (BEM) is used to solve the scattering problem of SH guided waves due to efficiently and accurately in computation, leading to the reflection and transmission coefficients of scattered waves. Two-dimensional, isotropic, linearly elastic, and traction-free plate structures are considered. This plate is a perfectly bonded bi-material that is split between upper and lower layers. The interface containes a finite length traction-free debonding which acts as a scatterer for propagated guided waves. The frequency domain, elastodynamic fundamental solutions of traction and displacement are utilized for boundary integral equations. Wave functions are formulated by the partial waves technique to obtain the dispersion curves and wave structures. Discretizing boundaries surrounding bi-material plate domains into constant elements yields a system of linear equations, which can be solved by a regular linear solver. Various parameters in numerical calculation are considered including materials, debonding lengths and locations with selected modes of an incident wave over several frequency ranges. Obtained results show the scattered guided SH waves have the potential to detect a debonding. Bi-material structures also affect the uncouple of symmetric and antisymmetric properties leading to the mode-conversion phenomena. Moreover, the resonance phenomena can also be observed where all the waveforms are reflected and cannot pass through the debonding. Such information will establish fundamental knowledge for non-destructive inspection and structural health monitoring.

Key Words: Inversion, Wave Source Imaging, Anti-plane Wave, Sparse estimation, LASSO

Recently, ultrasonic flaw imaging has become popular with the development of a multi-point measurement system such as a phased array method. Particularly, FMC/TFM (Full Matrix Capture / Total Focusing Method)[1] is a powerful post-processing tool to produce the best flaw image at each focusing point. In FMC/TFM, however, lots of data have to be handled, which are collected from each transmitter/receiver combination. Therefore, an effective inversion approach for flaw imaging using less data is expected. In this paper, an innovative wave inversion based on sparse estimation is investigated by numerical simulation.

The problem is to estimate an anti-plane wave source from waves observed at several points surrounding the source. The wave source is approximated as an equivalent body force, and the radiated waves are formulated in a simple integral form, which gives the relation between the radiated waves at observation points and the source parameters. Unfortunately, the discretized integral equation with unknown source parameters becomes ill-conditioned. To overcome this difficulty, the LASSO[2] approach is applied to solve the discretized integral equation on the assumption that the source parameters are distributed sparsely in the domain.

In numerical simulation, first, the anti-plane waves radiated by the given source are numerically calculated at the observation points. Then the location and strength of the equivalent body force are determined from the simulated wave field using LASSO. The applicability of the sparse estimation is demonstrated by several simple numerical examples.

Key Words: Guided Wave, Finite Element Method, Continuation Method, Dispersion Curve

In the non-destructive testing (NDT) and structural health monitoring (SHM), it is required to know dispersion relations to better understand a propagating wave in an elongated material. To analyze the dispersion phenomenon in terms of frequency and wavenumber, analytical approaches have been applied for elongated structures with simple-shaped cross-sections. On the other hand, numerical approaches are often used to calculate the dispersion curves for a waveguide with an arbitrary cross-section. Although several numerical methods have been proposed for the dispersion analysis in conventional researches, we focus on a semi-analytical finite element method [1] (SAFE) herein.

In the SAFE formulation, the target domain is discretized in the cross-section, while an analytical solution is adopted in the wave propagation direction. Then, the eigenvalue problem is constructed in a similar way to general finite element methods. The dispersion relation can be obtained to solve the eigenvalue problem for the wavenumber by sweeping the frequency. However, the dispersion curve becomes tangled for materials that have a complicated cross-section and an inhomogeneity. In particular, it is known that the dispersion curves for composite materials often exhibit an acute directional change. Thus, it sometimes would be difficult to classify each modal curve and to evaluate the continuity of the curve.

This study proposes a mode tracking method of the dispersion curves using a numerical continuation method [2] (NCM). In the proposed method, nonlinear algebraic equations are formulated from the eigenvalue equation provided by the conventional SAFE. Since the dispersion curves are smooth even in the discretized system, the NCM can track the dispersion curve continuously based on the Newton-type iteration method. To prevent a jump from a dispersion curve to other ones in the tracking process, we introduce several constraints.

Key Words: Time evolution, Multiple scattering, Point-like scatteres, Volterra type integral equation, Krylov subspace method, FFT

Concept of point-like scatterers is as a result of the mathematical idealization for cases that the spatial scale of the scatterers are very small compared to the wavelength of the back ground structure of the wavefield. Applications of point-like scatterers for scattering problems spreads to wide range of analyses such as crystallite granite. This study develops a method for a time evolution analysis of multiple scattering problem of point-like scatterers and investigates the properties of interaction effects in the time domain based on the numerical computations. The method employs the Volterra type integral equation with respect to the time evolution. The formulation itself is based on previous studies in the frequency domain (e.g. Foldy [1], Waterman and Truell [2], and Hu and Sini [3]). The fast Fourier transform and Krylov subspace method are employed for the analysis of the Volterra type integral equation, in which the kernel of the integral equation is derived from the Foldy model[1]. Numerical computations are carried out for one configuration model. Numerical results showed that time evolution of the scattered wave field is well explained by the retarded time as well as the geometrical attenuation of waves from each scatterer. Incorporation of statistical as well as renormalization approach to the present model is the task for the future.

Key Words: Damping, Reinforced Concrete, Dynamic, Nonlinear Model, Energy Balances

Earthquake events in recent years and their consideration in performance-based design have lead to the development of increasingly sophisticated physical models in structural computations. The nonlinear seismic behaviour of reinforced concrete (RC) structures is classically modeled through dissipative phenomena at two scales. At the material scale, nonlinear models describe some phenomena, such as concrete damage, friction, unilateral effects or plasticity. At the global scale, for dynamic analyses, energy dissipation is practically modelled with equivalent viscous damping.

To improve the description of energy dissipations when a nonlinear behaviour is considered, updated damping models are developed in literature usually based on the tangent stiffness matrix [2]. In this paper, a locally updated damping model is proposed based on the evolution of nonlinear variables such as concrete damage or friction. The model is first studied with a single degree-of-freedom (SDOF) model of a RC beam ($6\,\mathrm{m} \times 0.4\,\mathrm{m} \times 0.2\,\mathrm{m}$) showing accurate performances. Then, the construction of the matrix for a multi-fibre RC beam model is developed. Numerical analyses are then carried out to compare the performances of the proposed damping model with respect to more classical ones, as for example the Rayleigh damping model updated with the tangent stiffness matrix. The reference results are based on the experimental campaign carried out by T. Heitz [1]. A peculiar attention is given to the degradation of the beam according to frequency drop off. The evolution of the energy dissipations according to the degradation is investigated.

Finally, the proposed model is an improvement to classical damping models, such as Rayleigh ones, in terms of dynamic responses by dissipating more energy at the material level. The locally updated damping model is particularly improved by an explicit consideration of friction across cracked components.

Key Words: *Proportional Damping, Bell-Shaped Model, Softening Response, Negative Stiffness*

In the modelling of large-scale structures, energy dissipations not already accounted for using material hysteretic models, often called un-modelled damping, are usually incorporated using viscous damping such as Rayleigh damping due to mathematical convenience and computational efficiency. The use of the Rayleigh damping model during inelastic response after yielding occurs could, however, lead to large spurious damping forces in the order comparable to material constitutive forces. This problem has been well-documented and studied [e.g. 1, 2, 3].

Many remedies have been proposed to address the spurious damping forces. However, most of them are not computationally efficient, and some also deviate from the idea of modal damping ratio due to loss of proportionality, resulting in difficulty for model parameter calibration against experimentally measured modal damping ratios. Most models are also not suitable for structures experiencing softening response due to having negative damping ratio.

A new type of proportional damping models, called bell-shaped proportional damping model, has recently been proposed [4]. This new model has not only addressed the spurious damping forces, but also maintained the same order of computational efficiency as the Rayleigh model. This model has also been further improved such that, by using the tangent stiffness approach, it becomes suitable for structures experiencing softening response with negative stiffness [5]. The improved model, called Type 4, allows users to have flexible control of modal damping ratio for all interested frequency intervals, including those associated with negative stiffness.

In this study, the performance of the Type 4 damping model is evaluated numerically in a response history analysis of a multi-storey building under seismic loading. The results show that, compared to the Rayleigh model, the Type 4 model performs excellently in terms of always giving desirable positive energy dissipation even when the structure is experiencing softening response.

Key Words: *Machine Learning, Artificial Intelligence, Steel Deep W-shape Columns, Failure Mode Classification*

Machine learning approaches have received significant attention over the past few years in the field of civil engineering in general, and earthquake engineering in particular. Examples of their use in earthquake engineering can be found in Sediek et al. [1]. Generally, machine learning (ML) is a subset of artificial intelligence (AI) that uses sample datasets (i.e., training data) to tune the parameters of mathematical models which can be used to predict the response of new datasets that were not explicitly programmed in the mathematical models. Predicting the seismic failure mode of deep steel W-shape (DSW) columns is a potential application for such approaches in earthquake engineering. DSW columns can either fail in a global mode when subjected to an earthquake, where the column collapses globally with no plastic hinges at its ends; in a local mode, where the column fails due to the formation of "local" plastic hinges at its ends; or in a couple mode involving both local and global failure modes. Predicting the seismic failure mode of DSW columns is a challenging task due to its highly nonlinear decision surfaces that depend on many continuous and categorical parameters including geometric properties, boundary conditions and loading. Nevertheless, it is important for designing new DSW columns or deciding retrofit and rehabilitation strategies for existing DSW columns to predict their seismic failure modes. Therefore, this study explores the use of machine learning (ML) to predict the seismic failure mode of DSW columns. Steel Column Net (SCNet), a dataset of more than nine hundred experimental and numerical results of deep wide flange (W-shape) columns with different attributes is compiled. Three failure modes are distinguished in SCNet: local, global, and coupled modes. The efficiency of five machine learning (ML) classification models is explored to identify the failure modes of columns subjected to combined axial and lateral loading in a randomly assigned test set from SCNet. Among the ML classification techniques used, support vector machine and decision trees provide the best performance with a prediction accuracy of 89%.

Key Words: *Collapse Fragility, Risk Assessment, Deep Columns, Steel Buildings*

Deep, wide-flange columns have been widely used in steel building in the U.S. because of the high stiffness and strength-weight ratio. While the structural instability of deep columns has been extensively studied at the member level, the influence of out-of-plane displacement and vertical ground motion on collapse behaviour of space frames with deep columns is not yet explored. To address this shortcoming, the collapse risk assessment of four-story steel planar and space frames under various seismic excitations is computationally investigated. High-fidelity finite element models are employed and analysed using explicit dynamic solver to capture instability and collapse behavior in the frames. Simulation results suggest that adding another horizontal ground motion is severely detrimental to the collapse capacity of space frames under all ground motion sets, while the effect of vertical ground motion is significant only when it changes the collapse mode. Moreover, composite slab combined with gravity frames can greatly reduce the collapse risk. However, gravity frames could induce vertical collapse due to buckling of gravity columns or facture in shear connections. Based on the results, the currently available design recommendations for the use of deep steel columns in steel buildings are evaluated and further revised.

Key Words: *Reinforced Concrete, Bridge Column, Longitudinal Reinforcement, Aspect Ratio, Hysteresis Behaviour, Deteriorations, Hysteresis Model*

To study the effects of longitudinal reinforcement and aspect ratios on the deteriorated hysteresis behaviours of reinforced concrete (RC) bridge columns, five rectangular RC column specimens with hoop and tie reinforcements are tested under cyclic loading considering longitudinal reinforcement ratios of 0.75%, 1.5%, and 3.0% and aspect ratios of 3, 6, and 10 [1]. Furthermore, another five circular RC columns with spiral reinforcement and similar test scheme obtained by Leman and Moehle [2] are included to further compare the differences of deterioration characteristics resulting from various confining mechanisms. The deterioration characteristics are quantified and extracted from the test results through the calibration of a smooth hysteresis model [3] where each model parameter can represent a specific structural property. Test results show that the stiffness degradation and pinching severity of column would increase as its longitudinal reinforcement decreases. The pinching severity of column would also increase with decreasing aspect ratio, but the stiffness degradation is barely affected by the aspect ratio. Moreover, due to the well confinement effects, the severity of deteriorations of circular columns are less than those of rectangular columns with the same longitudinal reinforcement ratio and the minimum transverse reinforcements required by seismic design codes. Besides, the failure of rectangular columns is mainly caused by the loosening of transverse reinforcements at seismic hooks, leading to gradually deteriorated confinement and strength. In contrast, the failure of circular columns is primarily induced by the fracture of spirals, resulting in destruction of confinement mechanism and sudden strength loss.

[3] Hiroshima University, 739-8527, mario@hiroshima-u.ac.jp

Key Words: *Emergency Bridge, Scissors-type Bridge, Seismic Behaviour, Reinforcement Effect*

The Scissors Bridge is a deployable bridge designed for early bridging after a disaster [1]. By using a scissors structure for its main frame, the bridge can be transported in the assemble state, and it enables to reduce the number of workers and heavy machinery. Previous design studies have shown that the main frame of the scissors bridge is strongly affected by the bending moment [2]. It was also found that the effect of this bending moment could be reduced by installing the decks on the shafts in each scissor unit [3]. However, the reinforcing effect of the decks according to their position has not been fully clarified. In addition, it is necessary to clear the seismic performance of the scissors bridge considering used at disaster sites.

In this study, a parametric FE analysis was conducted in order to investigate the seismic performance of the scissors bridge focusing on the boundary conditions and the number of scissors units. Two different types of seismic waves, *the Kobe Earthquake* and *the Tohoku Earthquake*, were used for the scissors bridge with difference decks position: one is the deck type of bridge which was installed the decks on the upper shafts, and the other is the through type of bridge which was installed the decks on the bottom shafts.

The dynamic response factor of displacement and cross-sectional force was evaluated by comparing the results between static analysis and seismic response analysis. In case of the deck type of bridge, the dynamic response factor of the axial force increased from 10% to 30%. On the other hand, the dynamic response factor of the bending moment decreased from 20% to 40% compared to the case without decks. In case of the through type of bridge, the dynamic response factor of axial force decreased from 30% to 60%, but the dynamic response factor of the bending moment increased from 10% to 20% compared to the case without decks. From these results, it was found that so effective installing position for the axial force was the through type of bridge and for the bending moment was the deck type of bridge from the point of reducing the effect of its sectional force during the earthquake.

Key Words: secondary suspensions, dynamic stiffness, flexible carbody, rail vehicle dynamics.

Abstract. *The running behaviour of rail vehicles is highly influenced by suspension components. Dealing with ride comfort, secondary suspensions are adopted to reduce the vibrations transmitted to the carbody. In this context, the dynamics of the suspension elements themselves has to be properly included in multibody system. This paper proposes a strategy for modelling the passive vertical secondary suspension in the frequency domain. To this aim, a mathematical model is defined and its parameters are tuned to be representative of a real system. Then, a sensitivity analysis over the model parameters is proposed to discuss the suspension performances in terms of dynamic stiffness. Finally, a finite element model of the carbody is considered and coupled to the rear and front suspensions. The model is adopted to simulate the vehicle running on a rail track irregularity in the frequency domain, in the 0-30 Hz frequency range.*

Key Words: Frequency Response, Railhead Roughness, Uncertainty, FEM, Fourier Series

In order to understand the dynamic behavior of subway track and tunnel, it is important to evaluate the coupling system composed of train, track, tunnel and soil adequately. Railway vibration originates from the geometric and parametric excitations. The former, which may dominate the vibration, is induced by irregularities on the railhead and wheel tread. Since, in general, these profiles have uncertainties, the dynamic behavior is characterized by a random vibration. Therefore, the dynamic response should be assessed based on its average. In the case of conventional numerical methods, the dynamic interaction analysis is carried out for a given roughness generated over a finite range of the track model. Although the expected value of frequency spectrum can be approximately evaluated by smoothing over each 1/3 octave frequency band, this operation leads to a reduction in frequency resolution.

This paper presents a semi-analytical method for bogie-track-tunnel-soil dynamic interaction problems. The tunnel is modeled as an infinite cylindrical shell surrounded by an elastic region. The track is given by a periodically supported infinite rail. The railhead roughness is considered as a random process. Due to the periodicity of the track, the Floquet transform is applied to the interaction problem. Moreover, in order to reduce computational effort, the solution is represented by a Fourier series in the track direction [1]. Sections of the concrete slab and tunnel invert are discretized by finite elements. To evaluate the mathematical expectation of dynamic response, the relation between the power spectrum density of the roughness and the expected value of energy spectrum density (ESD) of acceleration at observation points inside the tunnel is derived explicitly [2]. It is found that the expectation of ESD is characterized by the superposition of vibrations originating from two wheelsets of a bogie.

Assessment of the pantograph-catenary current collection quality by using indirect measurements and Artificial Neural Networks

Santiago Gregori[1*], Manuel Tur[1], Jaime Gil[1] and F. Javier Fuenmayor[1]

[1] Instituto de Ingeniería Mecánica y Biomecánica, Universitat Politècnica de València, Camino de Vera s/n, 46022, Valencia (Spain), sangreve@upv.es, manuel.tur@mcm.upv.es, jaigiro@upv.es, ffuenmay@mcm.upv.es

Key Words: *ANN, Artificial Intelligence, Catenary, Interaction Force Measurement, Pantograph*

Current collection in high-speed trains is usually carried out by means of the sliding contact between the pantograph collectors and the catenary contact wire. This pantograph-catenary interaction force directly determines the current collection quality, which is usually characterised by some statistical parameters. High contact forces tend to accelerate wear on both contact wire and pantograph collectors, while low contact force values may eventually produce arcing with its consequent negative effects. For that reason, European standards [1] limit certain parameters such as the mean, minimum and standard deviation of the interaction force.

The current collection quality of a given pantograph-catenary couple is commonly assessed by direct measurements of the interaction force. This implies to use an instrumented pantograph and perform specific in-line tests which are generally costly. To alleviate the drawbacks that this procedure entails, in this work we propose a methodology to predict the main statistical indicators that quantify the current collection quality based on indirect measurements and artificial intelligence techniques. Specifically, Artificial Neural Networks (ANN) are trained from the vertical acceleration of the pantograph collector head, which is relatively easier to measure in practise.

In this work, the pantograph accelerations have been numerically obtained from thousands of simulations of the pantograph-catenary dynamic interaction problem with the efficient algorithm proposed in [2]. These simulations are performed with different pantograph velocities and different contact wire height profiles to account for installation errors present at actual catenaries. The good prediction accuracy of the trained ANN shows that the proposed methodology can be an appealing alternative to the in-line contact force measurement for current collection assessment.

Key Words: *Hardware in the Loop, Pantograph, Catenary, Periodic Models, Steady State*

Hardware-In-the Loop (HIL) testing has emerged as an appealing procedure to simulate the dynamic interaction between a real pantograph and a virtual catenary. In these tests, the pantograph contact strips interact with a linear actuator that simulates the catenary contact point. The interaction force is measured by load cells for feeding a numerical model of the catenary which provides the contact wire height profile that must reproduce the linear actuator. The aim of these tests is to replace homologation in-line tests, thus reducing the homologation cost.

To carry out HIL pantograph tests it is mandatory to solve the dynamic behaviour of the catenary model in real-time. This requirement usually leads to simplified models to describe the catenary system that limit the accuracy of the results [1]. In this work, we propose a complete framework to perform HIL pantograph tests by using a periodic catenary finite element model. This model only accounts for the steady-state regime, which is very representative of the general behaviour of the high-velocity pantograph-catenary interaction. In those catenaries, long straight sections with very similar spans are commonly installed. To achieve the steady-state solution in the HIL test rig, an iterative strategy is also described and numerically validated [2].

One of the main advantages of the model proposed is its ability to consider the non-linear behaviour of droppers, which slackens under compressive forces. Furthermore, actuator control-loop and sensor delays can be easily handled. The results obtained from HIL tests are compared to those obtained from pure simulations showing good agreement. Finally, an optimized catenary geometry has been tested in the HIL test rig to validate if the optimized model still behaves in an optimal manner when interacting with a real pantograph.

Key Words: *Railway Dynamics, Yaw Dampers, Multibody Dynamics, Vehicle Stability, Curve Negotiation*

Nowadays, the tendency to increase the competitiveness of railway vehicles by raising their commercial speed is widely diffused around the world. Such enhanced velocity levels must be reached without decreasing the standard safety levels.

Considering the straight track condition, yaw dampers are the most influencing secondary suspension components of the railway vehicle able to increase the stability during high-speed operations [1], [2]. The dampers contribute reduces the risk of hunting instability and, therefore, it increases the vehicle critical speed. The typical passive yaw dampers are designed to achieve this goal, but, unfortunately, they worsen the curving performances [3]. Indeed, the forces provided by the standard passive devices increase the bogies steering resistance during the negotiation of sharp curves, especially along curve entries and exits, with a consequent increase of the wheel-rail contact forces.

For this reasons, damper manufacturers are studying innovative solutions to modify the internal characteristics of the dampers according to the vehicle working conditions. The goal is to obtain devices able to combine the vehicle stability during the high-speed running and the curving performances in sharp curve negotiation.

In this context, the present work aims at developing a numerical model of the new yaw dampers, validated with experimental results collected on a specific test bench. Then, the numerical evaluation of the vehicle performances with the innovative yaw dampers is carried out by a co-simulation routine: a multibody vehicle model of a real test case, implemented in the Simpack® software, is run together with a Simulink® model of the yaw damper. The performances are analysed taking inspiration from the EN 14363 standard in terms of both high-speed running stability and low speed curve negotiation.

Key Words: Optimization under uncertainties, Bayesian inference, High-speed train dynamics

Controlling the energy consumption is an important stake in today's world. In the railway field, the energy consumed by high-speed trains depends on many variables such as the driver behaviour. Significant variations have been noticed for different drivers on the same journey. To help drivers, crossing points are defined along the journey, but differences still exist. The industrial objective of this work is to define a model, able to describe the train dynamics and to propose an optimization method, which aims to minimize the energy consumption.

This work is composed of two parts. First, a deterministic model is defined to describe the train longitudinal dynamics based on a Lagrangian approach [1]. This model is calibrated based on commercial trains measurements. Afterwards, the optimization of the command is performed using the CMA-ES method [2] to minimize the energy consumed while punctuality, security, and comfort constraints are respected. Nevertheless, the high-speed train system is complex, and taking into account the uncertainties of the model parameters is necessary. Therefore, a Bayesian inference method [3] is applied in order to include uncertainties in the previous deterministic model. Finally, an optimization under uncertainty method is used to find the optimal command.

The originality of this work lies on its transposability to real train systems. Indeed, pneumatic braking is distinguished from dynamic braking (able to recover a part of the energy consumed). The optimization method is applied to the driver command and it combines both punctuality and physical constraints. Many energy measurements are used to calibrate and validate the models and verify the quality of the optimal solution. Finally, the rolling environment of the train is determined carefully by the use of wind predictions, track declivity and curvature measurements.

Generalized Polynomial Chaos expansion (gPC) is a well-known method for uncertainty quantification of stochastic systems, in particular for smooth responses [1]. In the case of nonlinear systems exhibiting discontinuities in their surface response, it has been demonstrated that multi-element generalized polynomial chaos (ME-gPC)—which is based on an element decomposition of random space—provides accurate results. However, the definition of the elements, a key step of ME-gPC, is usually based on a tensor structure and the number of elements increases dramatically at high stochastic dimension [2]. In this study, the focus is made on the decomposition of the random space for nonlinear mechanical systems in order to efficiently apply gPC with a limited number of elements. More specifically, this decomposition relies on an automated detection procedure of the surface response discontinuities (referred to as *edges*) represented by cubic-spline curves. The proposed edge tracking detection is first detailed and validated on analytical test cases. Then, a specific implementation of ME-gPC is presented so that it may be efficiently applied on elements whose frontiers are defined by four cubic-splines in order to maximize the versatility of the random space decomposition. Finally, the proposed methodology is applied to the analysis of an academic Duffing system and an industrial compressor blade, NASA rotor 37, featuring blade-tip/casing contacts [3]. It is shown that the proposed developments yield accurate results both for the discontinuity detection and the response approximation in comparison to the reference Monte-Carlo simulations.

The development of new aircraft engine architectures is mainly focused on performance and energy efficiency. One way to achieve this objective is to reduce its weight by using composite materials but also to increase the by-pass ratio of these machines. These last two points lead to long and thin, and therefore very slender blades geometry. Such designs make these structures more flexible, which can then exhibit non-linear geometric behaviours. This geometry combined with the cyclic symmetry property of the bladed disk will generate specific non-linear behaviours such as non-linear energy localization or even internal resonances. Using a non-linear curved beam model taking into account large displacements, twist change and a profiled cross-section [1], we have been able to study the non-linear contributions of each term of the model and thus to have a good understanding of the involved physics. All of these simulations were carried out taking into account the effects of rotation on the beam. Finally, a numerical approach has been developed to deal with large models such as those encountered in industry. The strategy developed is based on non-linear reduction approaches adapted to geometric nonlinearities such as modal derivatives [2], companion modes [3] or normal form [4] of the motion equations. These results were compared to experimental data that allowed to validate the developed approaches. It should be noted that this work also made it possible to take advantage of the non-linear behaviour of the structure by using the properties of internal resonances. Indeed, we were able to decrease the level of vibration by transferring energy from one mode to another with better dynamic characteristics.

Probabilistic Learning Based Optimization of the Detuning of Bladed-Disks in Nonlinear Stochastic Dynamics in Presence of Mistuning.

Evangéline Capiez-Lernout[1*], **Christian Soize**[1]

[1] Université Gustave Eiffel, MSME UMR 8208 CNRS, 5 bd Descartes, 77454 Marne-la-Vallée Cedex 02, France, evangeline.capiez-lernout@univ-eiffel.fr, christian.soize@univ-eiffel.fr

Key Words: Bladed-disk, Detuning, Mistuning, Finite displacements, Uncertainty Quantification, Combinatorial optimization, Probabilistic learning on manifolds

The vibrational behavior of bladed-disks is known to be particularly complex in reason of mistuning amplifications but also in reason of geometrical nonlinear effects (use of lighter materials). In such a context, methodologies for the dynamical analysis based on the nonparametric probabilistic approach [1] odf the random mistuning combined to nonlinear reduced-order models allows for a better understanding of uncertainty propagation through the forced response [2]. The difficulty related to this unavoidable mistuning effects has led to consider the detuning (alternating between several blade types) as a way for inhibiting the amplifications. A computational methodology adapted to the detuning context of nonlinear dynamics of mistuned bladed-disks developed in [3] has shown very encouraging results. In this context, the present research deals with a novel formulation for the detuning optimization of a bladed-disk structure using a 12 bladed-disk computational model issued from [4]. The dynamical amplification is defined with respect to the pure mistuned configuration and involves scalar quantities that are defined from the extreme values of the maximum displacements occurring in the structure. The numerical procedure allows for obtaining a full data basis. Its analysis shows the existence of a few number of detuned configurations that reduce the mistuning amplification effects. A second part of this work consists in proposing a formulation of the combinatorial optimization problem for which a surrogate model of the cost function is constructed using the PLoM method [5], as a machine learning tool from a small training set. The optimal solution obtained is compared to the one obtained with the data basis.

Key Words: Reduced Order Modeling, Geometric Nonlinearities, Rotor/Stator Interaction

In the current economic and environmental context, aircraft engines manufacturers try to design more efficient engines in order to reduce their fuel consumption. First, aerodynamic losses are decreased by reducing the clearance between the blades and the surrounding casing. This can lead to contact events between the blades and the casing even in nominal operating conditions [1]. Then, the engine weight is reduced by designing lighter, and therefore more flexible, blades. As a consequence, the blades can undergo large displacements and deformations [2].

A methodology has been recently derived to study the contact interactions of single blades undergoing large displacements [3]. In this article, this methodology is extended to full bladed disks with cyclic symmetry. In order to be computationally efficient and compatible with the use of large industrial models, the methodology is based on a reduction procedure. Each sector of the high fidelity model is projected onto a basis composed of Craig-Bampton modes and a selection of their modal derivatives. The internal nonlinear forces due to large displacements are evaluated in the reduced basis with the stiffness evaluation procedure [4]. Contact is numerically handled with Lagrange multipliers.

The numerical strategy is applied on an open industrial compressor model, the NASA rotor 37, in order to promote reproducibility of results. This work demonstrates that reduced order models provide a computationally efficient alternative to full order finite element models for the accurate prediction of the time response of structures with both distributed and localized nonlinearities.

Key Words: *Implicit Dynamic, Composite Time Integration Scheme, Equivalent Node Secant, Frame Element, Vehicle-Bridge Interaction*

In order to simulate the vehicle-bridge interaction by using a numerical model with high stiffness elements for a long duration, Bathe composite time integration scheme is incorporated into the new implicit dynamic finite element analysis procedure proposed by Lee et al. [1-2] in this study. The Bathe scheme can be viewed as an extension of the trapezoidal rule in which the trapezoidal rule is combined with the 3-point Euler backward method. When analysing nonlinear dynamic problems with large deformations, long duration, and high stiffness elements, Bathe scheme demonstrates its simplicity and accuracy in previous studies [3-5]. On the other hand, the new analysis procedure introduced the concept of equivalent node secant coefficient to decouple the governing equilibrium equations so that the factorization of an effective matrix is no longer necessary. Compared to the traditional implicit dynamic finite element procedure, the new analysis procedure dramatically saves much computation time and possesses high reliability and accuracy as shown in the previous study. In particular, any kind of FE can be included in the analysis procedure as long as the element internal and damping nodal forces can be exactly evaluated.

High stiffness contact element can be used to simulate the vehicle-bridge interaction during nonlinear dynamic analysis. When a vehicle-bridge interaction system is subjected to extreme earthquake, highly nonlinear and discontinuous dynamic behaviour, such as vehicle uplift, collision and derailment, may occur. The hybrid integration method proposed in this study can effectively maintain the convergence and stability of the 3D numerical analysis. Finally, the vehicle-bridge interaction model is constructed by space truss/frame with high stiffness contact element. The analytical results obtained by proposed method are compared with those obtained by traditional implicit method to verify the accuracy and efficiency of the proposed hybrid integration method.

Key Words: *Vehicle-Rail-Bridge Interaction, Wheel Rail Contact, Finite Element, Nonlinear Dynamic Analysis*

Railway technology has been developing rapidly and the number of long-span railway bridges has been increasing. A long-span and heavy railway bridge may result in obvious vehicle-rail-bridge interaction due to its flexibility property and heavy dead load, especially for high-speed railway bridges under strong earthquakes. The purpose of this study is to simulate the vehicle-rail-bridge interaction of high-speed railway bridges under strong ground motions by using a new implicit dynamic finite element analysis procedure proposed by Lee et al. [1-2].

It is very difficult for traditional finite element analysis procedure to deal with problems with large deformation, collision, fracture, high velocity, high non-linearity and discontinuity. The new implicit dynamic finite element analysis procedure does not require assembling the structure stiffness and damping matrices. Without the factorization of an effective matrix, the computation efficiency is greatly superior to that of conventional implicit methods. Any kind of FE can be included in the analysis procedure as long as the element internal and damping nodal forces can be exactly evaluated. Therefore, the new dynamic finite element analysis procedure is used to simulate highly nonlinear and discontinuous dynamic behavior of long-span bridges as well as high-speed moving vehicle loads under strong earthquakes.

When a high-speed railway bridge is subjected to extreme earthquake, highly nonlinear and discontinuous dynamic behavior, such as vehicle uplife, collision and derailment, may occur. In this study the 3D simulations of vehicle sub-structures, moving loading, wheel-rail contact, vehicle uplife are developed and included in the new dynamic analysis procedure. Through extensive simulations of single-span long-span bridges, the obtained results are compared with the current design formula. The bridge seismic design, train design load mode and reasonable speed limit for long-span bridges are discussed.

Key Words: *Implicit Dynamic analysis, Eight-Node Hexahedral Element, Rigid Body Motion, Vehicle-Bridge Interaction, Bridge Deck*

This study is aimed at the simulation of vehicle-bridge interaction using a novel dynamic analysis procedure with geometrically nonlinear solid elements. The bridge deck is idealized by solid elements to investigate the concentrated stress in the deck while a heavy vehicle is passing through the bridge. Compared with the traditional implicit dynamic finite element procedure, the new implicit dynamic finite element analysis procedure proposed by Lee et al. [1-2] does not require assembling the structure stiffness and damping matrices. Without the factorization of an effective matrix, the computation efficiency is greatly superior to that of conventional implicit methods. Any kind of FE can be included in the analysis procedure as long as the element internal and damping nodal forces can be exactly evaluated. Therefore, the novel dynamic analysis procedure is adopted in this study.

A geometrically nonlinear eight-node hexahedral solid element is developed and included in the novel dynamic analysis procedure. The rigid body motion of the eight-node hexahedral element is subtracted from the total displacement based on co-rotational coordinate systems. After the pure deformation is determined, engineering strain and engineering stress can be applied to calculate the internal nodal forces. The proposed approach is more efficient than that using the Green-Lagrange strain and the second Piola-Kirchoff stress in geometric nonlinearity problems. Compared with the traditional finite element method for nonlinear geometrical structures, the proposed method can significantly reduce computation time. In addition, according to the previous researches this dynamic analysis procedure demonstrates high reliability and accuracy in large deformation structures. The analytical results obtained by using the developed element are compared with those obtained by ABAQUS software to verify the accuracy and efficiency of the proposed solid element. Finally, the stress distribution of the bridge deck while heavy vehicle passing through is investigated.

Abstract

Compared to conventional bridge structure with pier supports, the steel box-girders suspended by bracket structures of a monorail is flexible for most monorail transit system. Thus, as a train carriage travels on a series of flexible hanged box-girders, the vibration of train-monorail system can be regarded as the topic of *a heavy vehicle traveling on a light beam*. Obviously, the inertia effects of moving masses on dynamic response of a monorail would become significant. In this study, the spatial-varying of nature frequencies of a beam subjected to a moving mass will be conducted. On the other hand, as a high speed train moving on a bridge with resonant speeds, such a dynamic phenomenon would become noticeable once the VBI effect is taken into account for performing the interaction dynamic analysis of a train-bridge system. The numerical results revealed that the resonant speed would be slightly shifted to lower speeds due to the inertia effects of the train cars traveling on the bridge.

Key Words: *Digital Twins, Directed Energy Deposition, Additive Manufacturing, Multiscale modeling*

Digital process development for additive manufacturing is emerging as a sustainable, cost-attractive alternative to the traditional experimental trial-and-error approach whereby computer modeling and simulations are used to explore the process window for a given material, 3D printer, and part. At the same time, digitalization is a hard task requiring validated, high-fidelity models at different length scales (part and melt pool) and time scales (solidification to build time). Such challenges are equally valid for directed energy deposition (DED), which is typically characterized by a laser head following the movement of a robot code (g-code) to build the component. Here, we report on our efforts to achieve a design digital twin for the DED process by developing a fully in-house integrated model including thermal simulation at the scale of the part, classification of thermal history to identify key locations in the component, microstructure evolution, multi-bead multi-layer deposition of material, phase fraction model at the scale of the part including nonlocal mechanical properties, and residual stress and distortion. By using such design twin, users are able to explore the role of process parameters as well as of gcode, therefore developing the process to optimize the final part's microstructure, mechanical properties, and distortion.

A mixed interface-capturing and interface-tracking CFD framework for modeling metal AM processes at different scales

Jinhui Yan

Assistant Professor, University of Illinois at Urabana-Champiagn

In this talk, we present a novel computational framework by mixing interface-capturing/interface-tracking methods for simulating the thermal multi-phase flows in metal AM applications, focusing on better handling the gas-metal interface, where AM physics, such as phase transitions and laser-material interaction, mainly takes place. The framework, built on level set method and variational multi-scale formulation (VMS), features three major contributions: (1) a simple computational geometry-based re-initialization approach, which maintains excellent signed distance property on unstructured meshes, re-constructs an explicit representation of gas-metal interface from the level set, and facilitates the treatment of the multiple laser reflections during keyhole evolution in AM processes; (2) a fully coupled VMS formulation for thermal multi-phase governing equations, including Navier-Stokes, level set convection, and thermodynamics with melting, solidification, evaporation, and interfacial force models; and (3) a three-level recursive preconditioning technique to enhance the robustness of linear solvers. We first compare the geometry-based re-initialization with the Eikonal partial differential equation (PDE)-based approach on two benchmark problems on level set convection and bubble dynamics. The comparison shows the geometry-based approach attains equivalent and even better performance on key criteria than the PDE-based counterpart. We then apply the developed framework to simulate two AM experiments, which Argonne National Laboratory has recently conducted using in-situ high-speed, high-energy x-ray imaging. The proposed framework's accuracy is assessed by thoroughly comparing the simulated results against experimental measurements on various quantities. We also report important quantities that experiments can not measure to show the modeling capability.

A semi-analytical thermal modelling approach for multilaser powder bed fusion

Yang Yang[1] **and Can Ayas**[1*]

[1] Faculty of Mechanical, Maritime and Material Engineering, Delft University of Technology, Mekelweg 2, 2628 CD, Delft, The Netherlands, c.ayas@tudelft.nl

Key Words: Multi-laser, Cost efficient thermal modelling, Scanning strategy, Semi-analytical model.

The low production speed and limited part size are two critical limitations in laser powder bed fusion (LPBF) of metallic components. On the other hand, multilaser powder bed fusion e.g.[1] has been effective in improving productivity and reducing production time, thus allowing for the manufacturing of larger components. It is well known that the multi-laser powder bed fusion process parameters and the laser scanning strategy have a substantial effect on the temperature transients of the part and henceforth on the degree of deformations and residual stresses. LBPF process models can be instrumental in determining the optimal process parameters.

Ideally, the process model needs to be both accurate and computationally tractable. However, the LBPF process is a complicated multi-physics problem to analyse, which also requires a due account for the geometry of the part to be built. Since the thermal expansion/contraction cycles are critical for the part distortion and residual stress field, it is crucial to determine the temperature transients accurately. The steep temperature gradients are present due to the local nature of heating. The laser beams have a spot radius typically of tens of micrometres, while the parts produced have dimensions typically of tens of millimetres. This mismatch of characteristic length scales becomes prohibitive when a numerical scheme such as finite elements is used to solve the governing heat equation. This would require fine spatial and temporal discretisation to resolve the steep temperature gradients, which in turn requires an excessive number of elements and time steps, resulting in very high computational costs.

A semi-analytical thermal model [2] of the multi-laser powder bed fusion process is presented, which determines the temperature evolution by representing the moving laser spot with a finite number of point heat sources. The solution of the thermal problem is constructed from the superposition of analytical solutions for point sources and complementary numerical/analytical fields to impose the boundary conditions. The unique property of the formulation is that the numerical discretisation of the problem domain is decoupled from the steep gradients in the temperature field associated with localised laser heat input.

Key Words: Rapid solidification; additive manufacturing

A major challenge with classical rapid solidification processing, such as melt spinning or pulse laser melting, is the difficulty in producing three-dimensional parts that retain the novel microstructures produced by rapid solidification. However, with the advent of additive manufacturing (AM) it is possible to create objects with rapidly solidified microstructures. The interfacial velocities and temperature gradients found during AM are much different than in traditional castings, with high solidification rates (10^{-3} - 1 m/s) and high thermal gradients (10^5-10^7 K/m). These solidification and cooling rates can lead to ultra-fine microstructures and unexpected metastable phase formation. The presence of large thermal stresses can lead to hot-cracking and plastic deformation of the as-solidified metal alloy. Moreover, the highly directional nature of the solidification process yields very unusual grain structures. All these issues can have a major effect on the resulting properties of the part. Following an introduction of the challenges of predicting AM microstructures, a discussion of the development of grain structure during powder bed AM of stainless steel 316L will be given. The large-scale phase field simulations of the morphological development of grains illustrate the complicated interaction between interfacial mobility anisotropy, weld pool shape, laser scan strategy and multiple powder layers on the resulting grain morphology. A phase field model that is designed for the interfacial velocities characteristic of AM and allows the nonequilibrium properties of interfaces to be tuned for a chosen alloy system will also be discussed.

An Extended Cellular Automaton Finite Volume Method for Process-Microstructure Simulation of Wire-based Additive Manufacturing

Yanping Lian[1*], Feiyu Xiong[1]

[1] Beijing Institute of Technology, Beijing 100081 China, yanping.lian@bit.edu.cn

Key Words: *Additive Manufacturing, Thermal Fluid Flow, Grain Structure, Numerical Modelling*

Metallic additive manufacturing (AM) possesses tremendous advantages in building geometrically complex parts with tailorable microstructures and properties and thus has found potential to revolutionize the global part manufacturing landscape. Among many metallic AM technologies, wire-based AM is breaking size and weight barriers for heavy industries. However, due to many AM process parameters, trial-and-error experimentation for analysis and optimization is time-consuming and costly. Therefore, it is critical to developing individualized numerical methods for further understanding AM's process-structure relationship to guide and expedite the parameter optimization. This work proposes an extended cellular automaton finite volume method to simulate the wire-based melt pool, solidification, and grain evolutions during the wire-based AM. In the proposed method, we adopt the finite volume method for the thermal-fluid flow simulation, the cellular automaton for the grain nucleation and growth within the mushy zone, and the Motte Carlo Potts model for the grain coarsening in the heat-affected zone. The advantage of the proposed method over other integrated methods is that it resolves the grain coarsening in the heat-affected zone and considers the crystallographic orientation of the unmelted grains or nucleated grains in the Motte Carlo Potts model. We conducted a set of numerical examples of Ti6Al4V wire to demonstrate the proposed method's accuracy and capability and provide insights into the melting and solidification processes. A good agreement with experimental data in the literature shows that the proposed method is a valuable tool to simulate and analyze the process-microstructure relationship of the wire-based additive manufacturing process.

Key Words: *Solidification Microstructure, Metal Additive Manufacturing, Recrystallization*

ABSTRACT

Metal additive manufacturing (MAM) have been rapidly developed for almost twenty years, however, the mechanism of nucleation (or crystal introducing) mechanism in MAM processes has been a long-term unsolved problem. Only limited works shed lights on this area from experimental and simulation point of view, and no universal solution has yet been addressed. This work discusses the importance of nucleation in MAM and investigates the crystal introducing mechanism in laser wire DED fabricated Ti6Al4V. Besides the term 'nucleation', this phenomenon is generalized as the 'crystal introducing' because the crystals with different crystal orientations can be introduced to the printed domain without going through a nucleation scenario (growth from a successful critical nucleus in liquid phase). To investigate the crystal introducing mechanism in laser wire DED fabricated Ti6Al4V, a sample matrix under different fabrication conditions is fabricated under three hypothesises (stress, heat accumulation and the solid-state transformation). It is approved from different perspectives that the recrystallization is the main reason for the crystal introducing, and it is a comprehensive result of the residual stress and reheating. A more detailed investigation was carried out at the early stage of a recrystalized grain at the grain boundary of the prior beta grain boundary. The formation tendency of the recrystalized grain indicates its strong dependency on the grain boundary alpha phase. This study also approved that this type of recrystallization does not necessarily take place at the prior beta grain boundary area, even without grain boundaries, a single beta crystal can still be recrystalized into smaller grains under the fabrication condition of laser wire DED. Some of these recrystalized grains are able to participate into the following competitive grain growth, thus influence the solidification microstructure in the fabricated part dramatically.

Data-driven analysis of microstructure-property linkages for additively manufactured materials

Key Words: *Microstructure Characterisation and Reconstruction, AM, Ti-Al6-V4, Fatigue*

Additive manufacturing (AM) has huge potential to manufacture optimal structures but is still in the state of ongoing research and development as small variations in the process can have a major impact on the resultant material in terms of volume defects, surface characteristics or microstructure. These, in turn, influence the mechanical properties. In order to exploit the full potential of AM, understanding the underlying process-structure-property linkages is crucial.
In this contribution, we propose a general framework to computationally investigate the microstructure-property relationships. As experiments alone are prohibitively expensive, computational augmentation is employed. This allows to create the large data bases for the adopted data-driven approaches which enable profound correlations. The proposed general framework consists of four steps:

1. two-dimensional microstructure images (from experiment or synthetic) are characterised by translation-invariant descriptors;
2. three-dimensional microstructures are reconstructed from the descriptors [1];
3. numerical simulations are conducted to compute mechanical properties [2];
4. descriptors and properties are correlated. Descriptors of further microstructures are identified for improving the quality of the correlation or for finding optimal properties. Back to step 2.

This framework is applied and presented for two examples: The optimisation with regard to fatigue performance of microstructures with variable position and morphology of hard precipitates and a fixed crystal microstructure as well as the prediction of fatigue performance of Ti-6Al-4V specimens based on CT scans of their pore microstructure. The results show the framework's capability of identifying an optimal structure for desired properties as well as the capability of predicting the properties for a given, unseen structure.

Heat exchangers (HXs) have been widely used in various equipment and machines. It is very significant to implement structural design to improve heat exchange performance (HXP) and save energy accordingly. Topology optimization has been a popular methodology for this goal [1]. Moreover, additive manufacturing (AM) has been applied to practical fabrication of the complex HXs. In this work, the structural design and AM of cross-flow HXs are studied. A unit-based optimization framework is proposed to design the channel configuration in order to maximize heat exchange performance and meanwhile control pressure drop between the fluid inlet and outlet. A gradient-based optimization methodology is used. During the channel configuration evolution, for an intermediate design, filtering technique is adopted specifically to avoid sharp features and improve AM printability. Moreover, printability evaluation is considered for the optimized structures with respect to metal laser powder bed fusion (LPBF) AM process. Residual deformation is considered as an index to evaluate the printability. The entire HX containing the optimized thin-walled channels is modelled, and its residual deformation is predicted through sequential layer-by-layer simulation [2]. If weak printability is detected, some re-design work is added to the unit-based design. Finally, a new design can be achieved as the compromising solution that leads to better HXP (e.g., nearly 50% increase), limited pressure drop and good printability with respect to the LPBF AM process.

Development of a Process Simulator thru GPU Acceleration and Adaptive Remeshing for Studying Porosity Variation in Laser Power Bed Fusion

Albert C. To[1*], Alaa Olleak[1] and Florian Dugast[1]

[1] Department of Mechanical Engineering and Materials Science, University of Pittsburgh, Pittsburgh, PA 15261, albertto@pitt.edu

Key Words: *Additive Manufacturing, Process Simulation, Adaptive Remeshing, GPU*

As-built parts manufactured by laser powder bed fusion (L-PBF) suffer from the reduced fatigue strength due to the large pores caused by lack of fusion (lof) between scan lines. The lof porosity mainly depends on the melt pool size, which may change based on the geometrical features and scanning strategies, and process parameters. Unlike experimental approaches, process simulations (e.g. finite element analysis) can help deliver insights on the melt pool morphology, by which lof porosity can be estimated. Finite element method (FEM) based modeling approaches considering moving heat source can help predict the layer-by-layer lof porosity formation; however, they are computationally expensive as it requires large number of simulation steps, fine mesh to represent the powder layer and laser beam, and powerful computational resources.

This work presents the development of a computational framework to overcome the computational expense of simulating the L-PBF process. First, a matrix-free approach is used instead of the widely used global-matrix method utilizing high performance computing through (Graphical Processing Units) GPUs [1]. Second, an adaptive remeshing technique that significantly reduces the number of elements and nodes representing parts during the process is used. The power of using the matrix-free technique along with adaptive remeshing is demonstrated by performing detailed thermal process simulation for a relatively larger part using the moving heat source and true powder layer thickness where it was found that computational time could be reduced by at least 99%. In addition, two different parts and multiple scanning strategies are considered to show the influence of the scanning strategies and geometrical features (e.g. overhangs). The predictions are validated by experimental results.

Key Words: *Additive Manufacturing; Multiphysics modeling; SPH; Adaptive; Refinement; Coarsening.*

Numerical simulation of Additive Manufacturing (AM) processes using the Smoothed particle Hydrodynamics (SPH) method is usually performed with uniform particle size. Despite many remarkable and promising results reported mainly in CFD applications (see in [1] and [2], for example), the use of spatially varying particle distributions in SPH AM simulation remains relatively unexplored. The authors of [3] laid the groundwork for modeling a multi-resolution AM simulation with SPH; nevertheless, their approach does not permit particle coarsening and is presented for 2D applications with only one level of refinement.

In this work, we develop a highly-efficient 3D SPH simulation framework for AM applications by enabling both particle refinement and coarsening procedures. To further enhance the computational performance of the method, an optimized neighbor-search algorithm for non-uniform particle size scenarios is also implemented into the in-house code. The robustness and efficiency of this approach are demonstrated by running the computer program on a single CPU core to simulate a multi-track Laser Powder Bed Fusion (LPBF) process. The present multiphysics modeling approach accounts for all relevant physical phenomena and melt-pool dynamics encountered in LPBF, such as material phase change, surface tension forces, recoil pressure, and Marangoni effects.

As a result of this SPH development, the fully adaptive 3D LPBF simulation can save more than 60% of the computational cost and is completed in a fraction of the runtime required for a similar single-resolution case. To achieve more efficient AM simulations using SPH, the development proposed in this work needs to be coupled with parallel computing algorithms so an additively manufactured part as simple as 1x1x1 mm can be modeled within a reasonable calculation time. Such an achievement would provide deeper insights into the underlying physics of the AM process of interest and allow for process monitoring and optimization.

Key Words: Additive Manufacturing, Directed Energy Deposition, Residual stress, Extended One-dimensional Model

Residual stresses in directed energy deposition (DED) depend on the temperature history. Although fast numerical approaches have been developed for the thermal analysis [1], the efficient computation of residual stresses remains challenging, as 3D/2D finite elements (FE) method involves meshing along the layer thickness and/or height, which implies a very fine discretization along the print direction to avoid conditioning issues [2]. An alternative approach is proposed to significantly reduce computation time while capturing complex stress fields in the part. Since DED basically consists in adding a thin layer to the existing part, we propose an enriched 1D model immersed in the 3D space. Both layer thickness and height are internal parameters independent of the mesh size, which in turn can be coarser along the print direction. At each material point, 4 displacement vectors are introduced leading to 12 DOFs. Thus, kinematic conditions between a layer and its 4 neighbors (i.e., right, left, top and bottom) may be simply written. The model derivation through the virtual work principle will be broached, as well as a linear thermo-elastic behavior. In addition, several analytic calculations of multilayer structures representing both single and multi-track scanning strategies will be derived and used as exact references to validate a more general numerical implementation of the model. Future works will include the derivation of an elasto-plastic behavior and numerical optimization of the process parameters [3] based on the proposed 1D extended model.

High-Fidelity Multi-Physics Modeling of Process-Structure-Property Relationships in Additive Manufacturing

Wentao Yan

Department of Mechanical Engineering, National University of Singapore, Singapore, 117575,
mpeyanw@nus.edu.sg, https://blog.nus.edu.sg/yanwt/

Key Words: *Additive Manufacturing, Multiphysics Modeling, Process-Structure-Property Relationships, High-Fidelity*

The wide adoption of additive manufacturing is hindered by the lack of comprehensive understanding of process-structure-property relationships. To this end, we have developed and seamlessly integrated a series of high-fidelity multi-physics models, including: physically-informed heat source models to shed light into manufacturing processes, microstructures, and mechanical properties [1]. Specifically, multiphase flow models using the coupled computational fluid dynamics (CFD) and discrete element method (DEM) simulate the powder spreading procedure and powder spattering and denudation phenomena in the powder melting procedure [2,3]. The powder melting model is powerful to reproduce the molten pool flow and relevant defects (e.g., lack-of-fusion and keyhole pores) by incorporating the major physical factors, especially the physically-informed heat source models, i.e., for an electron beam from micro-scale simulations of electron-atom interactions and for a laser incorporating multi-reflection and Fresnel absorption. The microstructure evolutions at both the grain- and dendrite- scales are modelled using the phase field [4] and cellular automaton methods [5]. The mechanical properties and thermal stresses are simulated using the crystal plasticity finite element (FE) model, which incorporates the realistic geometry (rough surfaces and voids), temperature profiles and microstructures [6]. These models have proven to be useful in revealing the physical mechanisms, which have been validated against experiments.

The extreme scale ranges in both space and time involved in laser powder bed fusion (LPBF) process as well as the geometrical complexity of the parts produced by means of LPBF technology call for flexible numerical approaches. Therefore, immersed boundary methods seem to offer a valid alternative to the traditional mesh-conforming finite element method. In the present contribution, we adopt two methods of such a family of numerical methods to investigate some of the most challenging problems in LPBF simulations, namely the influence of process-induced defects and the spatio-temporal scale range.

A well established immersed methodology is the so-called Finite Cell Method (FCM), which has already been applied successfully in several contexts, from structural analysis to biomedical applications since it allows to easily deal with complex shape components otherwise non trivial or even impossible to mesh in a conform manner. In our contribution, we present the application of FCM in the context of high-fidelity thermal and thermomechanical analyses of LPBF processes. The proposed numerical scheme [1] is first validated with respect to experimental measurements of residual stresses taken from the literature and then applied to investigate the influence of lack-of-fusion defects on the melt pool morphology, providing a valuable tool to further understand the complex *process-structure-property* relationship in LPBF components.

Another promising immersed boundary technique is the two-level method, where the local and global scales of the problem are solved on two separate meshes weakly coupled in a way similar to a fat-boundary approach. To address the spatio-temporal scale range issues that burden LPBF processes simulations, we have combined the two-level formulation with a multi-rate time integration based on a predictor-corrector type scheme. Exploiting the peculiarity of the two-level method, we are able to treat differently - in a smooth and simple workflow - local and global effects in both the spatial and the temporal scale. We will present first the results of a thorough numerical verification of the proposed methodology on two- and three-dimensional problems, and then its application to a more challenging LPBF simulation, where we have observed a computational speed-up by a factor 4 compared to the spatial version of the two-level method with a monolithic time integration scheme.

Abstract:
One of the larger growing fields within additive manufacturing is the selective laser sintering process of semi-crystalline polymer powders. The powder particles are sintered together in local areas due the energy coming from a laser. This method allows for rapid manufacturing of complex parts, which are well suited for prototyping. The overall accuracy and stability of the process, along with part properties, are highly dependent on the involved process parameters. A better control of these parameters, will therefore lead to further optimization of the process. The current paper proposes a numerical modelling approach, for understanding the impact of major input parameters on the meso-scale thermal conditions, during the process. The model makes it possible, to analyze the influence of the laser-related input parameters, in relation to the temperature distribution and size of melt pool geometry, during the process. For validation, the predicted melt pool geometry is compared with the single-line track data found experimentally, where the melt pool geometry, can be compared to the numerical measurements by light optical microscopy and an in-situ infrared camera. Furthermore, an adaptive mesh refinement technique is developed and integrated in the model, which allows for modelling the thermal conditions of real-size parts within an acceptable computational time wtih a good agreement with experimental observations. The numerical approach is utilized through both costume code in Matlab, and by the commercial available software package COMSOL Multiphysics.

Multi-scale Analysis for Microstructure Evolution in Powder Bed Fusion Process

Sukeharu Nomoto[1*] and Makoto Watanabe[1]

[1] National Institute for Materials Science, 305-0047, NOMOTO.Sukeharu@nims.go.jp

Key Words: *Powder Bed Fusion, Rapid Solidification, Non-equilibrium, Multi-phase filed Method, Lattice Boltzmann Method, Microstructure Evolution*

It is well known that microstructure in powder bed fusion process of additive manufacturing consists of grain and sub-grain, of which scales are 10-100μm and 0.1-1μm orders, respectively. This peculiarity is caused by its rapid solidification conditions of high cooling rate and high temperature gradient, 10^5-10^7K/s and 10^6-10^8K/m, respectively. Sub-grains in a grain have a common crystalline direction. Their boundary shows segregation of solidification. Consequently, numerical sub-grain microstructure evolution is considered to lead to prediction of mechanical property and design for heat treatment condition in this process.

In this study, a non-equilibrium multi-phase field method, based on finite dissipation model, coupled with CALPHAD database was developed for rapid solidification in a nine components system of an engineering Ni alloy **[1]**. Columnar solidification microstructure evolutions were performed at various set of cooling rate and temperature gradient under an interface velocity, 0.1m/s. It was showed that the sub-grain (cell) space decreased as the cooling rate increased. This tendency was more agreement with the experimental measurement than multi-phase filed method using local equilibrium condition in the solidified interface.

The previous heat condition for the sub-grain microstructure evolution is decided by process conditions, laser beam power, beam radius, traveling velocity, *etc*. A new numerical methodology of grain scale microstructure evolution in powder bed fusion process was proposed by coupling with three-dimensional multi-phase filed for melting and solidification, lattice Boltzmann phase field method for gas and liquid flows with free surface and thermal calculation with moving heat source. By using this method, melting of powder bed, flow in melt pool and grain scale solidification were simulated. Sub-grain microstructure evolutions were demonstrated at cooling conditions in different positions in melt pool by week coupling with the grain scale simulation.

Key Words: *Additive manufacturing, Crystal plasticity, 316L stainless steel, Residual stress, Dislocation dynamics*

In metal additive manufacturing (AM) process, large temperature gradient and repeated heating-cooling cycles induce residual stress in as-built parts, which may lead to distortion and even cracks. A computational framework is developed to study how microscale residual stresses form and evolve in AM parts, including a thermal-fluid flow model, a phase field model for grain growth and a crystal plasticity finite element model (CPFEM). The framework is calibrated and validated by comparing with experimental results of two 316L stainless steel samples fabricated by different sets of process parameters. The generation, evolution and distribution of residual stress at grain scale are investigated by simulations. In addition, a continuous dislocation dynamics model is incorporated. The thermal history and deformation of grains extracted from CPFEM simulations are applied to dislocation model to study the formation and evolution of the dislocation structure during AM process. This work provides insights into the formation and evolution of residual stress at grain scale, and helps to further understand the formation of dislocation networks in AM material.

Nanoparticle-enhanced absorptivity of copper during laser powder bed fusion

Ottman Tertuliano[3], Philip DePond[1], David Doan[1], Manyalibo Matthews[2], Wendy Gu[1], Wei Cai[1], and Adrian Lew[1*]

Key Words: *Laser powder bed fusion, Copper absorptivity, In situ calorimetry, Nanoparticle decorated powder, Thermal models*

Laser powder bed fusion (LPBF) of pure copper for thermal and electrical applications is hampered by its low near-infrared absorptivity and high thermal diffusivity. These material properties make it very difficult to localize the thermal energy needed to produce high density 3D printed parts. Modification of metal powders via nanoparticle additives is a promising approach to increasing absorptivity, but the effect of nanoparticles on absorptivity and melting behavior during LPBF is not well understood. In this study, we developed an in situ calorimetry system to measure effective absorptivity during LPBF on copper substrates. We decorated copper substrates using three nanoparticle systems (CuS, TiB2, multilayer graphene flakes) and demonstrated an enhanced absorptivity of the decorated substrates relative to pure copper. Graphene nanoflakes resulted in the highest improved absorption relative to pure copper from 0.09 to 0.48, due to their stability at high laser scanning powers. A thermomechanical model with convective heat transfer provided confidence in the measurements by reproducing the experimental melt pool traces. Full 3D cylindrical prints demonstrated an improvement in relative density of the copper-graphene powder prints (in the range of 0.930–0.992), relative to that of as-purchased copper powder prints (in the range of 0.854–0.972). This work provides a fundamental study of nanoparticle-enabled LPBF of highly reflective metals and demonstrates a viable route for expanding the library of reliably printable metals. These results have been published in [1].

Key Words: *Additive Manufacturing, Particle damper, Laser powder bed fusion, Discrete element method.*

Particle damping is an effective passive method of vibration suppression. The remarkable advantages of particle damper, such as insensitivity to ambient temperature and availability at a wide range of frequencies, make it available for various applications [1]. However, a limitation for applying traditional particle damper is that an additional installation space is needed.

Additive manufacturing (AM), especially laser powder bed fusion (LPBF) technology, has been gradually adopted as an efficient method for fabricating multifunctional structures. By utilizing LPBF, a new integrated particle damper can be produced by deliberately leaving unfused powder inside the structure, named additively manufactured particle damper (AMPD). It has unique merits, such as neither mass nor cost is increased, and no additional space is required [2]. However, the damping mechanism and performance of AMPD are still unclear, more research is needed.

This research focuses on experimentally and numerically investigating the damping mechanism and performance of AMPD at a wide frequency range. A numerical simulation approach based on the discrete element method (DEM) was developed to predict the damping performance of a particle damper. To reduce the computational cost, a multi-unit particle damper (MUPD) was introduced, simulation model with only one unit cell was built A series of particle dampers of 316 L stainless steel with different numbers and sizes of unit cells were produced using LPBF. Experiments were carried out and compared with simulation results.

As a result, the numerical results of the proposed simulation model agreed well with experimental data, verifying that the proposed numerical method and simulation model are reasonable for analyzing the damping performance of additively manufactured multi-unit particle damper (AM-MUPD). The damping mechanism of AM-MUPD was clear by the numerical analysis. And the influence of different cavity numbers and sizes on the damping performance of AM-MUPDs was investigated experimentally.

Key Words: Coupled problems, Free surfaces, Incompressible flow with solidification, Marangoni effects, Operator splitting, Multi-grids, Laser surface melting

We present a multi-physics, multi-domain, model for the approximation of the coupled system formed by the temperature-dependent Navier-Stokes equations with free surfaces. The main applications are the industrial processes of shallow laser surface melting (SLSM), and laser polishing of thin surfaces. The goal is to simulate the effect of the free surface and the internal motion of the melting pool on the surface roughness during laser polishing.

We consider incompressible flow equations with solidification, by using a classical Boussinesq approximation. We add thermal effects with an enthalpy-based convection-diffusion heat equation, and we model the laser source through physically-consistent boundary conditions. We incorporate surface tension effects and Marangoni forces on the free surface to drive internal motion in the liquid metal.

The numerical method incorporates all the physical phenomena within an operator splitting strategy. Diffusion processes, such as heat diffusion, and the Stokes model are solved with a finite element method, while the transport phenomena are solved with a characteristics method. The volume-of-fluid approach is used to track the free surfaces between the (liquid or solidified) metal and the ambient air.

The numerical space discretization relies on a multi-grid, multi-domain, approach, relying on an unstructured finite element mesh and a structured Cartesian grid. Local mesh refinement is incorporated in order to accurately track the free surfaces. The multi-domain approach allows to solve the flow equations only in a neighborhood of the melting pool and the heat equation in a larger domain.

The numerical model is benchmark through some numerical experiments. In particular, we investigate the sensitivity of Marangoni effects and the influence of the free surface on the liquid metal during the re-melting process.

Key Words: *Additive manufacturing, segregation, Al-Si eutectic alloy, phase-field simulation*

Aluminum alloys are widely used for lightweight structures such as aerospace and automobiles owing to their low density. Further weight reduction is possible by utilizing topology optimization to minimize the volume of materials to achieve the required strength. Recently, additive manufacturing (AM) technologies have attracted much attention because they enable us to build complicated geometry 3-D parts with little difficulty. Moreover, the AM processes, in particular, powder bed fusion (PBF), can control material properties significantly via the control of solidification conditions and resultant microstructure, through the control of process parameter, such as power, diameter, and scanning speed of the laser beam. However, the relationship between solidification conditions and microstructures remains to be elucidated even for Al-Si alloys, which are commonly used in AM. In the previous study [1], the solidification of Al-Si alloys during PBF processes was simulated using the Multi-phase field (MPF) method, and only columnar crystalline grains appeared in the solidified microstructure. However, equiaxed crystalline grains were observed in the additively manufactured Al-Si alloy [2]. In this study, a heterogeneous nucleation mechanism was introduced to MPF simulation, and its effect on the solidification microstructure was investigated. In the actual PBF process, re-solidification occurs after the substrate is lowered by layer thickness. Therefore, the formation of re-solidified microstructures need to be investigated.

MPF simulation of an Al-10 mass % Si alloy was performed using microstructure evolution simulation software MICRESS for a region of 50 μm × 100 μm using a 50 × 100 grids domain with a one-dimensional temperature field. The system was cooled down with a cooling rate of 10^4 K/s. Then, the solidified model was re-melted at a heating rate of 10^4 K s^{-1}. After melting up to 75 μm of the material from the upper edge i.e., 75% of the simulation domain, the re-melted model was re-solidified at the cooling rate of 10^4 K s^{-1}, which is the same as the rate of the initial solidification.

In the simulation of solidification with heterogeneous nucleation, columnar α-Al crystals approximately 5 μm wide and elongated along the growth direction were formed. Then, eutectic regions comprised of α-Al and Si phases were formed between the dendritic columnar crystals and between their secondary arms. It is suggested that α-Al grains nucleated at the liquid/Si interface trigger further nucleation of Si crystal at the liquid/α-Al interface. The solidified Al-Si alloy model was heated until the melting of 75 μm from the upper edge. The solidified microstructure melted inhomogeneously: columnar dendrites of the α-Al phase were fully melted, whereas the regions of eutectic-microstructure were melted partially and the crystalline diamond-Si particles remained. Subsequently, in the re-solidification process, dendrites grew isotopically near the fusion line, and equiaxed grains of ~20 μm in diameter were formed.

Key Words: *additive manufacturing, segregation, precipitation, superalloy, phase-field method*

Ni-based superalloys have been mainly produced by casting followed by solution treatment for homogenization of solute distribution and subsequent aging treatment for the precipitation hardening. On the other hand, additive manufacturing (AM) technologies are emerging as a new process for fabricating parts various materials including made of superalloys. Generally, rapid solidification is effective to avoid the solute segregation. Solidification by AM, in particular, powder bed fusion (PBF) process is characterized by the high cooling rate of around 1 million K/s. Such a rapid cooling is expected to result in a uniform solute distribution. It might allow the aging treatment without homogenization pre-treatment. However, resent studies have revealed the very fine submicron-sized cellular structures are formed in Ni-based superalloys fabricated by PBF process. Solute segregations between the cellular crystals are expected to affect the precipitation behaviour of gamma-prime phase.

In the present study, phase field simulations have been conducted to investigate the precipitation of γ'-phase from the solute concentration field generated by rapid solidification as initial condition. The multiphase-field method was applied to the simulation of microstructural evolution in directional solidification under various solidification conditions focusing on the solute segregation. A composition consisting of five major elements of Inconel738LC alloy, to which the application of AM is highly demanded, was selected as the model alloy composition. Gibbs free energies of liquid phases and FCC phase were evaluated by using thermodynamic database TCNI-9. The mobility database MOBNI5 were employed for the mobilities of elements. Initially, cellular structure with intercellular micro-segregation was generated by simulating directional solidification under a condition with cooling rate of 10^6 K/s, solidification rate of 10^{-1} m/s, temperature gradient of 10^7 K/m, which is a typical solidification condition in PBF process. Aluminium and titanium, which are γ' forming elements, segregated while other elements depleted at the intercellular region. In the subsequent aging at 1050°C, the growth of γ' precipitates and the relaxation of the segregation occurred simultaneously, and there was no significant influence of the segregation on the precipitates. In the case of aging at 850°C, aluminium depletion occurred at the intercellular region while titanium segregation remained before precipitation. The composition of the γ'-precipitates at the intercellular region are different from that in the intracellular regions. If the difference is negligible, the aging treatment without homogenization pre-treatment is applicable to the alloy fabricated by PBF. If the difference is not negligible, the segregation needs to be eliminated by solution treatment before ageing treatment. These results are to be validated by experimental analysis, and the values of parameters used tentatively are to be tuned so that the segregation predicted by this approach will be useful for optimizing AM process and designing novel alloys more suitable for AM process.

Key Words: *Additive manufacturing, segregation, superalloy, phase-field simulation*

Superalloys are used for jet engines and gas turbine because of their excellent heat resistance and high-pressure resistance. Additive manufacturing (AM) is emerging as a new process for various materials including superalloys since it is expected not only to lower the costs by reducing the number of parts to be assembled but also to improve performance by controlling microstructures. Solidification microstructures formed by AM have characteristics different from those in cast counterparts, such as the absence of secondary dendrite arms, fine primary arm, and so on. For solidification of superalloys, it is important to control segregation as well as grain structure because it would cause cracking. The Scheil-Gulliver simulation is commonly used for predicting segregation in solidification under the imaginary extreme condition [1]. However, a more sophisticated method to predict the segregation taking the influences of the geometrical factors and kinetic factors is demanded. Phase-field method is suitable for this purpose. In the present study, the multiphase-field method was applied to the simulation of microstructural evolution in directional solidification under various solidification conditions with a special focus on the solute segregation.

Hastelloy-X was selected as the base of model alloys since it is one of the superalloys applicable to AM. Gibbs free energies of liquid phases and FCC phase were evaluated by using thermodynamic database TCNI-9. The mobility database MOBNI5 were employed for the mobilities of elements. For the mobility of solid/liquid phase change, the value for IN718 in a literature was used. Simulations were conducted under various solidification conditions in the range of $R = 10^{6}$~10^{-1} m/s and $G = 10^{3}$~10^{7} K/m with randomly orientated seed crystals finely distributed on the bottom edge of simulation box.

Geometrical grain selection occurred, and grains oriented to <100> in the solidification direction grew preferentially in all the cases. The widths of the columnar grains are comparable but larger than the experimentally observed one. The interdendritic segregation became more significant as the cooling rate increased, and was strongest for the case of the highest cooling rate of 10^{6} K/s ($R = 10^{-1}$ m/s, $G = 10^{7}$ K/m) which is a typical solidification condition in powder-bed fusion type AM process. The melting point for the composition of the interdendritic part with the segregation was much lower than that for the alloy composition, which would cause liquation cracking associated with residual stress in the AM process. Also, the composition was preferred for the precipitation of brittle intermetallic phases which need to be eliminated by solution treatment for after fabrication by AM process. These results are to be validated by experimental analysis, and the values of parameters used tentatively are to be tuned so that the segregation predicted by this approach will be useful for optimizing AM process and designing novel alloys more suitable for AM process.

This work was supported by Council for Science, Technology and Innovation (CSTI), Cross-ministerial Strategic Innovation Promotion Program (SIP), “Materials Integration for revolutionary design system of structural materials” (Funding agency: JST) and partly by JSPS-KAKENHI.

Key Words: *Wire and arc additive manufacturing, Young-Laplace equation, Bead topology, Electro-mechanical power source*

Metal additive manufacturing (MAM) has grown, in recent years, very strong interest in academic researches as well as industrial applications. Among MAM processes, wire and arc additive manufacturing (WAAM) became very popular through its advantages in manufacturing of medium and large-scale components [1].

The present work is carried out in the framework of the WAS project [2] which deals with WAAM process. The process relies on an automatized welding process in which a part is built by successively deposed metal bead.

We propose a physically based bead topology model using the equilibrium between the hydrostatic pressure and the capillarity force, under two-dimensional hypothesis. This equilibrium can be described by the Young-Laplace equation. The proposed model can also estimate a bead topology which is deposed on a complex support such as an inclined or a curved one. To do so, the Young equation is used to balance the forces at tri-phase point [3]. Moreover, a deposed melted metal volume is necessary for the bead topology model. By modelling a gas metal arc welding (GMAW) power source system [4], the volume can be estimated and be used as a physical parameter for the bead topology model. Combining the topology and the power source models, the coupling model allows to simulate the topology of a part made of deposed beads via WAAM. In addition to the modelling, experimental profiles of the beads are used to validate the model.

ACKNOWLEDGEMENTS

The authors would like to thank to the industrial partners of the AFH (Additive Factory Hub) consortium for their supports in the framework of the WAS project. This project is as well supported by the French government's aid in the framework of PIA (Programme d'Investissement d'Avenir) for Institut de Recherche Technologique SystemX.

Key Words: *Liquid metal jetting, multiphase flows, computational fluid dynamics, nozzle design.*

The Drop-on-Demand liquid metal jetting process is recognised as a relatively fast and affordable printing method for the 3D Additive Manufacturing industry. It is characterized by ejecting a sequence of droplets from a microfluidic nozzle attached to the end of a pump where the metal is molten and gets pushed down under pressure gradient, generated via magnetohydrodynamic or pneumatic forcing. Given the quality constraint of the final product, jetting speed is limited by the relaxation time of oscillating meniscus (liquid-gas interface) at the tip of the nozzle due to dynamic interplay between surface tension and the imposed pressure gradient. High-speed printing requires designing a nozzle that reduces the relaxation time without compromising the desired droplet size, shape, and speed. We present physics-based nozzle design rules to achieve high-throughput and stable jetting in drop-on-demand liquid metal 3D printing. The design rules are based on scaling laws that capture the change of meniscus oscillation relaxation time with geometric characteristics of the nozzle's inner profile. These characteristics include volume, cross-sectional area, and inner surface area of the nozzle. Using boundary layer theory for the simplified geometry, we show that the relaxation time of the meniscus is inversely proportional to the total inner surface area to the volume of the nozzle. High-fidelity multiphase flow simulations run in OpenFOAM verify this scaling. We use these laws to explore several design concepts with parameterized classes of shapes that reduce the meniscus relaxation time while preserving desired droplet specs. Finally, we show that for various nozzle profile concepts, the optimal performance can be achieved by increasing the ratio of the circumferential surface area to the bulk volume to the extent that is allowable by manufacturing constraints.

Key Words: *Variable lattice density optimization, Powder bed fusion, Thermal distortion, Inherent strain method, Thermo-mechanical analysis*

Reduction of the thermal distortion caused by metal additive manufacturing's fabrication process is an important issue. Considering the problem of forming an object with lattice structures inside it to reduce the thermal distortion, we perform lattice density distribution optimization and experimental verification. Assuming a cube with a sphere void as the base lattice shape, the optimization problem is constructed based on the recurrent formula inherent method, the sensitivity analysis, and the method of moving asymptotes (MMA). The design variable is the representative size of the lattice geometry. The lattice's effective stiffness tensor is derived using the homogenization method, and the approximation function between the design variable and the effective properties is derived. The inherent strain value is calibrated using some test pieces with uniform lattice densities. Herein, the optimization is performed for quasi-two-dimensional and three-dimensional examples. Its experimental verification is finally performed by selective later melting fabrication and clearance measurement caused by warping deformation.

Simulating Steering-Induced Defects in Composites Additive Manufacturing

Yi Wang[1*], Sarthak Mahapatra[1], Jonathan P.-H. Belnoue[1], Dmitry S. Ivanov[1] and Stephen R. Hallett[1]

[1] University of Bristol, Queens Road, Bristol, BS8 1QU, UK. yi.wang@bristol.ac.uk

Key Words: *Process Simulation, Composites, Automated Fibre Placement, Defects*

Additive manufacturing techniques for composites, such as automated tape laying (ATL) and automated fibre placement (AFP) have become more mainstream in the aerospace industry over the last 20 years. These techniques rely on the use of a computer-aided machine which places the composite prepreg layer-by-layer according to the part geometry and layup design. It has been shown that these methods allow reduced waste and improved work efficiency with an overall 70 to 85% reduction of the layup time. However, one of their key limitations is the generation of manufacture-induced defects that can result in up to 35% degradation of the structural performance of the finished part. With the increasing complexity and size of structures in which composites are used, the traditional trial-and-error approach to mitigate these defects becomes extremely costly. This explain the recent increase in scientific publications aiming at modelling and simulating the ATL/AFP deposition process, with a view to replacing the large numbers of physical trials that manufacturing process development currently requires.

However, in many cases, current state of the art simulation is limited to one single value for each process parameters. This is, in part, due to lack of constitutive models able to capture the complex mechanical behaviour of composite prepregs that show viscoelastic features and strongly depends on temperature and deformation rate. In the present contribution, a multi-body modelling platform of the AFP process is presented. Previous work on characterisation and modelling of composite prepregs [1,2] forms one of the building blocks of the current framework, which is shown to be able to capture final tape quality resulting from different combinations of temperature and deformation rate. This paper gives further insights into the understanding of automated manufacturing of composites and lays the ground for process optimization, defect mitigation and overall improvement of part quality.

Simulation of keyhole dynamics and keyhole pore formation during metal additive manufacturing

Lu Wang[1*] **and Wentao Yan1**[1]

[1] Department of Mechanical Engineering, National University of Singapore, 117575, Singapore, wang lu@u.nus.edu (https://blog.nus.edu.sg/yanwt/home/)

Key Words: Keyhole pore, Additive manufacturing, Multiphysics thermal-fluid flow model, Molten pool flow, Low ambient pressure

Metal additive manufacturing has gained extensive attention from research institutes and companies to fabricate intricate parts and functionally graded materials. However, the porosity of the as-built part deteriorates the mechanical property and even hinders the further application of metal additive manufacturing. Particularly, the mechanisms of keyhole pores associated with the keyhole fluctuation are not fully understood. To reveal the mechanisms of the keyhole pores formation, we developed a multiphysics thermal-fluid flow model [1, 2] incorporating heat transfer, liquid flow, metal evaporation, Marangoni effect, and Darcy's law to simulate the keyhole dynamics and keyhole pore formation process, and the results are validated with the in-situ X-ray images.

The geometry features of the simulated keyhole and melting pool showed a good agreement with the experimental observation by ultrahigh-speed X-ray imaging in Argonne National Lab. To understand the physical mechanisms of keyhole fluctuation, the laser energy distribution on the keyhole surface, and the driving forces on the keyhole surface were further analyzed.

The simulation results present the keyhole pore formation stages: instant bubble formation due to the keyhole instability and motion of the instant bubble when it pins on the solidification front. The simulation results indicate that the unevenly distributed recoil pressure on the keyhole surface is an important factor for keyhole collapse and penetration. Furthermore, comparing the keyhole pore formation under different laser scanning speeds shows that the keyhole pore is sensitive to the manufacturing parameters. The keyhole fluctuation features and energy absorptivity variation on the rear keyhole wall could be metrics to evaluate the likelihood of the keyhole pore formation.

Key Words: *heat evolution, space-time, melt pool shapes, validation*

The direct numerical simulation of metal additive manufacturing processes such as laser-based powder bed fusion of metals (PBF-LB/M) is challenging due to the vast differences in spatial and temporal scales. Classical approaches based on locally refined finite elements combined with time-stepping schemes can only address the spatial multi-scale nature and provide only limited scaling potential for massively parallel computations. We address these shortcomings in a space-time Galerkin framework where the finite element interpolation also includes the temporal direction. In this setting, we construct four-dimensional meshes that are locally refined towards the laser spot and allow for varying temporal accuracy depending on the position in space. By splitting the mesh into conforming time slabs, we recover a stepwise solution to solve the space-time problem locally in time at this slab; additionally, we can choose time-slab sizes significantly larger than classical time-stepping schemes. We use a continuous Galerkin-Petrov formulation of the nonlinear heat equation with an apparent heat capacity model to account for the phase change [1].

We validate our approach by computing the AMB2018-02 benchmark, where we obtain an excellent agreement with the measured melt pool shape. Further, we explore the range of validity of the approach by computing a range of Gaussian to doughnut shaped laser profiles by calibrating only towards one setting and checking the computational results against corresponding experiments [2]. This systematic study gives insight to when the convection based model turns invalid.

Finally, we apply the findings to a patch level and give an outlook on upscaling the computational model which offers the possibility for time and space parallel computations of heat evolutions in laser-based powder bed fusion processes.

[1] National Institute for Materials Science, 1-2-1 Sengen, Tsukuba, Ibaraki, 305-0047, Japan, BULGAREVICH.Dmitry@nims.go.jp

Key Words: *Selective Laser Melting, Digital Twinning, Crystal Plasticity Simulations*

Crystal plasticity (CP) simulation of selective laser melting (SLM) metal materials is a challenge due to typically very complex shape and size of various anisotropically distributed chemical/microstructure phases governed by laser heat gradients and scanning patterns. Even image segmentation of such phases is a nontrivial but important task for structure/property relation analysis [1,2]. To conduct accurately the CP simulations of material's mechanical properties, the sophisticated synthetic volume (SV) reconstruction is required. An example of complete workflow pipeline for tensile test CP simulations with statistically accurate distributions of necessary parameters in SV from SEM and EBSD data will be presented for SLM samples of Inconel 738LC. The data pipeline and simulations were mainly conducted with Dream3D and DAMASK open-source packages [3,4].

In SV reconstruction, the statistical distributions of microstructure object sizes for each phase, several shape parameters for each microstructure type, and grain crystallographic orientations were taken into account. Each step in the pipeline, including parameters for CP modelling, can be fine-tuned to achieve suitable correspondence between experimental and simulated results. Then, various 3D stress/strain maps (equivalent von Mises stress/strain, et. cet.) could be hopefully used to locate/analyse the possible mechanical damage initiation centres and explained by comparing with grain crystal orientation and Schmid's factor maps.

Key Words: deployable structures, shell element, orientation optimization, Turing pattern, 4D printing

Recently, programmed 3D shape or 4D printing is emerging as a new paradigm in additive manufacturing and receiving much attention since it provides printed structures with the ability to transform into various shapes or to alternate functions or stiffness over time according to environmental stimuli.

This study focuses on a computational design method for shape-morphing inflatable structures for 4D printing. Inflatable structures can easily change their shapes into 3D surfaces with a simple pressure input. These inflatable structures have been employed in science and engineering to enable the design of physical systems in diverse fields, including soft robots, airbags, and temporary shelters.

The present study addresses the programming of inflatable structures by designing the distribution of material orientations of their surface membrane. By prescribing the orientations, we can program the local deformation of the material and thus control their global shapes. For this purpose, we integrate a full physical simulation of the inflatable structures using the nonlinear shell finite element method in the inner loop of a gradient-based optimization algorithm that continuously modifies the distribution of the material orientations to improve design objectives. The material orientation in this optimization is a locally varying axial distribution where an orthotropic elastic material model including orientation tensor in its constitutive equation is utilized. The anisotropic membranes with the optimized distribution of the material orientations are fabricated by digital light processing (DLP) 3D printing[1]. Each pixel in the 3D printing, however, is limited to isotropic material. Therefore, the distribution of anisotropy is converted to a discretized texture pattern that induces an anisotropic deformation of the surface membrane. The anisotropic reaction-diffusion equations are then utilized to generate the space-filling discretized Turing pattern texture. Anisotropic diffusion coefficients in the reaction-diffusion equations are determined using the orientation tensors derived from the orientation optimization. The present method directly produces fabrication instruction or CAD data of the anisotropic materials.

In this contribution, several examples of the optimized shape-morphing inflatable structures are provided to illustrate the performance of the proposed design method.

Abstract: Lattices produced through additive manufacturing are gaining momentum in bio-inspired material science research for designing lightweight and high-strength meta-materials for various engineering applications. Among many categories of well-ordered porous architectures, the mathematically-derived sheet-based triply periodic minimal surface (TPMS) porous structures are perceived to yield superior mechanical functionality due to their ease-to-manipulate topological features, stretching-dominated deformation mode, and uniform stress distribution capabilities [1, 2]. This paper aims to evaluate the influence of relative density grading and hybridization on the quasi-static four-point bend (4PB) flexural properties of AlSi10Mg sheet-based TPMS latticed beams fabricated through the laser powder-bed fusion process. 4PB elastic-plastic simulations are performed to compare with the experimental findings. Sheet-based TPMS porous architectures such as the f-rhombic dodecahedron (FRD), primitive (P), and diamond (D) with an average relative density of 20% and 4PB specimens with tessellation of $12\times4\times4$ unit-cells are considered in this work, based on the preliminary investigation on the effective elastic properties of the sheet-based TPMS cubic lattices. Generally, the specific flexural stress-strain curves obtained from the 4PB simulations agreed well with experiments, and the equivalent plastic strain contour plots showed to reliably predict possible failure trajectories per experimental observations of the 4PB sheet-based TPMS latticed beams. Specifically, varying the through-thickness relative density of the 4PB sheet-based TPMS latticed beams, e.g., bilinearly, the final failure of the specimen is retarded due to deflection of the propagated cracks in-contrast to observations made with the uniform specimens. Also, relative density gradation improved the specific flexural strength of the sheet-based TPMS latticed beams. Hybridization of the sheet-based TPMS latticed beams is inspired by the constant bending moment region in the load-span of the 4PB beam specimens and results reveal an improvement in the specific flexural stiffness (using the P-D-FRD-D-P configuration). More importantly, hybridization mitigated shear-band failure through which the uniform and relative density graded specimens failed.

Parametric Visco-Hyperelastic Constitutive Modeling of Functionally Graded Polymers Manufactured via Grayscale Masked Stereolithography

Iman Valizadeh[1*] **and Oliver Weeger**[2]

[2] Technical University of Darmstadt, Dolivostr. 15, Darmstadt, 64293, Hessen, Germany, weeger@cps.tu-darmstadt.de

Key Words: Additive manufacturing, stereolithography, visco-hyperelasticity, functionally graded materials, photopolymerization, 3D printing

Grayscale masked stereolithography (MSLA) 3D printing enables the fabrication of graded structures from a single material, overcoming the limitation of vat-photopolymerization methods to a single material. Two main parameters affecting the curing of the resin in the stereolithography manufacturing method are the exposure time per layer and the intensity of the ultraviolet (UV) light in terms of the grayscale value of the mask, which have a significant influence on the resulting material properties. In our earlier work, the dependency of the resulting material properties on the parameters of the grayscale MSLA process was investigated and a grayscale-dependent hyperelastic material model was formulated [1]. Here, the concept of grayscale MSLA is extended by combining the two easily adjustable parameters exposure time and grayscale value into a single parameter, which we call the grayscale exposure. The advantage of expressing the degree of cure in terms of grayscale exposure is not only the reduction of design parameters from two to one, but also the fact that the printing time can be reduced through correlation of exposure time and grayscale. Then, a parametric visco-hyperelastic constitutive model is formulated for the strain rate-dependent behavior of the resulting material in finite deformations, which depends on the grayscale exposure. Hyperbolic tangent functions are utilized to express the material constants for different grayscale exposure. Furthermore, the grayscale exposure values are verified through a comparison of different couples of grayscale and exposure time. Finally, the constitutive model is validated with further experiments, showing a good agreement with experimental results.

Key Words: Shape memory polymers, Two-way shape memory effect, Constitutive model, 4D printing

Soft materials capable of autonomously changing their shape with an on-demand and reversible response are considered very interesting in the fields of soft actuators and robotics [1]. To this aim, thermally-triggered two-way shape memory polymers possess two promising features, known as one-way and two-way shape memory effect (SME). The one-way SME is a non-reversible feature, describing the ability of the material to recover its original "permanent" shape from a deformed "temporary" one when heated. Contrarily, the two-way SME is a reversible feature, representing material capability to reversibly switch between two distinguished configurations under repeated cooling-heating cycles.
The present work proposes a new phenomenological constitutive model to describe the one-way SME and the two-way SME under stress-driven and stress-free conditions in semicrystalline networks, starting from the formulation presented in [2]. Specifically, we focus on the synthesis and characterization of semicrystalline networks based on poly(ε-caprolactone) crosslinked by a sol-gel approach or by photocrosslinking. Experimental results are used to formulate, calibrate, and validate the model. The proposed model is shown to be useful for the design and development of autonomous actuation systems. To this purpose, the effect of the macromolecular architecture and the employed thermo-mechanical parameters is investigated. Preliminary results concerning the additive manufacturing of these systems as well as the actuation of metamaterial structures will be presented and discussed.

Macroscopic modelling and simulation of powder bed-based additive manufacturing of polymers

Dominic Soldner[1*], **Paul Steinmann**[1] **and Julia Mergheim**[1]

[1] Institute of Applied Mechanics (LTM) Friedrich-Alexander-Universität Erlangen-Nürnberg, Egerlandstr. 5 91058 Erlangen, Germany, dominic.soldner@fau.de (https://www.ltm.tf.fau.de/)

Key Words: Simulation, Selective Laser Sintering, Polymers, Crystallization

In powder bed-based additive manufacturing (AM) complex part geometries can be built in a layer-by-layer fashion using locally restricted melting of powdered material. For Selective Laser Sintering (SLS) of polymers this is achieved in a process that can be grouped into three stages: (i) the pre-heating stage where the build chamber is heated up to a desired process temperature, (ii) successive layer deposition and melting and (iii) the cooling stage. The melting is accomplished by means of the energy provided by a laser beam. Further, in contrast to powder bed-based AM of metals, solidification of the molten material occurs not immediately after melting. Molten and powder material rest side by side after the melting process. Throughout the process, non-isothermal crystallization activities are then responsible for solidification which can occur not only in stage (iii) but also during the second process stage as shown e.g. in [2]. In order to model this behaviour a Nakamura model for crystallization is extended to allow for a re-melting as it occurs in SLS [3] and integrated into a verified and validated numerical tool [2]. Since macroscopic modelling and simulation of these manufacturing processes can rapidly lead to computational expensive models, adaptivity in both the spatial and temporal regime are necessary to reduce the potentially high computational cost [1]. This includes the possibility of sub-time stepping, i.e. the separation of the temporal integration domain and corresponding fields into regions that may be integrated with different time-step sizes. This allows to employ small time-step sizes only where they are needed [3]. Further, a thermo-mechanical coupling approach is used for the prediction of the temperature, crystallization and displacement fields on a macroscopic scale.

Key Words: *thermo-mechanical model, part-scale model, flash heating, selective thermoplastic electrophotographic process*

Additive manufacturing (AM) is a breakthrough approach to industries, potentially relieving the limitation when producing complex geometries with traditional manufacturing processes. Selective thermoplastic electrophotographic process (STEP) is a brand-new AM process proposed by Evolve additive solutions Inc Solutions, Inc. The STEP process works based on layer-wise manufacturing by fusing 2D layers produced by electrophotography onto a 3D bulk structure. The principle of the 2D to 3D deposition process in STEP is through heating up both the incoming 2D layer and the bulk material and then applying pressure to fuse the 2D layer onto the already-built component. This deposition module in STEP is known as transfusion. With the two core modules, electrophotographic, and transfusion, STEP could create a fully dense and multi-material part [1], and the developers hope, it could be an alternative to injection molding.
In the present work we develop the first numerical model for the STEP process. It is a part-scale thermo-mechanical finite element model based on the flash heating (FH) [2] method in the commercial software package ABAQUS. FH is a part-scale method, originally developed to solve thermal problems in laser-based AM processes, without truly resolving the interaction between the heat source and the bulk material, but instead uniformly distributing the input energy on the recently-activated meta-layer. Both the part material, as well as the support material in the STEP machine are considered. The thermal and mechanical predictions are compared with relevant experimental measurements for validation purposes. A comprehensive manufacturing parametric study is also presented. This modelling approach will potentially pave the way for making a robust digital twin of the STEP process, that later could be integrated in the STEP process itself, serving as a feedback source for real-time correction of the input process parameters for achieving a close to defect-free end-product.

Additive Manufacturing (AM) technology is very attractive forming approach for fabricating products by laminating molten materials. Currently, AM technology is being used not only in the industrial filed but also in various fields such as the medical field based on various research and development activities. However, since it is difficult to control the fabricating process perfectly comparing to conventional existing forming methods, complexity and randomness in the mechanical properties and shape will be observed in the products. In particular, Fused Deposition Modelling (FDM) Method used in this study is a method of creating components by laminating molten resin under small pressure, which will result in a heterogeneous microstructure. Geometrical randomness in this heterogeneous microstructure will have an influence on the apparent mechanical properties, and therefore, it is necessary to be considered in design of such products.

For this problem, the results of stochastic homogenization analysis of components fabricated by FDM method have been reported[1]. Also, in response to this result, the results of an analysis using a model that considers the random field (RF) of the microstructure have been reported[2]. However, in this report, the RF of the microstructure considers the RF inside a certain specimen. In fact, the spatial autocorrelation, mean and standard deviation in the RF will be different from them of each specimen, so they need to be considered.

In this study, multiscale probability analysis considering a difference of probabilistic property in each specimen. Specifically, RF using the moving window method[3], Monte Carlo (MC) simulation, and multiscale stochastic analysis based on the homogenization method were used to calculate the apparent elastic modulus and compare it with the experiment to investigate the effect of considering the RF of each specimen.

In this presentation, a procedure for creating an analytical model that considers the characteristics of the RF obtained from specimen observation is introduced, and numerical results are shown for discussion on the effectiveness of considering RF for each specimen.

Acknowlegment : This work was supported by JSPS KAKENHI Grant Number 20H02035.

Accelerated constrained shape optimization

Long Chen[1*], Kai-Uwe Bletzinger[1], and Ihar Antonau[1]

{long.chen, kub, ihar.antonau}@tum.de

Key Words: Constrained shape optimization, gradient-based optimization, Nesterov's Accelerated Gradient

High-fidelity shape optimization based on Finite Element mesh is inherent large-scale, in which millions of design variables may be considered in industrial applications. Gradient-based optimization is almost the only viable solution strategy. In many practical circumstances, a number of constraints need to be considered, such as cost, material limits, manufacturability, and usability. Needless to say, it is a genuine engineering work how practical constraints can be modeled so that a gradient-based optimization can be applied. Motivated by these applications and inspired by singular value decomposition, a gradient descent akin method (GDAM) has been developed for solving constrained optimization problems. At each iteration, a search direction is computed using a linear combination of the negative and normalized objective and constraint gradient. While the principled idea behind GDAM is similar to that of gradient descent, we show its connection to the classical logarithmic barrier method and argue that it may be considered a first-order interior-point method. Vanilla implementation of GDAM has demonstrated its potential in solving large-scale shape optimization problems. However, a large number of iterations may still be needed for difficult problems. In this work, we present an accelerated version of GDAM for constrained shape optimizations based on Nesterov's Accelerated Gradient (NAG). NAG is an optimal method in terms of oracle complexity for unconstrained minimizations. Its convergence rate $o(1/k^2)$, with k as the iteration number, excels the gradient descent method with a rate of $o(1/k)$. In this contribution, we present an implementation how NAG can be applied to GDAM (denoted as GDAM + NAG) and show computational results. In common benchmark tests, GDAM + NAG achieves 10x faster convergence rate compared to GDAM. Finally, we show a large-scale constrained shape optimization, where the iteration number is reduced from approx. 200 to 20. Our results strongly suggest the practical relevance of the present algorithm.

Key Words: CAD-Free parameterization, Adaptive Vertex Morphing, Shape Optimization, Relaxed Gradient Projection

There are various methods to parameterize the design space for large shape optimization problems. One of them is Vertex Morphing (VM) [1]. It is a node-based shape parameterization technique that directly uses the surface nodes of the Finite Element model as a design parameters. Vertex morphing filters the shape update and sensitivities to keep the design surface smooth and continuous. Nowadays, the Vertex Morphing technique is a successful shape parameterization technique used in academia and industry. [2] [3]

In our work, we present an extended version of Vertex Morphing, "Adaptive Vertex Morphing" (AVM). The main idea of the AVM method is to separate two roles of the filtering radius and extend the design possibility of Vertex Morphing parameterization. On the one hand, the radius should be sufficiently big to filter sensitivities and generate smooth shape updates. On the other hand, the size of the radius is an additional design parameter, which controls the final design. Adaptive Vertex Morphing computes respective radii for each node every optimization iteration, based on the local mesh size, to ensure that the filtering is successful during the optimization process. Additionally, a user can set up local or global radius values to "constraint" the shape update modes to a specific wavelength and better control the final design.

Key Words: *Multiphysics Problems, CHT, Discrete Adjoint, Industrial Applications*

Power electronics as used in electric cars derate their performance above certain temperatures, if not sufficiently cooled. Residential gas/hydrogen boilers require careful design for optimal efficiency and minimal emissions. In both application fields, a free-shape optimized design of the heat exchanger and surrounding components promises substantial performance gains that are relevant to fulfil the regulator's and customer demands.

The discrete adjoint method using automatic differentiation to compute shape gradients for CHT problems [1] will be outlined together with an efficient way to evaluate a pin-shape performance, essential in many heat exchangers, using streamwise periodic flow. Validation of the discrete adjoint gradient against finite differences shows excellent agreement for all tested configurations. These sensitivities are used in a shape optimization process using FFD-boxes and competing objective functions (system pressure drop and surface temperature or similar). Beyond shape optimization, the value of accurate shape sensitivities on its own for industry will be highlighted, as suitable shape parameterization with an effective enforcement of geometry constraints are not a trivial step.

In addition to the results of steady state simulations, validated gradients for a simple unsteady CHT setup using the discrete adjoint method are implemented and available. The unsteady multizone adjoint requires additional care [2] in terms of implementation and especially objective function definition.

The implementations that were used to produce the results are available to the public via the open-source C++ code SU2 [3]. The contributions are embedded in a code framework that encourages collaboration between academia and industry to extend features and usability.

This work aims at optimizing a large-scale wind tunnel model conceived to investigate the aerodynamic and acoustic performance of distributed electrical propulsion (DEP) on aircraft wings in high lift conditions. The aim of the optimization process is to obtain the best possible improvements in Noise and Aerodynamic performance by modifying the propellers' layout of the Wing-DEP wind tunnel model. A multi-objective, multi-point design approach is adopted based on evolutionary computing. The robustness of the obtained solution set is also investigated. The research work is carried out in the framework of VENUS EU-funded project GA N. 886019.

Basic Examinations of Non-parametric Shape Optimization Problems and their Applications to Real-World Problems

Hideyuki Azegami[1*]

[1] Department of Research, Nagoya Industrial Science Research Institute, Yotuya Noa 2F, 1-13 Yotuyadori, Chikusa-ku, Nagoya City, Aichi Prefecture 464-0819, Japan, azegami.h@gmail.com

Key Words: Shape Optimization, Topology optimization, Function Space, Fréchet Derivative, Gradient Method, Newton Method

In this talk, the "Large-scale problems" in the scope of the minisymposium "Shape Optimization for Large-Scale Problems" is involved in the definition of design variables using functions, which formulations are referred as distributed parameter systems or non-parametric systems. Since the degrees of freedom of the functions are infinity, there is a possibility which becomes "Large-scale problems".

The target problems discussed in this talk are topology optimization problems of density variation type and shape optimization problems of domain variation type. The key point in the formulations is how to select the vector spaces for the design variables. Thanks to the functional analysis, we can define appropriate function spaces for the two types of problems, and evaluate the Fréchet derivatives of cost functions with respective to arbitrary variations of the design variables. To solve the problems, we can consider gradient methods and Newton methods defined in the function spaces of the design variables[1].

The aim of this talk is to introduce the aforementioned theories briefly, and shows the results of the basic examinations using computer programs developed by means of a programing language by the finite element method, FreeFEM. Especially, how the convergence phenomena reflect the theoretical results regarding regularity of boundary in the numerical results is discussed using concrete problems.

In addition, the applicability of these optimization frameworks to real-world problems are then illustrated through several examples that were due to the students and researchers from the presenter's laboratory.

Data-Driven Analysis, Design, and Optimization in Fluids Engineering

Koji Shimoyama[1*]

[1] Institute of Fluid Science, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai 980-8577, Japan, shimoyama@tohoku.ac.jp (http://www.ifs.tohoku.ac.jp/shimoyama/)

Key Words: Fluids Engineering, Data Science, Bayesian Optimization, Surrogate Modeling, Shape Optimization, Topology Optimization

Fluids engineering involves complex nonlinear physics due to viscosity, shock wave, turbulence, etc. It is essential but costly to analyze the physics of fluids for engineering applications, such as vehicle and turbomachinery. Nowadays, data science is expected to leverage practical applications of fluids engineering for various purposes, mainly design and optimization.

Design and optimization ask designers to analyze many design candidates to be evaluated, one of which is expected to be optimal. Data science can replace expensive analysis with an inexpensive estimation of the quality of interest (*e.g.*, performance) for any unknown design candidate based on the database available for the existing design candidates. Hence, design science helps the designers to find the optimal design candidate efficiently. However, the inexpensive estimation based on data science may disagree with true evaluation by expensive analysis, which affects the fidelity of the optimized design.

Our research group has been working on Bayesian optimization, which aims to find the optimal design under uncertainty in the estimation based on data science in a data-driven way, as an effective analysis and design tool. Bayesian optimization is promising to balance exploration and exploitation, i.e., fidelity and quality of the optimal design within a realistic database size.

This talk will present our original learning-based surrogate modeling, which can model any nonlinear response in the quality of interest to be estimated for Bayesian optimization [1]. Moreover, this talk will present some applications of Bayesian optimization to real-world design, *e.g.*, shape optimization of a low-boom supersonic transport [2] and topology optimization of a lattice-structured heat sink [3].

Key Words: Discrete Adjoints, Multiphysics, MDO, Algorithmic Differentiation, Shape Optimization

The discrete adjoint approach to design offers a computationally inexpensive and precise way to obtain sensitivity information for optimization problems in Computational Fluid Dynamics [1] and related fields. For partitioned multiphysics problems, like fluid-structure interaction, conjugate heat transfer or even more complex combinations of different kinds of physics [2], the gradient of an objective function with respect to design parameters can analogously be derived from *coupled* discrete adjoint solutions, computed for each sub-discipline. The difficulty is, however, to capture and include their adjoint coupling terms, so-called cross derivatives or cross terms, that originate from the exchange of solution data between solvers during the primal simulation process.
In this talk, we will present a methodology [3] whereby adjoint solutions can be computed efficiently and in a way that is completely independent of the underlying physical sub-problems, the associated numerical solution methods, and the number and type of couplings between them. Furthermore, by applying the reverse mode of algorithmic differentiation to each discipline, and by using a specialized recording strategy, diagonal terms and cross terms can be evaluated individually, thereby allowing different solution methods for the generic coupled problem (for example block-Jacobi or block-Gauss-Seidel).
On the basis of an implementation in the open-source multiphysics simulation and design software SU2 [4], we demonstrate how the same algorithm can be applied for shape sensitivity analysis on multiphysics problems coming from heat transport (a pin-fin heat exchanger), from aerodynamics (a wing that deforms under flow tractions) or from propulsion (a turbine blade in high-temperature flow).

Higher-Order Shape Optimization Based on Variational Derivatives

Stephan Schmidt[1*]

[1] Humboldt University Berlin, Department of Mathematics, Unter den Linden 6, 10099 Berlin,
s.schmidt@hu-berlin.de

Key Words: Variational Shape Hessians, Adjoints and Material Derivatives, Shape Newton Schemes

A variational approach for higher order shape optimization based on the distributed formulation of the shape derivative is considered. Within this approach, the adjoint is used to eliminate material derivatives instead of partial derivatives, which leads to a very convenient way to derive a Newton scheme for shape optimization. In particular, this approach also allows an interpretation of the Sobolev gradient descent methods as an approximation of the shape Hessian when the perimeter is used as a regularizer.

The methodology quite naturally leads to a variational formulation to compute the 2nd order shape updates and opens the door to novel numerical schemes, not only in classical aerodynamic shape optimization, but also to construct particularly fast solvers for free surface flows and microfluids.

Large-Scale Industrial Shape Optimization Applications in Maritime Two-Phase Flows –Learning from the Adjoint–

Niklas Kühl[1]* **and Thomas Rung**

[1] Hamburg University of Technology, Institute for Fluid Dynamics and Ship Theory, Am Schwarzenberg-Campus 4, D-21075 Hamburg, Germany, niklas.kuehl@tuhh.de

Key Words: Adjoint-Based Shape Optimization, Computational Turbulent Maritime Two-Phase Flow

The presentation outlines strategies to advance gradient-based optimization methods based upon the continuous adjoint approach for CAD-free (non-parametrized) marine engineering shapes which are exposed to immiscible two-phase flows at very large Reynolds ($Re>10^8$) and Froude number ($Fn>0.35$). Issues addressed refer to the relevance of adjoint consistency, the preservation of industrial process capability and the computation of geometrically constraint shape gradients in compliance with the deformation of the mesh. It is seen that potential weaknesses revealed by an adjoint approach, e.g. when aiming at the development of closed analytical solutions or in conjunction with convergence problems, are often attributable to weaknesses of the primal flow model. To this end, a twist of the research question can lead to fruitful insights, which can significantly improve the numerical robustness and the accuracy of large scale practical applications. Contributions refer to the development of an efficient engineering Cahn-Hilliard (CH) Volume-of-Fluid (VoF) branch [1]. In line with analytical considerations for a model problem, a nonlinear Equation of State (EoS) is derived to relate an indicator function with the fluid properties. This allows for a robust and consistent adjoint two-phase formulation [2]. A second focus is put to improving adjoint turbulent flow models using mixing-length arguments to replace the frozen turbulence strategy [3] by an algebraic expression derived from the adjoint momentum equation in the logarithmic layer. Thirdly, an implicit surface metric approach is presented to simultaneously extract an inherently smooth shape gradient and mesh deformation from the same procedure. Moreover, attention is devoted to the compliance of the shape update with local and global geometrical constraints, i.e. constant volume or maximum outer dimensions. Finally, an adaptive floatation module is added to the gradient-based optimization procedure. Applications relate to maritime two-phase flows at the industrial level in full-scale.

Key Words: *Level-Set Method, Shape and Topology Optimization, Shape Sensitivity Analysis*

In 2019, ANSYS was the first software editor to deliver level-set based Topology Optimization (TO) [1]. This disruptive technology facilitates both the formulation and handling of several manufacturing and mechanical criteria that are commonly used in industry, thus expanding the applicability of TO for real-world applications. ANSYS is also delivering a real-time topology optimization engine based on GPU computing [3] that fits for early stage of the conception cycle when it comes to quickly sketch designs or explore different scenarios.

The watertight level-set description offers several advantages:
- Formulation of independent geometric criteria without relying on complicated filtering techniques. This is advantageous when several constraints need to be applied simultaneously to account for manufacturability: Minimum and Maximum Member Size, Pull-Out, Overhang, Center of Gravity, Moment of Inertia, Volume, etc.
- Requires no dedicated treatment in the construction of material interpolation schemes or the formulation of mechanical constraints such as eigenfrequencies, stress etc., which allows to combine them efficiently in the formulation of the optimization problem.
- Post-treatment of the TO results under minimal effort and maximal fidelity. Using SpaceClaim of ANSYS, the back-to-CAD process is user-friendly and nearly instantaneous, saving significant amount of work for the user. At the same time, since no interpretation step of densities is needed, the design validation process becomes quite straightforward.

Key Words: *wire arc additive manufacturing, reduced order modelling, model calibration*

Numerical simulations are essential in predicting the behavior of systems in many engineering fields and industrial sectors. The development of accurate virtual representations of actual physical products or processes (also known as digital twins) allows huge savings in cost and resources. In fact, digital twins would allow reducing the number of real, physical prototypes, tests, and experiments, thus also increasing the sustainability of production processes and products' lifetime. Standard numerical methods fail in providing real time simulations, especially for complex processes such as additive manufacturing applications.

This work aims to use a reduced order model for efficient wire arc additive manufacturing simulations, calibrations and real-time process control. Model reduction, e.g. the proper generalized decomposition [1,2] method, is a popular concept to decrease the computational effort. A new mapping approach [3] was applied to simulate a moving heat source with the proper generalized decomposition. Using this procedure even complex models can be simulated in real-time. The physical model is later on calibrated with the use of a stochastic model updating process and the reduced order model, leading to an optimized real-time simulation.

In this contribution, a proper generalized decomposition model for a bead-on-plate wire arc additive manufacturing is presented. It is also coupled with a stochastic model updating process identifying the heat source characteristics as well as the boundary conditions of the transient thermal problem, whereas the heat source shape is simulated using a Goldak heat source [4].

Towards Part-Scale Simulation of Metal Additive Manufacturing

Sebastian D. Proell[1], **Wolfgang A. Wall**[1] **and Christoph Meier**[1*]

[1] Institute for Computational Mechanics, Technical University of Munich, Boltzmannstraße 15, 85748, Garching b. München, Germany, christoph.anton.meier@tum.de, http://www.lnm.ed.tum.de

Key Words: Metal Additive Manufacturing, Part-Scale Simulation, Model Hierarchie

The strongly localized energy input prevalent in many metal additive manufacturing (AM) processes gives rise to large thermal distortions as well as high residual stresses, which in combination with residual porosity might even induce cracking of the part already during the production process. While predictive thermomechanical models would be highly desirable for systematic process and geometry optimization, the inherent multi-scale nature of these processes still prohibits part-scale simulations with geometrically resolved heat source path. Apart from computational efficiency, also the aspect of constitutive modeling, taking into account the strongly inhomogeneous and anisotropic evolution of microstructure and resulting material properties during the process, is critical for an accurate residual stress prediction.

In [1], the authors proposed a thermomechanical model for metal AM processes, in which the boundaries between powder, melt and solid phase are described as diffuse interfaces. The underlying constitutive law, derived via Voigt-type spatial homogenization, incorporates a reference strain term in rate form that allows to consistently represent a stress-free state for newly solidifying material at melt temperature. In our talk we will present strategies to formulate models of different detailedness on basis of this material law. It will be demonstrated how the resulting hierarchical modeling framework, embedded in a parallel code platform, can be employed to foster computationally efficient simulations on part-scale.

A second focus of the talk will lie on coupled microstructure and material modeling. In [2], a physics-based and data-supported microstructure model for Ti-6Al-4V has been proposed, which predicts metallurgical phase fractions in a continuum sense instead of resolving individual crystal structures. In our talk we will present a general procedure to utilize this computationally efficient microstructure model for thermomechanical part-scale simulations based on microstructure-informed material laws.

Full-scale reconstruction of kinematically enhanced constitutive modelling approach

Maria Onoufriou[1*], Jonathan P.-H. Belnoue[2] and Stephen R. Hallett[3]

Bristol Composites Institute (ACCIS), Advanced Composites Collaboration for Innovation and Science, University of Bristol, University Walk, Bristol BS8 1TR, UK

Key Words: *Consolidation, Process-Modelling, Kinematic enrichment, Variability*

Out of tolerance thickness variations and fibre path defects are a reccurring issue in thick tapered laminates, resulting in a knock-down in mechanical properties and potentially preventing composite manufacturing processes from becoming commercially viable. The industry currently relies on experience and trial and error to design and optimise manufacturing methods. Manufacturing trials however are very costly, and due to the complexity of modern composite systems and the large number of process parameters involved, understanding their impact on product quality presents a significant challenge. Hence, process models that can predict deformation and the final geometry of the part are becoming increasingly desirable.

Fibre path defects commonly form during consolidation prior to curing, because of the compliance of the uncured prepreg plies. Belnoue et al. presented a phenomenological analytical model which considers the transition from squeezing to bleeding flow, which was experimentally observed by Hubert and Poursatrip. The model was validated using experimental data and was implemented as a hyper-viscoelastic material model in a commercial finite element package, via a user material subroutine. It was later successfully used to investigate wrinkle formation mechanisms in lab-scale, industrially relevant geometries. However, the ply-by-ply approach utilised was computationally expensive, making it unlikely to be effective in the design phase of real-size components in industry. To tackle this issue, a kinematically enriched constitutive modelling approach, inspired by the work of Nguyen et al., was developed to predict the mechanical response of the prepreg ply stacks. This method was also implemented in a commercial finite element package via a user material subroutine. It was successfully used to predict wrinkles on the same geometries as the high-fidelity approach, which served to validate the new modelling framework. It was shown to be computationally efficient enough to be used as a design tool, allowing the evaluation of a wide range of geometrical configurations and process parameters. However, due to the "homogenisation" of the laminate which is employed by this method, detailed information on individual ply deformation and interaction was not captured.

In the present contribution, the effort to create a post-processing tool for the kinematically enhanced constitutive modelling approach in order to calculate and visualise the deformation of the individual plies is described. In the "homogenised" laminate simulation, the homogenised strains and strain rates are decomposed in the individual layers at every time increment. Therefore, it is possible for the strains of each layer to be extracted from the simulation and be mapped back onto a ply-by-ply geometry, making it possible for the deformation of the individual plies to be visualised in a much more computationally efficient way than the original high fidelity approach.

A study of a highly tapered thick composite laminate using the updated process is described. Initially, the consolidation of a baseline laminate was simulated using the "homogenised" modelling framework. During the simulation, the individual ply strains were extracted and used to calculate the ply displacements, which were then mapped back onto the initial ply-by-ply geometry. The new approach was then used to numerically study the effect of ply length and thickness variability on the quality of the finished part. The variability study results are discussed.

Multiscale Stochastic Analysis of Short Fiber Reinforced Composites Fabricated by the Injection Molding Considering Random Variation in Fiber Orientation Distribution

Seiya Yamamoto[1*] and Sei-ichiro Sakata[2]

[2] Kindai University, 3-4-1, Kowakae, Higashiosaka-city, Osaka, 577-8502, Japan, sakata@mech.kindai.ac.jp

Key Words: *Short fiber reinforced composite material, Fiber orientation distribution, X-ray computed tomography, Injection molding, Multiscale stochastic stress analysis*

Composite materials have superior specific strength and stiffness to homogeneous materials, but the material properties of composite materials are more complicated than those of single materials. For example, in fiber reinforced composites, variations in the component material properties and shape of microstructure have a complex effect on the apparent average properties of the composite. Therefore, the analysis of these effects has been reported in recent years [1].

The injection molding is one of the methods for forming process of short fiber reinforced composites. In the case injection molding using short fiber reinforced resin, fiber orientation and fiber shape can have a significant influence on the mechanical properties of molded products. Therefore, analysis that considering the properties of fibers in molded products have been reported [2]. In the previous reports, fiber orientation was assumed to be uniformly distributed random variable. However, in fact, the velocity distribution of the resin during filling and the cavity pressure are considered to affect the fiber orientation. In recent years, necessity of considering the fiber orientation in molded products has been recognized. However, in injection molding process, the properties were not identical for each molded product even in case of manufacturing same conditions, and inaccuracy was observed in the properties. Therefore, a stochastic analysis that takes these factors into account will be needed.

In this paper, injection molded specimens reinforced by short fibers were subjected to x-ray computed tomography (CT) to extract the three-dimensional fiber orientation distribution and fiber length, and a stochastic analysis was performed with a detailed numerical model reflecting the fiber characteristics of the short fiber reinforced composites. Referring to the measured fiber orientation angle and fiber length as stochastic parameters, stochastic homogenization and stochastic microscopic stress analysis are attempted using Monte Carlo (MC) simulation and multiscale analysis. Influences of random fiber orientation and fiber length variation on probabilistic characteristics of apparent mechanical properties and microscopic stresses of short fiber reinforced composites fabricated by injection molding are investigated.

Relation between Cutting Resistance and Crack Progress

Shiro Yoshida[1*] and Haruki Sato[2]

[1] SHONAN R&D, 3-19-17-402 Katase-Kaigan, Fujisawa 251-0035, JAPAN
E-mail:Sir_Yoshida@nifty.com (URL:http://sir-yoshida.com/ENGLISH/index.html)

E-mail:haruki-sato@n-s-k.co.jp (URL:https://www.n-s-k.co.jp/en/)

Key Words: *Cutting Resistance, Fracture Mechanics, Energy Release Rate, Trace Control, Robotic Arm*

When materials are cut with a knife, cutting resistance is a combination of (1) the reaction force (compressive) and (2) the frictional force between the knife edge and materials. When cutting resin material, the frictional force is dominant, and this mechanism is effectively used for cutting resin material for final shaping, under supersonic motion of Piezo electric material.

Meanwhile, in the field of fracture mechanics, crack progress possibility is evaluated by the stressintensity factor which is calculated from energy release rate around crack tip. In this context, a model of wedge shape rigid body and V-shaped groove is prepared for a reciprocating motion, in which the tangential friction force and the energy release rate are calculated. As a result of this calculation, the maximum energy release rate is obtained at the fore end of wedge motion.

In addition, thick plates with rectangular shape and arc shape are prepared, which are under the moving concentrated force and the gravity force. In this case, the element death function is used effectively for modelling the material vanish, and free fall of material due to the gravity force.

As an experimental validation, the experimental setup is prepared which is composed of robotic arm, and a supersonic cutter at the tip of the arm. Because this cutter penetrates the resin plate reciprocally at a high speed, the cutting resistance reduces significantly. For example, when a CFRP plate is continuously cut, the cutting resistance is reduced by 0.8(%), 1.5(%) and 3.8(%) for CFRP plate with the thickness of 0.5(mm), 1.0(mm) and 2.0(mm) respectively.

On the other hand, when the high speed supersonic cutter is activated, the temperature of the CFRP plates with the thickness of 0.5(mm), 1.0(mm) and 2.0(mm) rise up to 47(deg), 56(deg) and 84(deg) respectively. According to the earlier study, the tensile stiffness reduces 20(%) when the temperature of CFRP plate rises higher than 60(degC).

In other words, the high speed motion of the supersonic cutter causes the friction force between the cutter and the material, and at the same time, the temperature rise of the material. Further study is needed to clarify which mechanism is dominant for the reduction of the cutting resistance.

Development of atomistic simulation approach at diffusive time scale: an extension of cluster activation method to a continuous space

Ryo Yamada[1*] and Munekazu Ohno[2]

Division of Materials Science and Engineering, Faculty of Engineering, Hokkaido University,
Kita 13 Nishi 8, Kita-ku, Sapporo, Hokkaido 060-8628, Japan

Key Words: *Computer Simulation, Cluster Activation Method, Diffusive Time Scale, Solidification, Grain Growth, Grain Boundary Energy*

Atomistic behaviours in metals and alloys have been broadly investigated using molecular dynamics (MD) simulation. The applicability of MD simulation, however, is limited to a phenomenon at relatively small time scale because of its large computational burden. Recently, phase-field crystal (PFC) method has attracted lots of attentions because it can simulate atomistic behaviours at diffusive time scale [1]. The PFC method is versatile, and a variety of phenomena have been simulated, such as solidification, phase separation, and dislocation dynamics. However, it is basically a phenomenological approach, and a determination of input parameters in PFC method is not an easy task, which limits the applicability. In this work, a new atomistic simulation model is proposed, which is an extension of cluster activation method (CAM) [2, 3] from discrete to continuous spaces.

The original CAM is a method of statistical mechanics based on discrete lattice and can simulate solid-solid phase transformations, such as phase separation and ordering phenomena, by solving master equations that determine a time evolution of occupation probability of each atomic species at Bravais lattice points [2, 3]. By extending the method to a continuous space, which is called continuous CAM in this work, local atomic displacement, dislocation, grain boundary, and liquid phase can be represented using the occupation probability at each grid point which is finely distributed compared to the Bravais lattice spacing.

In this work, a variety of phenomena in a pure metal, such as solidification, nucleation of solid, and grain coarsening, was simulated using continuous CAM, where Lennard-Jones potential was employed for the simplicity. It was confirmed that a quite similar solidified microstructure with PFC method [4] can be produced by continuous CAM. Furthermore, the dependency of grain boundary energy on orientational mismatch between neighbouring grains fits well with the Read-Shockley equation for small misfit orientations. It is noteworthy that the continuous CAM employs interatomic interaction energies as main input parameters, which is in contrast with the fact that the PFC method needs phenomenological input parameters.

Key Words: *Nanoglass, Kinetic Monte Carlo Mesoscale Model, Eigenstrain, Grain size*

The most intrinsic way to improve the ductility of amorphous alloy is to impede the occurrences of shear bands. A new conceptual amorphous alloy, nanoglass (NG), which is composed of grains with glassy interfaces has gotten numerous attractions [1]. Simulations and experiments have also shown that NGs possess more ability to accommodate plastic deformation rather than metallic glasses (MGs) [2]. To investigate the effects of grain sizes on mechanical behaviors of NGs, we develop a kinetic Monte Carlo mesoscale model. In the proposed model, eigenstrains with Gaussian distribution are utilized to characterize the plastic strains of amorphous alloy. Moreover, a new softening mechanism which increases the standard deviations of eigenstrains in local shear transformation zones (STZ) according to the von-Mises plastic strain is proposed to decrease the activation barriers of STZs. Numerical results reveal that the ductilities of NGs are dominated by grain sizes. The flow stress in the stress-strain curve drops from severely to gradually by decreasing the grain size. In addition, the strain distribution of NGs transforms from a single shear band to homogenous deformation when the grain sizes decreased. Parametric study is also performed to investigate the effects of STZ modes on the mechanical behaviours of NGs.

The wave rectification devices can be applied in the areas of noise/vibration isolation, speech signal processing and medical ultrasonic imaging. Among them, a lot of research effort has been directed to the design and implementation of acoustic/elastic wave diodes[1,2]. In this study, we attempted to design a elastic wave diode on phononic crystal (PnC) plate with the properties of partial bandgap, which means wave would be blocked along some, but not all, directions. The genetic algorithm was adopted to carry out the topology optimization for the periodic hole structure on PnC plate to achieve the maximized partial band gap between two prescribed consecutive dispersive branches. COMSOL Multiphysics was adopted to analyze the band structure and the corresponding modes for all the unit cells. The dispersive waves can be classified as symmetric, antisymmetric Lamb wave and non-Lamb waves by the modal judgment. It was assumed the unit cell was arranged in square lattice. The genetic algorithm was employed to design the unit cell in order to achieve the maximization of full or partial band gaps under the constraint of filling ratio. The full wave calculation was used to calculate the wave transmission of the design structure on PnC plate as numerical verification. Experimental measurements were also carried out using ceramic piezoelectric transducer on the optimized periodic stucutre of the plate.

Key Words: *Visualization, Graph Neural Networks, Shape Memory Alloys, Microstructures, Crystal Variant, Ultra-large atomistic simulation, Taiwania3*

Shape Memory Alloys (SMAs) have outstanding mechanical and thermal coupling properties, and also exhibit unique properties when subjected to external environmental stimuli. These properties are dominated by microstructural evolution in nanoscale to mesoscale. This indicates that size effect is an issue in the corresponding atomistic simulations. In the current work, the service of supercomputer, Taiwania3, provided in NCHC in Taiwan, is used to enable ultra-large molecular dynamics (MD) simulation for the indentation process in NiTi SMAs. The model size is up to 250 nm * 250 nm * 210 nm, with 800 million atoms with the indentation depth of 9 nm.

While common post-processing methods, such as CNA[1] and PTM[2], can only distinguish the difference between austenite and martensite phases[3], a graph neural network based post-processing tool, MVIM-G, is used here to illustrate the martensite variants based on the phase transformation matrices. Thus, the detailed martensite microstructure, including the orthorhombic, monoclinic, and R phases in SMAs can be revealed in our model. In addition, for such the huge computational results, a decentralized computational approach is needed to investigate the microstructure evolutions during the indentation. The results are divided into thousands of independent pieces based on their spatial relationship, and are visualized by parallel rendering. The current work eliminates boundary and size effects in the MD results and is expected to be beneficial to the field of atomistic study and simulation.

Key Words: *gas mixture, interface, mechanical properties, confinement*

The increasing demand for higher CO_2 capture rates is driving novel and sustainable carbon removal processes. Membrane separation is one of the leading gas capture technologies. Carbon nanotubes (CNTs) [1], due to their unique properties, have been considered promising materials for developing the next generation of membranes [2,3]. A fundamental understanding of these systems' mechanical properties is essential for such applications. In this context, molecular dynamics (MD) simulations were carried out to investigate the mechanical properties of single-walled carbon nanotubes (SWCNTs) filled with CH_4/CO_2 gas mixture under tensile and compressive strain. Initially, armchair (*ar*) and zigzag (*zz*) SWCNTs were loaded with CO_2 and CH_4 using Grand Canonical Monte Carlo simulations. MD simulations were conducted at temperature and pressure of 313.15K and 200 atm, respectively. The nanotube's diameters range from approximately 8 to 19 Å, and the number of molecules varies according to the nanotube's size. For instance, the smaller *ar* nanotube has a 50:50 composition (CO_2:CH_4) and 0,0465 molecules/Å^3, while the largest has 72:28 composition and 0,0210 molecules/Å^3. In general, SWCNTs show a higher selectivity towards CO_2 than CH_4. Under tension, filled SWCNTs present a similar mechanical response to empty ones, regardless of the gas composition, chirality, and diameter. We also observed that the fillers do not affect the nanotubes' fracture and buckling patterns compared to the empty nanotubes. Overall, the filled SWCNTs' mechanical behavior is similar to the empty ones when under tension, showing a minor effect of the gas composition on their performance. Our results confirm carbon nanotubes as promising nanostructures for applications involving gas separation.

Key Words: *Mechanical Energy Storage, Diamane, Energy Density, Atomistic Simulation*

Electro-chemical batteries such as lithium-ion batteries (LIBs) that have a high energy and power density (from 150 to 300 Wh/kg) and long life-span are the most popular portable power supplier in our modern society[1-2]. Whereas, huge battery consumption not only causes excessive usage of minerals or strategic materials, but also lead to a large amount of end-of-life battery packs that threaten the environment and human health. At small scale, researchers have demonstrated that micro-/nanoscale biomedical robots are capable of carrying out a wide range of tasks including surgery, gene therapy, drug delivery, diagnosis, and other tasks that are hardly achievable traditionally. The practical engineering deployment of high-end electromechanical systems/devices, especially in harsh or biological environments (like outer space and deep-sea exploration, and biomedical applications), relies heavily on the development of a compact, stable, safe, sustainable, and high-energy density storage/power supply system.

This work proposed a spiral-based nanoscale mechanical energy storage scheme utilizing the newly synthesized two-dimensional (2D) diamane. Such spiral structure or 1D van der Waals structures have already been successfully fabricated based on different 2D nanostructures[3-4]. Atomistic simulations show that the diamane spiral can achieve a high theoretical gravimetric energy density of about 564 Wh/kg, about 14500 times of steel spring. Fundamental principles that dominate the limit of energy storage in the contact spiral and tracked spiral are discussed in detail with the corporation of theoretical models, respectively. The obtained insights suggest that the 2D vdW solids could be promising candidates to construct spiral structures with a high gravimetric energy density.

Keywords: Polymer Nanocomposite, Carbon nanothread, Random dispersion, Functionalized fillers, Mechanical Property, Molecular Dynamics Simulation

Summary of presentation

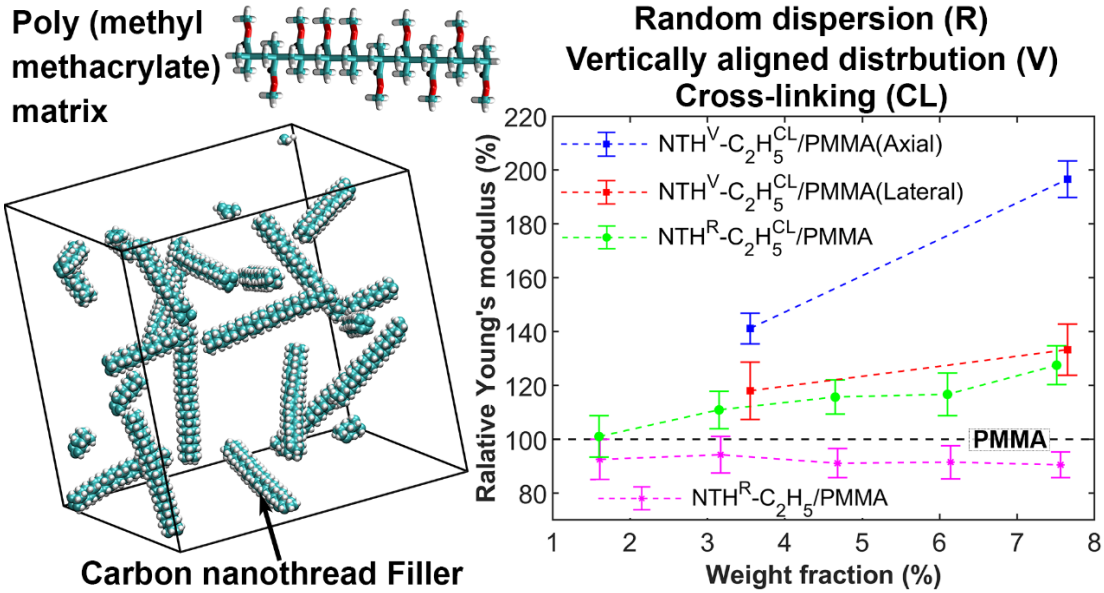
This work investigates the role of the random dispersed carbon nanothread (NTH) to reinforce poly(methyl methacrylate) (PMMA) nanocomposite. It is found the 1D fillers cause deterioration in the tensile properties due to the weak intermolecular force and enlarged continuous interphases within the PMMA matrix. The PMMA sample with 6.0% NTH is about 2.38±0.18 GPa (~19.1% smaller than PMMA). Further investigations reveal introducing functional groups (such as 13% –COOH functionalized NTH) can turn the negative impacts into positive enhancements. Furthermore, Young's modulus received up to 27.5% increment than pure PMMA for

the presence of covalent bonds between NTHs and PMMA chains due to the effective load-transfer. It is noteworthy that the enhancement is significantly influenced by the NTHs' length, weight fraction, functionalized and cross-linking percentage. In addition, the ideal samples with vertically aligned NTH fillers are further investigated and compared, the cross-linking can further enhance axial and lateral Young's modulus (up to 96.6% and 33.2% higher than PMMA). Specially, a high cross-linking percentage causes additional voids due to the inconsistent movement between cross-linked and non-cross-linked PMMA chains. These results signify the importance of dispersion and interfacial modification toward better mechanical performance, which should shed light on the design and fabrication of high-performance polymer nanocomposites.

Contribution

Low-dimensional nanostructures have been widely used as reinforcements for polymer nanocomposites. However, majority of studies have considered the samples containing a single or perfectly aligned nanofillers, which is usually not the case for the as-synthesized samples. Through molecular dynamics simulation, this work systematically assessed the tensile performance of poly(methyl methacrylate) (PMMA) nanocomposite with randomly dispersed carbon nanothread (NTH) - a new one-dimensional ultrathin nanofiller. It is found that NTH causes deterioration on the tensile properties due to the introduction of continuous lower density interphases surrounding the filler, while such negative impacts can be turned into positive enhancements by functionalization. In particular, the cross-linking at the NTH/PMMA interface is able to effectively promote the enhancement effect from the nanofiller. Our results show that the samples with random but vertically aligned NTHs outperform their counterpart with randomly dispersed NTHs. Overall, it is shown that the enhancement effect is significantly influenced by the NTHs dispersion, length, weight fraction, functionalization and cross-linking. This study provides a comprehensive understanding of the influence on the tensile performance of polymer nanocomposites from the dispersion of nanofillers, which should benefit on the fabrication and

application of high-performance polymer nanocomposites.



Vacancy Diffusion in Nickel Alloys under High Pressure through Atomistic Simulations

Bin Dong[1*], Haifei Zhan[2] and Chaofeng Lü[3]

[3] Zhejiang University, 866 Yuhangtang Rd, Hangzhou 310058, P.R. China, lucf@zju.edu.cn

Key Words: *Nickel Alloys, Vacancy Diffusion, High-pressure, Collective Variable-driven Hyperdynamics*

To achieve high propulsion ratio requirements for aero engines, the stress on the engine blades is getting higher and higher [1,2]. Due to the outstanding creep performance, nickel-based single crystal superalloys become a key material for aeroengine blades. The creep phenomenon is a long-time deformation process that involves with dislocation movement, grain sliding, and directional diffusion. It is critical to study the vacancy diffusion in nickel-based single crystal superalloys, especially under high-pressure as induced by the high centrifugal force in aero engine. Due to the limitation of time scale, traditional molecular dynamics (MD) is unable to capture the infrequent vacancy diffusion event [3]. In this study, collective variable-driven hyperdynamics (CVHD) is used to accelerate the vacancy diffusion event in the Ni-Al-Re superalloys with varying pressure. As expected,, the diffusion rate of vacancies in the nickel-based single crystal superalloys increases when the pressure increases. This work provides atomistic insights for the diffusion phenomenon in Ni alloys, which could benefit the design of next-generation high-performance alloys.

Bandgap property of a metaplate with multiple resonators

Jung-San Chen*, Yi-Chen Wu, De-Wei Kao, Yu-Siang Huang

Department of Engineering Science, National Cheng Kung University, Tainan 701, Taiwan
jschen273@mail.ncku.edu.tw

Key Words: *metaplate, bandgap, flexural wave motion, membrane-mass system*

Acoustic metamaterials possessing unusual properties have been viewed as good candidates for the manipulation of elastic/acoustic waves. Liu et al. [1] first presented the advantage of the local resonant mechanism which broke the phononic crystals' limitation. Since then, this novel concept has been widely applied in various kinds of engineering structures. There are many different types of forms in locally resonant units, such as a spring-mass system [2,3], a soft rubber cylinder in epoxy host [4], a spiral structure [5], and a beam-like structure [6]. The decorated membrane resonators also has shown their good performance in wave blocking at low frequencies [7]. By adjusting the geometric or physical properties of the resonator, the desired bandgap range can be achieved. In this study, a metamaterial plate consisting of a perforated plate equipped with multiple membrane-mass systems is proposed. A theoretical model based on extended plane wave expansion method is developed to predict bandgap location and width for the present structure. Finite element simulations and experiment measurements are carried out to verify the analytical results. Parameter studies are conducted to reveal the effect of parameters on bandgap property. The use of the double-layered structure can increase the bandwidth of the attenuation zone.

Key Words: *Composite Material, Machine Learning, Genetic Algorithm, Finite Element Method, Tensile Test, 3D Printing*

Designing composite materials with tailored stiffness and toughness is challenging due to the astronomical number of possible material and geometry combinations. Although various studies have applied machine techniques and optimization methods to tackle this problem, we still lack a complete understanding of material effects at different positions and a systematic experimental procedure to validate the results. Here we study a 2D binary composite system with an edge crack and grid-like structure using Genetic Algorithm (GA) [1] and Conditional Variational Autoencoder (CVAE) [2], which can design composite with desired stiffness and toughness. We use finite element simulations to generate a machine learning dataset and perform tensile tests on 3D-printed specimens to validate our results. We show that adding soft material behind the crack tip, instead of ahead of the tip, tremendously increases the overall toughness of the composite. We also show that while GA generates composite designs with slightly better accuracy, CVAE takes considerably less time to generate designs. Our findings may provide insights on the effect of adding soft material at different locations of a composite system and may also provide guidelines on conducting experiments to validate the results.

Key Words: *Nanocomposites, Mechanical Property, Graphene Platelet, Modelling*

This study aims to characterize the mechanical properties of nanocomposites with aligned graphene platelets. Both analytical model and experiments were conducted and the results were compared with each other. For the modelling, the mechanical properties of nanocomposites were characterized using Mori-Tanaka micromechanical model in which the graphene platelets were assumed to be disk-like plates aligned in one certain direction. The distribution of the aspect ratio of the platelets and the orientation of the graphene plates were considered in the micromechanical model. On the other hand, the nanocomposites were fabricated by compounding the epoxy resin and graphene platelets using mechanical mixer together followed by sonication. The mixture of graphene platelets and epoxy was subjected to electrical field in order align the graphene platelets. Coupon specimens with the aligned graphene were tested under tensile loading. The Young's moduli of the nanocomposites with different degree loadings of graphene platelets were measured and the results were compared to the model predictions. Results indicated that the micromechanical model can characterize the mechanical properties of the nanocomposites with the aligned graphene platelets.

Seed-pod-inspired Shape Transformation via 4D Printing

Key Words: *Seed pods, shape transformation, 4D printing*

Plant tissue can perform complex motion via shape transformation to achieve various purposes—this effect origins from the interaction between multi-scale structures and mechanical properties in plant materials [1]. For example, pine cones absorb water to fold scales to prevent seeds from damp [2].

Bauhinia x *blakeana*, or the Hong Kong Orchid Tree, is a natural hybrid of great horticultural value cultivated in gardens, streets, and parks. Its seed pods open between April and August and have two distinctive chirality-creating mechanisms, referred to as "inversion" and "eversion" here—the initially flat pod valve is turned into a helix but with different chirality. Inversion tends to occur around April, whereas eversion tends to occur later in August. Previous studies have discussed the shape transformation of many kinds of seed pods and utilized simulation and synthesis gel models to verify the transformation mechanism [1, 3]. However, it is still unclear how these two different helical morphologies may be created by changing the layered structure and composition. In this paper, we create a multi-layered seed pod model by 4D printing to reproduce inversion and eversion morphology. We then speculate how the seed pods transform. 4D printing, a combination of 3D printing and active materials, is convenient and controls the deformed shape through parameterization. By contrast, the conventional gel model requires a molding process and cannot be easily parameterized. Furthermore, we verify the feasibility of the 4D printing model by simulation, and the results are consistent. In the future, we will investigate the microstructure of the layered cells in the seed pods and measure the mechanical properties of the plant materials, which will be used to fine-tune our 4D printing model to mimic the actual situation of the *Bauhinia blakeana* seed pods.

Key Words: Carbon Nano-Coil, Molecular Dynamics Simulation, AIREBO Potential

Contrary to straight carbon nanotubes, there is no theoretical model for carbon nanocoils (CNC) due to the difference between internal and external diameter of the coil. Some researchers performed molecular dynamics simulations on CNCs[1, 2]; however, simulated CNCs usually show kink and facet shape due to buckling of internal circle. Here we obtained a CNC with flat ribbon cable shape (referred as FRCNC) from initial circular tube made of unit rings of zigzag or armchair carbon nanotube (CNT), by molecular dynamics simulation with AIREBO potential. FRCNC has no defect or all carbon atoms show six-membered ring. The formation of FRCNC depends on the relationships between the unit ring radius (or tube radius), unit ring structure (zigzag or armchair), coil radius and the initial location radius R where the ring distance d is set to that of natural C-C bond length (right schematic). On the other hand, formed FRCNC always shows R' almost identical to the location radius R, and the flat ribbon width w is almost constant, $w \approx 0.34$ nm. This value is the equilibrium distance between graphene sheet in AIREBO potential. Thus the obtained FRCNC maybe a potential dependent phenomena; however, we discuss the formation mechanism and mechanical properties of the FRCNCs as a new type of carbon material.

[2] University of Fukui, Mechanical and System Engineering, lei@u-fukui.ac.jp

Key Words: *Graphene/Aluminium composites, Mechanical properties, Deformation mechanism, Molecular dynamics simulation*

In this paper, the mechanical properties of the Graphene/Aluminium (Gr/Al) composites under uniaxial tensile and compression were investigated using molecular dynamics (MD) simulation method. Six different simulation models are used to investigate that graphene significantly improves the stiffness and strength of Gr/Al composites. Moreover, the research results shows that the existence of graphene layer can effectively prevent the propagation of dislocations at the interface, so the mechanical properties of the composites are improved. The dislocation movement of Al matrix during compression was further investigated. It was found that stair-rod dislocation and hirth dislocation occurred in Al matrix, which was helpful to improve the mechanical properties of the composites. In addition, the average curvature of compressed graphene surface is measured, and the deformation characteristics of composite graphene are considered by geometric method. The deformation mechanism of composites is studied by comparing the effects of deformation behavior, compressive stress, potential energy and dislocation.

Optimal Shape Design of Graphene Sheets by Introducing Lattice Defects

Jin-Xing Shi[1*] and Xiao-Wen Lei[2]

Key Words: *Frequency, Graphene Sheets, Lattice Defects, Optimal shape design, Stiffness*

Since they were produced in 2004 [1], graphene sheets (GSs) have been attracted plenty of attention among scholars because of their superior material properties. In especial, GSs have been supposed to be the base materials adopted in nanoelectromechanical systems (NEMS) [2].

In this study, we foucs on two basic mechanical properties, stiffness and fundamental frequency, of GSs and propose a consistent optimal shape design methodology of GSs by introducing lattice defects. This methodology consists of the molecular mechanics (MM) method, the free-form optimization method, the Phase-Field-Crystal (PFC) method, Voronoi tessellation, and molecular dynamics (MD) simulation. Details are shown as following.

At first, based on the MM method, C–C bonds of GSs are simulated as equivalent continuum beams by a combination of molecular and continuum mechanics [3], so the atomic structures of perfect 2-dimensional GSs, i.e., the initial shape of GSs, can be treated as frame structures. Then, we adopt the free-form optimization method for frames [4] to determine the optimal shapes of GSs in stiffness maximization problem and fundamental frequency maximization problem. However, the obtained optimal shapes and GSs do not satisfy the stationary-action principle due to the complicated interatomic force among carbon atoms. Hence, to obtain the stable atomic structures of the determined optimal shapes of GSs, we introduce lattice defects in the optimal shapes of GSs using a combination of PFC method, Voronoi tessellation, and MD simulation [5].

The optimal results [6,7] show that the stiffnesses or the fundamental frequencies of given GSs can be significantly enhanced using this proposed methodology, which is helpful for designing GSs as base materials in NEMS.

Key Words: *MWCNT, vibration, natural frequency, interlayer distance*

Since 1991 after the discovery of carbon nanotube (CNT), CNT plays an important role in the field of nanotechnology because of their unique structural, mechanical properties and electrical properties [1][2]. The density of CNT is very low which is about half of aluminium, and the strength of CNT is about 20 times stronger than steel, making them an excellent material with high natural frequencies. In this study, we aim to design a model which can considered to be used as a nanoscale sensor by using Multi-Walled Carbon Nanotubes (MWCNT) which has higher frequency than the Single-Walled (SW) CNT. The vibration analysis of MWCNT is performed using the molecular dynamics (MD) method. We design different kinds of MWCNT including SWCNT, Double-Walled (DW) CNT, Triple-Walled (TW) CNT and Quadruple-Walled (QW) CNT with different lengths, similar to the shape of a probe. The diameter of the innermost layer CNT in the analytical model is 3.892Å. The interlayer distance of the MWCNT is set to be the same value which is Δr=3.114Å due to the van der Waals force between the adjoined layers. The results show that with the increasing of layers of MWCNT, the natural frequency becomes higher. Then, we use QWCNT as our model for vibration analysis by changing the radius of the innermost layer. The interlayer distance of the QWCNT is set to be around Δr=3.114Å, and the height of each layer is fixed in this simulation. The results show that the natural frequencies become higher, when the radius of the innermost layer increases. In next simulation, the radius of the innermost layer of the model QWCNT is set to be 1.946Å, and interlayer distance is set to be around Δr=3.114Å. The results show that the natural frequencies become higher, when the length of the QWCNT decreases. From these results, MWCNT has high natural frequency, and it is highly likely to be utilized as a nanoscale sensor.

Key Words: *Isolated Element Method, Fracture Mechanics Analysis, Stress Intensity Factor*

This paper presents an application of the isolated element method (IEM) to fracture mechanics analysis. In the IEM, the body of interest is described as a collection of isolated elements [1]. The displacement functions are defined independently for each isolated element. The principle of minimum potential energy that is expanded to satisfy the continuity of the displacement at the interface between neighbouring isolated elements is applied. Using these remarkable properties of the IEM over the conventional finite element method (FEM), the IEM is applied to fracture mechanics problems. In the IEM, the local refinement of isolated elements near the crack tip can be achieved without smooth connection of neighbouring isolated elements. In addition, higher order displacement function and the displacement function for crack tip can be locally used for isolated elements near the crack tip. These special techniques can enable us analysing the fracture mechanics problems without extensive efforts to generate finite element mesh with a particular design near the crack tip and with a sufficient numerical accuracy.

As a demonstration of the application of the IEM to fracture mechanics problems, a plate with a crack under tension loading is analysed. The problem has a simple geometry and boundary conditions, and thus, symmetric (displacement) boundary condition can be applied. In the symmetric boundary condition, the displacement in the loading axis direction is fixed at the ligament part of the crack. However, the displacement in the IEM solution at the ligament part cannot be perfectly fixed. The stress intensity factor calculated using the displacement extrapolation method also has a subsequent numerical error. To improve the numerical accuracy of the IEM in the fracture mechanics analysis, the displacement function of the isolated elements at the ligament part is rearranged to satisfy the displacement boundary condition. The centre of the displacement function is shifted to the ligament part, and some terms in the displacement function is removed to completely satisfy the displacement boundary condition. The numerical results using the special displacement function at the ligament part shows a perfect satisfaction of the displacement boundary condition. Using the numerical solution of the displacement near the crack tip, the stress intensity factor is calculated. The numerical accuracy of the stress intensity factor can be drastically improved compared to the IEM solution without the special displacement function. Furthermore, the crack tip displacement solution is embedded into the displacement function for isolated elements near the crack tip. We found that the application of the crack tip displacement function can also improve the numerical accuracy of the stress intensity factor calculation.

Key Words: *Radiation damage, Molecular Dynamics, Binary Collision Approximation, Machine learning*

For the safe operation of nuclear reactors, it is important to understand and control the effects of radiation damage on the mechanical properties of nuclear materials. Radiation damage consists of various processes occurring on different time scales, such as the radiation damage formation in ns~ps, the recovery of radiation defects just after the formation in ps~ns, and the long-term evolution of defect complexes in hour~year. For the radiation damage formation process, two computational methods have been widely used. One is the binary collision approximation (BCA) [1] and the other is the molecular dynamics (MD). BCA has the advantage of high computational efficiency because it approximates many-body atomic collisions to two-body atomic collisions, but it cannot give accurate defect structures due to its approximation. On the other hand, MD can simulate many-body collisions as they are, and thus can give an accurate defect microstructure if an accurate potential model is prepared. Therefore, in order to achieve accurate and effective computer simulation of radiation defect formation, it is important to seamlessly couple BCA and MD and to prepare an accurate potential model for MD. In this paper, we present our recent attempt to solve these two problems by applying machine learning (ML).

For seamless coupling of BCA and MD, we constructed two machines based on the MD collision simulation results up to several tens of keV. Specifically, one machine generates a pseudo-random defect structure satisfying statistics such as defect number distribution and defect position distribution, referring to the MD simulation results. The other machine is trained to classify the MD-generated defect structure and the random defect structure, and determines whether the generated quasi-random defect structure by the first machine is reasonable or not. By using the BCA code until the damage energy becomes several tens of keV, and then switching to the machines, we can generate defect structures similar to MD at a speed comparable to BCA.

To create a highly accurate MD potential model, we constructed a moment tensor potential [2], a kind of ML potential model, by referring to the results of first-principles calculations for various defect structures and material properties. The constructed ML potential model agrees well with the first-principles calculations and shows much better performance than the conventional potential model. It was confirmed that the generated ML potential can be used stably in collision simulations. In this presentation, we will discuss an effective way to generate ML potentials for radiation damage simulations.

Key Words: *Open structure, finite element method, elastic modulus*

In this study, the authors create various open structures that reflect an atomic-level structure database. And we design open structures with higher Young's modulus, shear modulus and bulk modulus. In a modeling process for the open structure, the atomic positions were imported from the Materials Project, an open access materials database. Then we modeled open structures by considering the atomic positions as vertices and connecting them with circular 1D beams. As a result, open structures were modeled with various atomic arrangements belonging to different space groups. In a test process, the mechanical properties were calculated by compression along the x-, y- and z-axis using the FEM tool. Authors introduce open structures with the higher Young's modulus, shear modulus and bulk modulus. We discuss what geometric factors strongly affect the moduli of elasticity in open structures.

Key Words: *Composites, Deterioration, Ultraviolet Radiation, Moisture, Heat, Homogenization, Fatigue, Damage, Flexure*

Glass fiber-reinforced polymer composites (GFRPs) are made by combining polymer with reinforcement glass fiber yarns to produce lightweight yet strong materials. This study is to build a Multiphysics and Multiscale model to predict the synergistic effect of environmental exposure to fatigue-damage of the composite.
Based on the authors' previous UV/moisture exposure experiment-computational study, this extended study couples environmental deterioration induced material weakening to continuum fatigue-damage model. The extended research developed a fatigue-damage model at the structural length scale, using diffusion coefficient tensor and stiffness tensor homogenized from a plain-woven RVE at mesoscale length scale. The experimental validated computational model shows that environmental exposure causes material degradation, which leads to a mild change of damage variable field and considerable change of fatigue parameter after 1000 hours of accelerated cyclical UV/moisture exposure. The synthetic effects of these two changes reduce structural stability. The most significant effect is observed by measuring bending moments after the tension-tension fatigue test. After 100,000 cycles, the bending moment of cyclic UV/moisture degraded samples decreased up to 40 percent compared to undegraded samples. This model can be incorporated into many commercial finite element codes for a sustainability study of composite structures/systems. In future work, the models developed in this study will be combined with life cycle assessment (LCA) tools to better support sustainability focused design of new material, thus reducing costs and environmental impacts of the built environment.

Effects of powder trajectory for Y_2O_3-A_2O_3 interface formation during plasma spray coating: A multiscale analysis

Youngoh Kim[1, 2*] and Joonmyung Choi[1, 2]

[1] Hanyang University, 222 Wangsimni-ro, Seongdong-gu, Seoul 04763, Korea

Key Words: *Multiscale mechanics, Direct simulation Monte Carlo, Molecular dynamics, Plasma spray coating, Yttria thin film*

Yttria is one of the protective materials due to its excellent mechanical and thermal stability. In addition, the tunable bandgap and high dielectric constant make yttria a promising material for optoelectronic devices [1]. This versatile yttria thin film has great advantages in that it can be applied to complex shapes through plasma spray coating [2]. Nevertheless, the plasma spray coating has been performed relying on empirical indicators from numerous experiments. The absence of a theoretical understanding of these plasma spray coatings motivates our works. In this study, we present a multiscale analysis method to explain the origin of interface formation by plasma spray coating.

Our multiscale framework consists of the direct simulation Monte-Carlo (DSMC) method and molecular dynamics (MD). The solution of the Boltzmann transport equation to obtain the trajectory and spatial distribution of powder is approximate through the DSMC methods. Meanwhile, the formation of the interface according to the particle incidence is analyzed through MD simulations.

To evaluate the effect of powder feed and spray distance on the film formation, spatial particle distribution was extracted. The spray cone angle was proportional to the number of powder particles. This tendency is due to the high probability of particle collision in space. Meanwhile, the large cone angle is a major factor in determining the incident trajectory of the particles constructing the interface. We investigate the formation of the Y-O-Al network structure with the incident trajectory of the particles using molecular dynamics simulations. The interface formed by the particles at a gentle incidence angle to the surface had poor adhesion strength as well as a significantly lower density of the Y-O-Al network. These results provide a crucial foundation for analyzing the interface under plasma spray coating.

Fatigue Crack Growth Simulation of Multiple Surface Cracks Using Discrete Dislocation Dynamics Method

Shinya Terahara[1*], Akiyuki Takahashi[2] and Nasr Ghoniem[3]

Key Words: *Discrete Dislocation Dynamics, Fatigue Crack Growth, Multiple Surface Crack, Superposition Principle*

This paper presents an application of the discrete dislocation dynamics (DDD) method to fatigue crack growth simulations of multiple surface cracks. Sheng et al., have developed a DDD based fracture mechanics analysis technique for surface cracks [1]. The boundary conditions of the finite elastic body with cracks can be satisfied by the application of the superposition principle. In the application of the superposition principle, the entire dislocation (crack) problem in a finite elastic body is defined as a summation of a dislocation problem in an infinite elastic body and a correction problem. The correction problem is an elastic problem and is solved by the finite element method (FEM). The boundary condition of the correction problem is determined to eliminate the virtual traction calculated in the dislocation problem. In the calculation of the virtual traction in the dislocation problem, the virtual traction becomes singular along the dislocation line at the free surface. Sheng et al., added a virtual dislocation loop outside the finite elastic body to remove the singularity along the dislocation line at the free surface. Finally, they demonstrated that the DDD based fracture mechanics analysis technique can calculate the stress intensity factor with a sufficient numerical accuracy. In the fracture mechanics analysis using the finite element method (FEM), the elements near the crack tip must be very fine to obtain a numerical solution with sufficient numerical accuracy, and re-meshing is necessary to perform the fatigue crack growth simulation. In some cases, the re-meshing could be a bottleneck to perform the fatigue crack growth simulation particularly of multiple cracks including their coalescence. On the other hand, in the DDD for fracture mechanics analysis, the crack is modelled with a collection of pile-up discrete dislocations, and therefore, the crack shape can be easily modelled and updated by changing the shape of the dislocation line. Therefore, it is easy to deal with the complex dislocation shape and interactions in the fatigue crack growth process.

In this paper, the DDD method for surface cracks is applied to the fatigue crack growth problems of multiple surface cracks. The elastic interaction of multiple surface cracks can be naturally considered in the numerical simulation. The crack geometry change due to the fatigue crack growth is calculated by the Paris law. The crack shape updated by the fatigue crack growth can be easily modelled by updating the shape of dislocation line, which describes the crack front shape. The crack coalescence is also dealt with in the fatigue crack growth simulation. The coalescence can be easily performed as the dislocation annihilation process, which is normally used in the DDD simulation of plasticity, particularly for the Frank-Read source simulation. Finally, as the demonstration of the DDD based fatigue crack growth simulation, the coalescence and penetration of multiple surface cracks are presented.

Recently, tungsten(W) as a plasma-facing-material(PFM) in the extreme environment of nuclear fusion has been spotlighted as an important material in related fields due to its excellent physical properties [1]. However, as the harsh condition of nuclear fusion suffers hydrogen bombardment accompanied with intense irradiations, which leads degradation of the material such as formation of defects and hydrogen embrittlement, it is not easy to guarantee PFMs life [2, 3]. Therefore, understanding the mechanisms and influence of the trapping of hydrogen in neutron irradiated W is important. In this study, hydrogen retention models by Molecular dynamics simulations describing the interaction between H and dislocation are presented. The properties of the W and trapping rate of hydrogen are calculated with varying external conditions such as stress and temperature gradient as well as number and type of dislocations.

Interfacial properties of Liquid crystal polymer and MWCNT nanocomposite at high filler concentrations: A molecular dynamic study

Hongdeok Kim[1,2*] and Joonmyung Choi[1,2]

[1] Hanyang University, 222 Wangsimni-ro, Seongdong-gu, Seoul, 04763, South Korea
[2] BK21 FOUR ERICA-ACE Center, Hanyang University, 55 Hanyangdaehak-ro, Sangnok-gu Ansan, 15588, Republic of Korea, jm02209@hanyang.ac.kr, joonchoi@hanyang.ac.kr

Key Words: *Molecular dynamics, Polymer nanocomposites, Mechanical properties, Interface*

Fabrication of liquid crystal polymer (LCP) nanocomposites using a multi-walled carbon nanotube (MWCNT) sheet has attract significant interests as it complements the low mechanical properties and offers multi-functionality [1]. In this study, we investigated the interfacial properties between LCP and MWCNT from the mechanical and structural point of view. The neat LCP and LCP/MWCNT microstructures were constructed in all-atom molecular dynamics environment, and load transfer characteristics as well as internal stress distributions were thoroughly evaluated. Key design consideration of this study is the concentration of MWCNT filler in the nanocomposites. Since the LCP/MWCNT is experimentally fabricated by penetrating liquid crystal into a densified MWCNT sheet, the filler generally has a high volume fraction of 25 % or more. Therefore, different MWCNT volume fractions from 25 % to 48 % were prepared.

To evaluate the alignment characteristics of LCP by interaction with filler, an orientaional order was derived in the radial direction of the MWCNT. In the vicinity of the nanotube surface, the both components constituting LCP, mesogen and side chain, showed high directionality. This is because the rigid core of the LCP consisting of three aromatic rings has the maximum contact area when aligned parallel to the nanotube. These aromatic rings are distributed with two different conformations (parallel and T-shaped alignment) depending on the distance with MWCNT and form a layered structure. In other word, MWCNTs significantly enhance the crystallinity of adjacent LCPs.

To evaluate the interfacial load transfer, tensile simulation of LCP/MWCNT nanocomposites was carried out. The results indicate improved elastic stiffness in both axial and transverse directions as the concentration of MWCNT increases. As the volume fraction occupied by MWCNT increases, the region with high crystallinity in the LCP matrix becomes predominant. This not only greatly improved the effective properties of LCP but also enabled strong coupling with MWCNT, resulting in more effective load transfer.

The present study is the first to explore the interface of LCP-MWCNT at non-dilute filler concentrations. Polymer nanocomposites using MWCNT sheets lacked microscopic insight compared to their experimental novelty. Therefore, this study can be utilized as a guide for the robust design of applications.

Nanoparticle sintering becomes a new choice for high-temperature packaging for microelectronic applications due to the low sintering temperature of nanoparticles when compared with macro-sized ones while having a good property with high stability. Conventionally, silver nanoparticles are deemed to be ideal because of their high stability, electrical and thermal conductivity, yet the actual usage is limited due to their high price. In this respect, a Cu@Ag core/shell nanoparticle has been suggested by substituting a part of the molecule with the cheaper metal. In addition to a reduction of cost, the core/shell nanoparticle has several advantages of reasonable conductivity and resistance to oxidation.
In this study, we investigate Cu@Ag core/shell nanoparticle sintering using molecular dynamics simulation. Firstly, we investigate heat-induced sintering in terms of melting temperature and microstructure evolution. Additionally, we study the pressure-assisted sintering (PAS), which allows further reduction of pores without excessive heat, preventing damage of heat-sensitive substrates e.g., polymer. We also investigated the effect of interfaces to the sintered structure, which are underpinned by comparing mechanical, and lattice properties of structures with different sintering path.

Plasma etching time prediction model of high aspect ratio pattern using molecular dynamics with data processing

Junghwan Um[1,2], Keonwook Kang[2]

[1]*Memory Division, Samsung Electronics Co. Ltd, Gyeonggi-do 18448, Republic of Korea, truballer@yonsei.ac.kr*

Key Words: *Molecular dynamics, Etching, High aspect ratio contact, Data processing*

During the semiconductor process, more than 90% of the etching is performed using plasma. Plasma discharged with various etching gases emits ions with energy and angle distribution, radicals with high chemical reaction rate, and electrons with isotropic velocity distribution to the substrate. These particles are transported into the substrate to be etched, and etching occurs as the conditions of ion-assisted surface activation, heterogeneous reaction by radicals, and charge build up by electron and ion [1]. With the recent development of V-NAND, the aspect ratio of the trench structure risen sharply due to the rapid increase in stack thickness. In the early days of V-NAND, it was possible to predict the situation intuitively for structures with a small aspect ratio. However, it becomes difficult to predict the state of the particles reaching the deep bottom for etching as the frequency of wall collisions of particles transported inside the high aspect ratio pattern increases. Therefore, understanding the states of ions, radicals, and electrons after wall collision is essential for etching prediction. Therefore, in this study, the energy dissipation efficiency, energy loss and angle deviation after wall collision are calculated using molecular dynamics with ReaxFF [2]. Based on the calculated results, a regression analysis with a tendency for the input and output values was performed, and the results of calculating the etching time for each depth from the state of each particle predicted after wall collision were reinforced by learning through Bayesian regularization. At this time, the radicals supplied as a pattern together provide the radical concentration at each depth from the diffusion model reflecting the appropriate diffusivity and rate constant from OES data of plasma. Finally, a high aspect ratio etch time prediction model including charging effect was constructed by adding a component that slows down ions by calculating the electric field formed from charge separation due to the difference in velocity distribution between electrons and ions. Through this model, it is expected that the etching time by plasma state can be predicted in the structure of next generation products.

Quantitative Evaluation of Kink Strengthening in LPSO-type Magnesium Alloy Using Higher-order Gradient Crystal Plasticity

Yuichi Tadano[1*]

[1] Saga University, 1 Honjo-machi, Saga 840-8502, Japan, tadano@me.saga-u.ac.jp

Key Words: *Kink Strengthening, LPSO-type Magnesium Alloy, Higher-order Gradient Crystal Plasticity, Meshfree Method*

Magnesium alloys with the long period stacking order (LPSO) structure show the superior strength and are expected as the next generation structural material. In the LPSO materials, kink deformation is an important deformation mechanism as well as slip deformation in the crystalline scale and may be the origin of the material strengthening. Therefore, understanding the kink strengthening phenomena is essential. In the LPSO-type magnesium alloy, band-shaped kink is sometimes observed. Kink band causes the strain gradient around the band. The higher-order gradient crystal plasticity is an efficient way to represent the strain gradient effect in the crystalline scale. In this model, an additional governing equation expressing the dislocation density filed is introduced, and both the displacement and dislocation density fields can be solved simultaneously.

In this study, a higher-order gradient crystal plasticity analysis is conducted to evaluate the stress field around kink band to understand the strengthening mechanism due to kink. The finite element method sometimes provides an improper solution in the higher-order gradient crystal plasticity analysis; therefore, the reproducing kernel particle method, which is a kind of meshfree method, is introduced into the higher-order gradient crystal plasticity analysis.

The numerical result shows there are two main origins of kink strengthening, i.e., the geometrical strengthening and defect strengthening. The former one is also known as the geometrical hardening and caused by the rotation of crystal orientation. The latter one is a strengthening by geometrically necessary dislocation density around the kink boundary. Although both mechanisms cannot be negligible in the kink strengthening, the present result suggests that the defect strengthening is more dominant in the strengthening of LPSO-type magnesium alloy.

Reduction of Interstitial Mobility in W by Transition Metal Multicomponent Alloying

Younggak Shin[1*], Byeongchan Lee[2] and Keonwook Kang[3]

Key Words: *First Principles Calculations, Interstitial Defects, Alloys*

Tungsten (W) is one of the promising base materials for plasma facing components in fusion reactor thanks to its excellent thermo-mechanical properties**[1]**. However, W is also known to have poor performance against irradiation damage. Its weakness comes from a lack of point-defect-controlling mechanism; specifically, the migration energy barrier of a self-interstitial atom (SIA) in unary W is extremely low.

Meanwhile, solute atoms in alloys can attract point defects and can change the mobility of them. In W-based transition metal binary systems, solute atoms such as Re prefers to make solute-SIA mixed dumbbell and migrates through the non-dissociative migration mechanism**[2]**. This non-dissociative migration mechanism raises the migration energy barrier up to some level. However, the migration energy gap between vacancy and interstitial remains still huge.

To control mobility of interstitial further, adding additional alloying agent is unavoidable. Thus, we chose W-Ta-Re system as the first ternary system to investigate, and, have conducted both energetics and dynamics analysis via first-principles calculations to find stable interstitial defect structure and check its mobility.

It is confirmed that, in such system, Ta and Re pair strongly attracts a W SIA, forming a Ta-Re-SIA triple complex. The interaction is stronger than that between Re and SIA in binary system. The strong interaction restricts the well-known non-dissociative migration motion of Re-SIA mixed dumbbell and effectively reduce the interstitial mobility. Reduced mobility in such ternary system can offer the increase in the odds of vacancy-interstitial recombination in collision cascades and the retardation of interstitial clustering.

Abstract

In memory semiconductors for a high-aspect-ratio structure, it is common to observe shape distortion such as bowing and tilting in a plasma etching. Since this distortion leads to degradation of device performance, it is essential to analyse the cause based on an understanding of the etching process. In this study, the authors present a Monte Carlo (MC) based etching computational simulation technique by considering recoil atoms produced in the substrate via collision cascade after ion bombardment. We confirm the relationship between ion energy and etching amount in the ion-assisted chemical etching process through the number of recoil atoms [1]. The model also shows that the results qualitatively agree with well-known etching phenomena such as feature size dependent etching (FSDE) and aspect-ratio dependent etching (ARDE) [2].

Key Words: *Virtual Dislocation Core, Dislocation Dynamics, Dislocation-precipitate Interaction*

This paper presents a virtual dislocation core (VDC) model for dislocation dynamics (DD) simulation of dislocation-precipitate interactions. In the conventional DD method, dislocations are described as a curved line with a directional displacement jump equivalent to the Burgers vector. The elastic interaction between dislocations and the self-interaction can be accounted for in the calculation of the force acting on the dislocations. The force is then converted to the dislocation velocity based on a simple mobility (linear) law. However, in the DD method, the influence of the structural change in the dislocation core during the dislocation-precipitate interaction process cannot be considered. Takahashi et al. has proposed a DD simulation technique, which is an application of discretized Peierls-Nabarro model to the dislocation-precipitate interactions [1]. In the method, dislocations are discritzed with several fractional dislocations, and the dislocation core structure is described as the 2-dimensional planar arrangement of the fractional dislocations. The lattice restoring force arising from the difference in the generalized stacking fault energy in the matrix and the precipitate is changed according to the position of the fractional dislocation. The method can consider the influence of the structural change in the dislocation core, and however, the necessary computational cost is quite high. In addition, the numerical stability is also problematic due to the close interaction of fractional dislocations within the dislocation core.

In this study, a VDC model is proposed to enable us simulating the dislocation-precipitate interactions using the DD method with a realistic computational cost and high numerical stability. In the VDC, the dislocation core structure is locally defined as a 1-dimensional arrangement of virtual fractional dislocation (VFD) at the integral point along the dislocation segment. The VFD experiences the self-force and the elastic interaction force calculated in the DD method. In addition, the lattice restoring stress and the elastic interaction between VDC within the dislocation core are also considered. Thus, dislocations can be modelled as a single curved line, which drastically reduces the computational cost and improves the numerical stability compared to the DD simulation with full fractional dislocations. As a demonstration of the dislocation-precipitate interaction simulation using the VDC model, the γ-precipitate interaction with dislocation is simulated, and the critical resolved shear stress (CRSS) of the interaction is calculated. The CRSS calculated with the VDC model is comparable to that calculated using the DD method with the full fractional dislocations. Moreover, the dislocation shape and the core structure calculated with the VDC model are in good agreement with those calculated with the DD method with full fractional dislocations. The VDC model is further applied to the dislocation-sheared spherical precipitate interaction problem. The lattice restoring stress for the matrix, precipitate and the interface between the matrix and precipitate is used. The CRSS and the interaction mechanism are discussed in the paper.

Key Words: *Grain Boundary, Dislocation, Defect interaction, Nudged elastic band method*

It is well established that the strength and ductility of the polycrystalline metals are significantly influenced by the interaction between the dislocations and grain boundaries (GBs). Several representative phenomena are observed when the dislocation impinges the GB: 1) the dislocation is absorbed into the GB; 2) the dislocation transmits through the GB and slips on a certain plane in adjacent grains; and 3) the dislocations plie up before the GB, which imitates a wall or barrier to the movement of dislocations. Several factors can affect the interaction mechanisms and critical interaction shear stress (CISS), such as the local GB structure, GB energy, material elements, type of dislocations, and so on.

To investigate the influences of GB energy on the defect interaction, molecular dynamic (MD) simulations were performed for edge dislocation-<112> axis symmetric tilt GBs in Cu. It was found that the CISS would decrease when the GB energy increases if we only consider the weakest point alone the GB plane. Meanwhile, the interactions between a screw dislocation and coherent twin boundary (CTB) were implemented to interpret the material influence on the CISS in Cu, Al, Ni, Ag, Au, Pd. The CISS will be influenced by the difference between the unstacking fault energy and stacking fault energy.

Furthermore, as the dislocation-GB interactions were usually treated as the thermally activated process which could be accurately estimated by the transition state theory, we used the nudged elastic band (NEB) method to determine the saddle point and energy barrier of the interaction in a certain deformation state. It was found that the energy barrier would decrease when the shear stress increases because the high-stress state promoted the interaction and reduced the energy that should be externally introduced to trigger the interaction. The subsequently derived activation volumes ($13\sim31\,b^3$) and strain rate sensitivities corresponded well with the experimental data for the edge dislocation-<112>axis GB in Cu. A similar process was also applied to the screw-CTB interaction, the activation volumes and strain rate sensitivities corresponded well with the experiments. This process also quantitatively linked the MD to the realistic experiments.

Key Words: *Alloy design, Mechanical Properties, Dislocation Core, First-principles Calculations*

Dislocation has been regarded as the essential lattice defect in plastic deformation, especially in metallic materials. The fundamental properties of the dislocation core have a dominant influence on the intrinsic ductility or brittleness of materials. The interaction between dislocations and other crystal defects plays a critical role in determining the mechanical properties of metals. The classical strengthening mechanism was developed by this central premise, and the mechanical properties of metals have been developed by understanding and controlling the dislocation behavior.

Especially, plastic deformation in BCC metals is achieved by a fundamental motion of screw dislocations through a kink mechanism. Alloy elements influence the mechanical properties significantly, where the classical strengthening mechanism can no longer be applied to the alloy design due to the complex effect derived from the electronic structure. The first-principles calculations have been widely applied to calculate the dislocation core of various metals directly. The core structure of dislocation in pure BCC metals and the effects of solutes on core structure have been investigated by the first-principles calculations. In the present study, we evaluated softening/strengthening behavior of dilute and highly-concentrated BCC alloys by the first-principles calculations. The introduction of dislocations within our periodic cell was accomplished by applying a continuum linear elastic theory solution for the periodic dislocation dipole array [1]. Then, we proposed new analytical models describing the kink process of screw dislocations, in which the fundamental properties are evaluated by the electronic structure calculations. The analytical models based on the solid solution and the line-tension model were applied efficiently to predict the fundamental mechanical properties. The first-principles calculations of dislocation core provided a clear trend in interactions between a solute and a screw dislocation depending on the type of alloying elements, revealing that the electronic structure around the dislocation core strongly influences the kink process. Furthermore, the analytical model reproduced the macroscopic solid solution softening/strengthening behavior in dilute alloys and the unique slip behavior in highly-concentrated alloys.

Atomistic Investigation of Hydrogen Influence on the Mobility of Edge Dislocations in Alpha-Iron

Sunday Temitope Oyinbo[1*], Ryosuke Matsumoto[2]

[1,2] Kyoto University of Advanced Science, 18 Yamanouchi Gotanda-cho, Ukyo-ku, Kyoto 615-8577, Japan, [1] Sunday.t.oyinbo@kuas.ac.jp, [2] matsumoto.ryosuke@kuas.ac.jp

Key Words: *Edge dislocation, Molecular dynamics, Alpha iron, dislocation mobility, Hydrogen concentration*

It is worthwhile to investigate the interplay between impurities and dislocations in metals from both a basic and a practical standpoint since there are several intriguing topics to consider. In a crystal, impurity atoms, complexes, and impurity clusters scattered throughout the crystal all have an effect on the mobility of dislocations via a variety of mechanisms. In this study, we use extensive molecular dynamics (MD) calculations, based on a highly-accurate interatomic potential to examine how hydrogen atoms impact the mechanisms behind the mobilities of edge dislocations in body-centred cubic (bcc) alpha-Iron (α -Fe) at a temperature ranging from 300 K to 500 K. The edge-dislocation mobility in α-Fe is shown to be temperature and hydrogen concentration-dependent in this MD investigation. It is demonstrated from the results that hydrogen impurities that are efficient in locking dislocations exist in the form of complexes that are scattered discretely along the dislocation line and that these complexes operate as extremely effective impediments to the mobility of edge dislocations. The hydrogen impact on the edge dislocation motion from the dislocation velocities versus shear stress reveals that the movement of edge dislocations in α-Fe with Hydrogen is much damped as the hydrogen concentration increases. Increased hydrogen concentration produces internal strain in the α-Fe cristal; hence, the shear stress increases with decreasing dislocation mobility. According to the atomistic structure study results, when the dislocation velocity is very low (less than 1 m/s), the movement of Hydrogen atoms with the edge dislocation segment is enhanced because the longer time is given for Hydrogen to catch up the dislocation motion. Therefore, the synchronized motion of the Hydrogen and dislocation segment is increased with decreasing dislocation velocity. Furthermore, the drag coefficient calculated from the dislocation velocity vs stress graph reveals that it decreases with temperature in α-Fe containing hydrogen atoms. As the temperature decreases, it is clear that Hydrogen has a more significant influence on edge-dislocation mobilities with increased shear stress, as seen by the data. Even with small cell size, a unique locking mechanism is identified in the α-Fe, which increases the necessary stress for dislocation migration in α-Fe. Specifically, our studies indicate the prominent processes of edge-dislocation motion in α-Fe, as well as particular implications of temperature and Hydrogen on these mechanisms, all of which have the potential to have a considerable influence on the mechanical properties of α-Fe. As a result of this research, it is concluded that temperature and hydrogen concentration is very significant determinants of deformation in hydrogen-containing metals since much lower temperatures are used for Hydrogen storage applications [1,2].

Key Words: Fracture, Iron, Interatomic Potential, Machine Learning

Predicting fracture of iron-based alloys (steels) as a function of alloying/chemistry and loading conditions is crucial to optimize their mechanical performance for many applications. Fracture is controlled by multi-scale mechanisms that originate at the atomistic scale. Therefore, understanding fracture of pure iron at the atomistic scale is essential to build a predictive model of fracture for iron-based alloys.

Molecular dynamics (MD) is a suitable tool to explore atomistic mechanisms occurring at crack tips. The reliability and accuracy of MD depends on the interatomic potential (IAP). Many Fe IAPs have been published, but none of them is capable of reproducing the experimental evidence of fracture in iron [1]. Here, we develop a new Gaussian Approximation Potential (GAP) for fracture in iron, by extending a previous Fe GAP [2]. We enrich the existing density function theory (DFT) database [3] by adding crack-relevant configurations, including highly deformed primitive cells and surface separation.

The new Fe GAP preserves DFT-accurate properties (elastic constants, surface energies, and Bain path). Together with other state-of-the-art IAPs, mode-I fracture process of single-crystal iron is studied for several crack fronts and planes, by performing molecular statics. The cleavage plane and critical stress intensity factor are compared with experiments and with Griffith theory. The competition between cleavage on $\{100\}$ and $\{110\}$ planes is studied and simulations, theory, and experiments are compared. Our study provides a systematic strategy for improving machine learning IAPs for fracture.

Key Words: *Wiredrawing, Plastic deformation, Iron and steel, Magnesium, Molecular Dynamics*

Wiredrawing is a conventional method for plastic working to make wires narrower and it has been applied to wide variety of metallic materials. Industrial needs for smaller sized wires, such as those with micro-meter or nano-meter size dimension, are now continuing, whereas there is no clear insight of the wiredrawing when the process size comes to such an extremely narrow region. This study aims to acquire the possibility of fabrication technique of very small wires and to establish the theoretical foundation concerning wiredrawing process in nanometer-sized region. Contrast to conventional simulating method based on finite element analysis (FEA) which has been already widespread in industry, molecular dynamics (MD) analysis (atomistic simulations) will become a central methodology to investigate the process in near future.

So far, material models of pure iron (Fe) and pearlitic steel which contains carbon atoms as well as Fe atoms are well established by the present authors [1], and theoretical prediction concerning plastic deformation mechanism and atomic processes in drawing of Fe-based materials has been paid attention. Recently, our simulations are going to be applied to pure-magnesium (Mg) nanometer-sized wire. The Mg material contains well-known difficulty in any cold plastic working due to restriction of slip systems inherent to hexagonal closed-packed (h.c.p.) structures. We will compare our previous results of plastic process in wiredrawing of Fe-based (body-centered cubic: b.c.c.) material [1] with h.c.p. wires.

In the simulation of metallic wire, a conical die with semi-angle of 7 degrees is spatially fixed and the wire passes through the die with a given drawing speed. Since intact interaction energy between die and wire atoms offered by EAM potential function is tremendously large, the interaction for pairs in the vicinity of the interface is adequately reduced by modifying the strength. Simultaneously, the wires are subjected to plastic strain which is needed for the reduction ratio of the diameter. By using wire models made of Mg single crystal with various crystal orientations, it is found that deformation twinning works very effective for accumulation of the plastic strain. On the other hand, it is observed that slip systems inherent to Mg crystal are fatally limited in contrast to pure Fe crystal, as crystallographically predicted. We can observe atomistic processes of formation and propagation of twin planes, basal slips and their combination, which are unique to the Mg crystal. Interestingly, deformation twins are followed by phase transformation from h.c.p. phase to b.c.c. phase. It is concluded that nanometer-sized wiredrawing is theoretically possible for the Mg material, but deformation process there is totally different from Fe-based material and drawing orientation strongly affects the plasticity. Therefore, we can suggest that a selective condition of wiredrawing certainly exists for Mg in any size-scale.

Key Words: *Dislocation, Disconnection, Interface, Molecular Dynamics, Martensitic Transformation*

Line defects like dislocations and disconnections play critical roles in the thermodynamics and kinetics of interfaces in crystalline solids; the Burgers vector content of the defects accommodates mismatch and misorientation across the interface, while the step character of disconnections enables migration of the interface via their glide motion. While the continuum perspective on interfacial line defects has greatly matured in recent years thanks largely to the development of the topological model by Pond and Hirth [1], atomistic analysis of interfacial line defect structures is still in its infancy. This is largely due to the difficulty of identifying and characterizing interfacial line defects in atomistic datasets. While the revolutionary dislocation extraction algorithm (DXA) tool can automatically identify interfacial dislocations, it requires the specification of an atomic motif for the interface structure [2,3]. This is labor-intensive and often difficult to accomplish in practice. Furthermore, DXA cannot identify disconnections. Building on the success of DXA, we develop a new technique for identifying interfacial line defects which is based on the concept of constructing Burgers circuits between coincidence sites in the interface. This technique does not require any structural input about the interface and can identify both interfacial dislocations and disconnections. Using this new technique, which we call the dislocation and disconnection extraction algorithm (DDXA), we analyze interfacial migration during martensitic transformation in Fe, revealing the key interplay between bulk and interfacial line defects.

Key Words: *Crystal plasticity, Grain boundary, Bicrystal, Hardening with slip transfer, Dislocation density, Finite element analysis*

Precise prediction on strength of polycrystalline materials needs the knowledge of hardening behaviour with slip transfer across grain boundaries (GBs). In this study, plastic deformation near GB of bicrystal was numerically analized using crystal plasticity finite element method (CPFEM). To describe the hardening behaviour by CPFEM, a constitutive equation based on Kocks-Mecking model [1] with slip transfer effect across GB was proposed and implemented by using a user material subroutine of LS-DYNA. For the description of GB interaction, the geometrically necessary dislocation (GND) density near GB induced by strain gradient was affected by the transmission factor representing the degree of slip transfer across GB. In the present model, the factor is based on a criterion considering the intersection between slip plane and GB proposed by Shen et al. [2]. To discuss the validity of the introduced GB model based on CPFEM, two models were considered; one is a bicrystal subjected to uniaxial tension normal to GB and the other is one subjected to simple shear perpendicular to GB. The former is for numerical verification comparing with the reference [3], and the latter for that to the GB interaction criterion. The preferential slip system across GB and the plastic deformation near GB were especially discussed for several kinds of GBs of aluminium bicrystals.

Key Words: *Nanoscale, Schmid's law, Dislocation*

The mechanical properties of nanoscale metallic materials differ from those of bulk materials because of lack of dislocation sources inside the materials [1] and the increased influence of surfaces [2]. For example, Cao *et al*. indicated by molecular dynamics (MD) simulation that the yield stresses differ between quadrangular prism and cylinder nanorods of Cu single crystal with the same crystal orientation [2]. In the case of bulk materials with the same crystal orientations, the yield stress is independent of the cross-section shape and the critical resolved shear stress, τ_{CRSS}, is constant (Schmid's law). The research by Cao *et al*. suggests in contrast that Schmid's law may not hold in the nanoscale materials. However, the effect of surface orientations and edge between them, which should play a vital role in slip occurrence in nanorods, has not been clarified.

In this study, we performed a uniaxial tensile deformation simulation using MD for Cu single crystal nanorod models in which the cross-section shape was systematically changed. To evaluate the basic slip deformation, we set a crystal orientation of the nanorods so that the slip of the specimen under the uniaxial tensile load becomes a single slip. The cross-section shapes of the nanorods were square (Sqr), square rotated by 45 degrees (Sqr45), regular octagon (Oct), and circle (Cir). The length of one side of Sqr and Sqr45 models and the diameter of Cir model were 20 nm, and the length of one side of Oct model was 8.28 nm. The lengths in the loading direction of all models were 34 nm. With the periodic boundary condition only along the loading direction, we conducted MD simulation at 300 K to evaluate the slip deformation and calculate τ_{CRSS}.

In the Sqr, Oct and Cir models, the deformation occurs only in the main slip system, and the τ_{CRSS} of each rod was 1.34, 1.59 and 1.69 GPa, respectively. On the other hand, although the crystal orientation is the same as that of the other models, the deformation in the Sqr45 nanorod occurs in the second slip system and the τ_{CRSS} is 1.00 GPa. These results indicate that the cross-section shape remarkably affects the slip deformation and that Schmid's law does not hold in the nanoscale materials. To investigate the effect of surface edge on the slip deformation, we also conducted MD simulation for nanorods with varying chamfers in square. We will discuss the detailed mechanism in the presentation.

Effects of Dynamic Segregation on Grain Boundary Migration in High-entropy Alloys

Kohei Shiotani[1*], Tomoaki Niiyama[2] and Tomotsugu Shimokawa[3]

[1] Kanazawa University, 920-1192, k.shiotani@stu.kanazawa-u.ac.jp

[3] Kanazawa University, 920-1192, simokawa@se.kanazawa-u.ac.jp

Key Words: *High-entropy alloy, Molecular dynamics, Grain boundary, Segregation, Solute-drag*

High-entropy alloys (HEAs), which are solid solution materials obtained by mixing more than five elements with near equiatomic fractions, have attracted significant attention because of their excellent mechanical properties such as thermal stability at high temperatures [1]. The excellent thermal stability of HEAs needs to suppress the activation of grain boundary (GB) migration that causes grain growth. Hence, understanding a detailed atomic behavior at GBs in HEAs is indispensable to elucidate the mechanism realizing the thermal stability of HEAs. Elemental segregation to GBs, where equiatomic fraction breaks, have been reported in HEAs [2]. This suggests that dynamic GB segregation and drag of atoms might occur when the migration of the GBs is sufficiently slow. These dynamic phenomena could increase a driving force required for the continuous GB migration. However, it is not easy to capture the dynamic behavior of atoms using only experimental approaches. In this study, we investigate the influence of the dynamic GB segregation on the GB migration in HEAs through molecular dynamics (MD) simulations.

Equiatomic FeNiCrCoCu-HEAs with a Σ17(530)[001] high-angle tilt GB is modeled with interatomic interactions developed by Farkas *et al* [3]. The GB is moved by an applied shear strain parallel to the GB plane. In this study, we investigate GB velocity dependence of GB migration through controlling shear strain rate. These simulations are performed at $T = 0.85\ T_m$, where $T_m = 2090$ K is melting temperature of the HEAs. For the comparison with HEAs, we conduct the same analyses with an interatomic potential of pure Cu developed by Mishin *et al* [4].

The GB migrates at various velocities from 0.07 m/s to 15 m/s under different driving forces. In pure Cu, the relation between the GB velocity and the driving force is almost linear. The HEA also exhibits the same linear relation, but the susceptibility of the GB velocity to the driving force in the low GB velocity region significantly smaller than that in the high-velocity region. We confirm dynamic GB segregation occurs in the low-velocity region. The effect of the segregation on the GB migration could be explained in terms of the reduction of atomic diffusion at GBs because the GB migration requires atomic rearrangements at the GBs which would be reflected in the atomic diffusion. To examine the effect of GB segregation on GB migration, we compare the activation energy of the atomic diffusion under no external load between two types of GBs; a GB where the elements are assigned randomly and a GB where the elements are assigned closely to thermal equilibrium obtained by a hybrid procedure of Monte Carlo and MD simulations. The later GB distribution mimics the composition of the dynamically segregated GB. The activation energy of diffusion in the thermally equilibrated GB is higher than that in the randomly assigned GB. Therefore, the dynamic GB segregation increases the energy barrier for GB diffusion, which can be related to an increase in the driving force required for the GB migration at lower velocities.

Key Words: *Deformation Twin, Nucleation, Magnesium, Nudged Elastic Band Method*

Magnesium has attracted much attention from engineering viewpoint because of its low density and relatively high specific strength. At room temperature, magnesium has only the major slip systems of basal slip and non-basal slips are difficult to be activated. Deformation twinning is an essential mode of plastic deformation. There are two typical modes of twinning. While the critical resolved shear stress (CRSS) for the $\{10\bar{1}1\}$ compressive twinning is high, the $\{10\bar{1}2\}$ tensile twinning has low CRSS and appears in an early stage of plastic deformation, related to the low dislocation energy and the low Peierls barrier of $\{10\bar{1}2\}$ twinning dislocation [1]. Although $\{10\bar{1}2\}$ twins are considered to generate preferentially from inhomogeneous regions associated with grain boundaries and dislocations [2], understanding homogeneous nucleation of twins gives us fundamental information on $\{10\bar{1}2\}$ twinning. In this study, we energetically evaluate homogeneous nucleation of $\{10\bar{1}2\}$ twin using the nudged elastic band (NEB) method. The NEB analyses of homogeneous twin nucleation under shear strain are carried out and the shear strain dependence of the activation energy barrier is discussed. The NEB results are compared with a simple nucleation model.

Key Words: *Al alloys, Aging, Solute cluster, Density functional theory, Monte Carlo method*

Al-Mg-Si alloys are widely used in the automotive and aeronautical industries because of their excellent properties, including high strength-to-weight ratios, good formability, and high corrosion resistance. The hardness of the alloys is increased through aging, in which the formation of solute clusters and metastable precipitates hinders the motion of dislocations. During precipitation of Al-Mg-Si alloys, solute atoms diffuse and aggregate to form nanosized clusters while maintaining coherency in the matrix. Then, the metastable β" phase, which is the main strengthening phase of the alloys, begins to nucleate as the clusters grow. Because the strength of the alloys changes significantly depending on the temperature during aging [1], solute clusters formed before nucleation of the β" phase are believed to affect the resultant strength of the alloys. Therefore, identifying the specific process involved in the short-range ordering of solute atoms during aging is essential in controlling the mechanical properties of this alloy system and in designing new alloys with superior performance. A previous experimental study [2] revealed that the compositions and thermal stabilities of solute clusters in Al-Mg-Si alloys changed dramatically depending on temperature. However, the details of the atomic structures of solute clusters have yet to be clarified.

In this study, we evaluated the interaction energies between solute atoms and vacancies in the Al matrix using first-principles calculations and constructed a multi-body potential for the Al-Mg-Si system. Atomistic Monte Carlo (MC) simulations were then performed to analyze the formation behaviors and thermal stabilities of solute clusters. Equilibrium MC simulations without detailed balance [3] were conducted to simulate the thermal equilibration of the Al-Mg-Si system under various temperatures. Results indicated that the temperature range in which the solute clusters were formed was limited, and the sizes and compositions of the clusters changed temporarily with temperature. At low temperatures, the sizes of the clusters were relatively small and their compositions were widely distributed from Si-rich to Mg-rich. In addition to many small Si-rich clusters, Mg-Si or Mg-rich clusters with $L1_0$-type ordered structures were formed. However, at high temperatures, the sizes of the clusters were relatively large and their compositions asymptotically approached Mg/Si = 2 (i.e., Mg-rich) as the cluster size increased. The Mg-rich clusters formed at high temperatures also had internal $L1_0$-type structures. We found that Mg-Si or Mg-rich clusters that were initially formed under low temperatures grew under higher temperatures, whereas Si-rich clusters maintained their sizes and compositions during MC sampling. Our results on the relationship between cluster size and Mg/Si ratio were consistent with those of the experimental counterpart [4]. Our study provides a modeling approach that efficiently uses first-principles-calculated energies and an MC model in a scale-bridging manner to elucidate the thermodynamic characteristics of the formation of solute clusters.

Key Words: *Field Theory of Multiscale Plasticity, Inhomogeneity, Bauschinger effect, Crystal plasticity, Strain gradient plasticity, Finite element method*

INTRODUCTION

The Bauschinger effect intrinsically involves multiscale problems of complex kinds when it comes to its rational modeling beyond phenomenological approaches that rely on kinematic hardening laws, despite being one of the classical issues in plasticity. The associated transient and permanent softening behaviors, including apparent reduction in the elastic moduli as well as the early re-yielding phenomena, stem strongly from deformation-induced inhomogeneous fields to be developed in plural scales, e.g., intra-granularly evolving dislocation substructures and those associated with inter-granular nonuniformities.

The present study intends to tackle this issue from the persepctive of evolving inhomogeneous fields that naturally bring about irreversibilities during load reversal based on Field Theory of Multiscale Plasticity[1] (FTMP). FTMP allows us to reproduce dislocation substructure evolutions in single crystals, simply by additively introducing the incompatibility tensor-based defect degrees of freedom in an appropriate manner in the hardening law to be used.

CONDITIONS

We extend such series of simulations to polycrystal models under tension-compression straining, with 163, 613, 1351, and 2377 grains, respectively, by allocating six typical orientations of $(100)[001]$, $(110)[001]$, $(100)[011]$, $(\bar{1}\bar{1}0)[\bar{1}10]$, $(1\bar{1}0)[111]$, and $(11\bar{1})[123]$ randomly to them, where the intragranular substructure evolutions are simulated simultaneously.

RESULTS AND CONCLUSION

The transient softening tends to appear even in the 163 model and is shown to be enhanced with increasing number of grains, while the permanent softening seems to require sufficent number of grains for it to naturally emerge. Contributions from intra and inter-granular inhomogeneities are examined by carefully separating each by taking differences among simulation results obtained under selected conditions with and without the incompatibility models.

At the same time, the associated energy conversions from elastically-stored states to local plastcity measured by variations of the incompatibility is scrutinized based on duality diagram representation scheme, where the diagram is constructed by plotting the incompatibility trace against the fluctuation of the elastic strain energy. SThe ratio of the ordinate to the abscessa of the diagram at the maximum tension, referred to as duality coefficient, representing the energy conversion rate, is demosntrated to correlate well the Bauschinger strain, as a measure of transient softening. This eloquently implies that the irreversibilities causing transient softening stem majorly from the inhomogeneous fields evolved during the forward loading.

The comparison among the four models is further made to systematically examine the effect of inter-granular inhomgeneities on the transient softening.

Key Words: *Mille-feuille structure, Kinking, Crystal plasticity, Finite element analysis, Single crystal, Elastic energy*

Kink-strengthening for mille-feuille structures has attracted many attentions in recent years. This study aims at identifying the kink formation/strengthening mechanisms via numerical reproductions of emerging kink-like morphologies. Reproducing ridge kink morphologies and the attendant strengthening for a single crystal Mg model are explored based on CP-FEM devised with FTMP (Field Theory of Multiscale Plasticity). In FTMP, defects in a crystal are considered as torsion and curvature, and these are calculated as dislocation density tensor and incompatibility tensor in continuum mechanics. By introducing these two into the hardening ratio in the hardening development law, the theory can reproduce the heterogeneous deformation inside the material. The incompatibility tensor-based relevant underlying microscopic degrees of freedom satisfying rank-1 connectivity condition, referred to as "kink model," is introduced either explicitly or implicitly to the conventional slip-based constitutive framework. The use of the explicit model exhibits realistically-resembling ridge kink morphologies. The energy release associated with the kink also approximates the results observed in experiments. whereas the implicit model allows raised stress response accompanied by relatively heterogeneous kinking structures, provided appropriate initial imperfections as well as mille-feuille structures that can effectively store excessive elastic strain energy. We have predicted that the mechanism of kink generation is the mutual exchange of energy stored in each of the hard and soft layers. The simulation results described above include an experimentally-observed unique feature reported based on the AE (acoustic emission) technique, demonstrated to exhibit power-law type distributions both in the strain energy fluctuation and the incompatibility from the early stage of deformation even before the massive emergence of kink-like regions, analogous to the AE observations. They lead us to tentatively conclude that the layered structure associated with the incompatibility-based relevant degrees of freedom, in addition to a sufficient constraint of the basal slip activity, can play pivotal roles in reproducing the targeted feature. Extended discussions of all the above are further made via the corresponding duality diagram and scale-free representations. Also demonstrated is a successful reproduction of the peculiarly-deformed specimen under slightly-inclined tension experimentally observed recently, shown to brought about by kinking deformation as well. This further backs up the validity of our simulation model.

Influence of Interface Properties and Misfit Dislocation Networks on The Stress Fields in Multilayered Material

Hideo Koguchi[1*]

[1] Niigata Institute of Technology, 945-1195, hkoguchi@niit.ac.jp

Key Words: *Multilayered Materials, Misfit Dislocation Networks, Interface Properties*

Anisotropic multilayered materials in a nanoscale thickness have been applied to the electronic devices such as a semiconductor, sensors, MEMS and NEMS. Misfit dislocation networks frequently occur at the interface in multilayered structures composed of different crystal structures. Furthermore, atomic structures near the interface are different from each bulk structure. The interface energy occurs in a similar manner to the surface energy[1]. Then, the interface energy can be expressed a function of surface strain. The interface stresses and interface elasticity originated from the atomic structures near the interface are calculated from the first derivative and the second derivative of the interface energy with respect to the interface strain. In the present paper, the interface properties, such as the interface stresses and interface elasticity, are obtained using the molecular statics analysis. On the other hand, stress and displacement fields for the multilayered structures with misfit dislocation networks are deduced using a three-dimensional Stroh's formalism[2][3]. Until now, the transfer matrix method was usually applied for analyzing the stress and the displacement around a misfit dislocation at the interface in the multilayered materials[4]. When the interface properties are taken into the boundary condition at the interface, the transfer matrix method cannot be used. So, a new method is needed to develop for the analysis. Furthermore, when the boundary conditions for the top surface and the bottom surface are prescribed, the unknown vectors using in the displacement and traction expressions become very complicated. In the present analysis, a simplified expressions for the unknown vectors including all boundary conditions, such as the interface properties, are deduced through some recursive formulae of the *m*-th layer. Then, the expressions for displacement and traction for arbitrary number of layer could be explicitly deduced. The procedure for the expressions can be extended to isotropic materials. The interaction of misfit dislocation networks existing at different interface is investigated and also the influence of the interface properties on the interaction is clarified. The stress and displacement fields for the derived solutions are compared with those obtained by the molecular statics analysis to demonstrate the validity of the solutions.

Key Words: BCC iron, Dislocation, Obstacle, neural network atomic potential

Interaction between dislocations and obstacles, such as void and precipitates are important in the strength of BCC iron. Because of size of dislocation core which is typically less than 1 nm, the investigation of the interaction between dislocations and obstacles requires the use of atomic modeling. Because of long range elastic interaction of dislocations, atomic modeling for dislocation dynamics require usually 100,000$\sim$ atoms. Therefore, usually, empirical atomic potentials, such as embedded atom method (EAM) are used for investigation of dynamic interactions between dislocations and obstacles. However, the predicted structure and energetics of the dislocation core by empirical inter-atomic potentials are not consistent with the results of first principles calculations based on density functional theory (DFT). Thus, the exact details of the interaction between dislocations and obstacles are still obscure. To overcome this problem, we constructed the atomic potential with DFT accuracy based on an artificial neural network (ANN) framework. [1]. In this research, by using the ANN potential, to investigate the interaction between edge dislocation and obstacles, we performed 1000,000 atoms molecular dynamics simulation with DFT accuracy.

This study was partially supported by JSPS KAKENHI Grant Numbers JP 21K04631.

Key Words: *Local stiffness, MAX phase, First-principles calculation, Atomic stress*

In recent materials science, controlling heterogeneity, where different microstructures coexist in a single material, has been regarded as a fundamental strategy to achieve both strength and durability in structural materials. The elastic state is also spatially inhomogeneous in such structures; however, any computational method has not yet been established to reveal such an inhomogeneous elastic state at the atomic level.

We have developed a local stiffness calculation scheme based on the first-principles atomic stress calculation [1][2] and have applied this method to the MAX phases, Ti_3AC_2 (A = Al, Ga, In), which possess an atomic-level stacking structure (Fig. 1). As shown in Table 1, the computational results obtained by this scheme properly represents the difference between the soft layer (Ti-A-Ti) and the hard layer (Ti-C-Ti-C-Ti) inside the MAX phases. In the presentation, we will discuss the details of the local stiffness calculation and the electronic structure of the MAX phases behind their local stiffness.

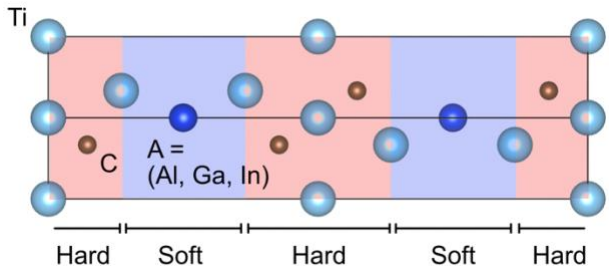

Fig. 1: Layered structure of Ti_3AC_2 MAX phase.

Table 1: Local stiffness [GPa] of Ti_3AC_2.

A	Layer	C_{11}	C_{33}	C_{44}
Al	Hard	427	335	133
	Soft	315	304	129
Ga	Hard	427	393	149
	Soft	311	262	119
In	Hard	398	362	137
	Soft	300	227	92

Key Words: *FTMP, Compression test, Plastic deformation, Slip, Dislocation, Simulation*

This study attempts to clarify a sort of an application limit of FTMP (The Field Theory of Multiscale Plasticity) [1] in describing semi-discrete microscopic processes of dislocations, through a systematic series of simulations on micropillar compressions against single crystal samples. Micropillar tests [2] have been recently attracted attentions as a direct measure to tangibly investigate mechanical properties of materials in micrometer regions, and have been further extended to nanometer regions. The marked features include intermittent as well as isolated nucleation and expansions of dislocation loops generated from a limited number of sources that are statistically pre-existed within the sample to be tested, resulting in extremely high yield stress followed by strain bursts with eventual terminations due to source starvations [3], leaving finely and massively stepped surface morphologies through which dislocation loops had been passed away. FTMP, on the other hand, possessing prominent descriptive capabilities for deformation-induced inhomogeneities of evolving kinds, has been demonstrated to enable crystal plasticity-based finite element (CP-FE) simulations to easily and naturally reproduce dislocation substructures with various morphologies and the associated misorientation developments, simply by adding the incompatibility tensor-related appropriate defect degrees of freedom to the hardening law being employed,[1] and recently has been successfully applied also to "kinking" related stuff in Mg, including both their formations and contributions to the strengthening. Here, we perform some preliminary approaches aiming at reproducing the above features, assuming a 2D single crystal sample with nearly ideal strength, equipped with a few regions having high Schmid factor, as a source of dislocation generations. Demonstrated tentatively are expanding dislocated regions at the onset of the first strain burst, as well as the resultant emergence of surface steps. The results are further examined in detail by visualizing the energy transfer from elastically-stored states to local plasticity via the variation of the incompatibility field, by using duality diagram representation scheme, where the diagram correlates the trace of the incompatibility tensor with the fluctuation of the elastic strain energy. There observed an abrupt increase in the incompatibility with strain energy fluctuation nearly unchanged at around the onset of the strain burst, representing a nucleation of a set of dislocations from one of the introduced source regions. The completion of the present study will greatly extend the wing of the possibilities of continuum mechanics-based top-down approach toward micro-plasticity.

Key Words: *Screw Dislocation, Size Dependent, Differential Geometry, Finite Element Method*

In this research, we investigate the size dependent elasto-plastic deformation of screw dislocations in a nano-scale object. Our method is based on the continuum mechanics on the Riemann-Cartan manifold [1-3]. This mathematical framework introduces the three different configurations, reference R, intermediate B, and current S configurations, in order to express the elasto-plastic deformation. Here, the first map, from R to B, represents the plastic deformation and the second one, from B to S, corresponds to the elastic relaxation. The total deformation gradient is expressed by the multiplicative decomposition of the respective deformation gradients: F_p and F_e.

For a given distribution of the dislocation density, we solve the weak form of Cartan first structure equation to obtain the plastic deformation gradient F_p and Riemannian metric of the intermediate state B. The elastic deformation gradient F_e is then obtained from the minimization of strain energy functional. Note that, from a mathematical viewpoint, the elastic deformation is understood as the embedding of the Riemann-Cartan manifold into the conventional Euclidean space. We solved the variational problems numerically using the finite element method.

We investigated the stress and displacement fields of screw dislocations in a three-dimensional rectangular bar with the aspect ratio 1:1:10. Size of the bar is in the order of nano meters. The first model includes a single screw dislocation whose Burgers vector and dislocation line is set parallel to the longitudinal direction. Present numerical analysis revealed that the stress fields show no singularity even at the dislocation core. Deformation fields showed novel twisting phenomenon, which is called Eshelby twist, and the magnitude showed notable size dependence. That is, magnitude of the twisting angle increases monotonically with decreasing the size. The second model includes five twist boundaries along the longitudinal direction. Here, each boundary includes a pair of screw dislocations whose dislocation lines cross perpendicular in the boundary planes. Numerical analysis showed similar twisting as well as the size dependence of deformation. We will discuss the similarity of the two different configurations of screw dislocations from a view point of the differential geometry.

Key Words: *Diamond-like Carbon, Deposition Process, Residual Stress, Mechanical Property, Molecular Dynamics*

Diamond-like carbon (DLC) film has superior tribological properties such as low friction and high wear resistance. However, one of the major problems with DLC films is the delamination during operation, which reduces the adhesion strength. High residual stress inside the film is reportedly one of the causes of DLC film delamination [1]. Thus, it is essential to elucidate the mechanism of residual stress generation in a DLC film during deposition. Numerical simulation studies for such mechanism are indispensable [2] as the experimental measurement of residual stress is challenging.

Recently, we elucidated through molecular dynamics (MD) simulations the residual stress mechanism in a DLC film during the deposition of carbon on a diamond substrate [3]. We performed the MD simulations using LAMMPS, which is a free and open-source software for classical molecular dynamics. Here, we found that the compressive stress in the film is caused by the structural change from sp^2 to sp^3 during the deposition process. As the bond length of sp^3 structure is larger than that of sp^2, the structure transition from sp^2 to sp^3 and the growth of sp^3 cluster causes the compression stress in the film.

In this study, the deposition processes of carbon on an Fe substrate were simulated by MD using LAMMPS. We compared the results with our previous work with a diamond substrate [3] to investigate the effect of substrate material on the stress generation in the DLC film.

While the fatigue mechanism in macroscopic metal materials is well described by self-organization of dislocation structures, presumably such a description can no longer account for fatigue in nanometer- or submicron-sized materials because the dimension of a specimen is smaller than that of slip bands consisting of dislocation structures [1,2]. The fatigue mechanism of materials with nanometer or submicron dimensions, which we call "nano-micro fatigue", has been little understood, urging establishment of theories to explain the mechanism.

To tackle this fascinating but challenging problem, we are performing multiscale simulations covering the atomistic, mesoscale and micrometer scale levels. We first discuss atomistic model simulation with molecular dynamics (MD) of single crystal nano-sized metal models to observe dislocation behaviors under monotonic and cyclic loading. In a MD simulation of nanofilms under cyclic loads, we found slip localization when the initial structure contained distributed vacancies while slip deformations were almost evenly distributed in a pristine model, indicating an increased fatigue strength in nanometer-sized specimens where few defects are expected. We also performed a MD simulation of nanorods to find some peculiar behaviour at the nanoscale; e.g., activation of different slip systems depending on the temperature, nontrivial effects of surface edge structure on slip behavior, etc.

We are also performing simulation of dislocation structure formation by means of the rate equation approach, which solves differential equations of the development of density distributions of mobile and immobile dislocations under mutual interactions [3]. Using a thin film model, we confirmed that certain combinations of input parameters such as dislocation diffusivities and mobile-immobile dislocation interactions produce formation of aligned dislocation density peaks with certain distances between them, which is indicative of the dislocation wall structure. Whether the formation occurs and the dislocation structure (e.g. distances between dislocation walls) depend on the parameters. As it is difficult to determine the parameters for the phenomenological model, we constructed an artificial neural network (ANN) model to map between input parameters of a simulation method and output simulation results, which enables us to find parameters that result in realistic dislocation structures observed in experiment.

Key Words: *Skyrmions, Phase-field model, Temperature, Topological defect, thermodynamics*

Controlling static and dynamic behaviors of the bubble-like magnetic skyrmion exhibits great potential in the application of spintronics. Especially, as a natural property, temperature plays an important role in the control of skyrmion behaviors. For example, statically, the temperature can lead to the phase transition of the topological magnetic structures (such as skyrmions) by affecting their stability; dynamically, fluctuated or inhomogeneous temperature fields can drive the skyrmion motion. However, due to the limitation of existing hypothesis-based simulation methods, the study of temperature-related behaviors of skyrmions from the perspective of thermodynamic free energy is rare. Here, we developed a temperature-related phase field simulation to predict and explain the skyrmion behaviors in temperature fields. Statically, we demonstrate the skyrmion lattice of a room-temperature ferromagnetic thin film lose the thermal stability near the 340 K, and obtain the temperature-magnetic field-strain phase diagrams of topological structures in MnSi thin film, which consists with the experimental results very well. Dynamically, we study the rectilinear motion of the individual asymmetrical skyrmion driven by temperature gradients, i.e., acceleration and deacceleration of skyrmions, and propose a kinematic equation to describe it. Therefore, our work demonstrates the temperature-related phase field simulation is a reliable method to simulate the skyrmion behaviors in temperature fields, and propose the thermodynamics explanation on both static and dynamic features of skyrmions, which is anticipated to be the theoretical support for further research about temperature-related behaviors of skyrmions, i.e., elementary development of topological defect dynamics, and their potential applications in functional devices.

Key Words: *High entropy alloys, Crystal plasticity, Finite element analysis, Rolling texture, Mechanical anisotropy*

The crystal plasticity FE analysis considering the microscopic information describes the mechanical response of polycrystalline metals at the grain level. When the crystal orientation information of the actual material is applied to the analytical model for the crystal plasticity FE analysis, the crystal orientation is often randomly extracted from the EBSD measurement data. The number of crystal grains in crystal plasticity FE analysis is limited to a small number compared to the actual crystalline metals due to the problem of calculation cost. The conventional method of randomly selecting the crystal orientation does not reproduce the analytical model, and it results in significant variations in the analytical results depending on the combination of crystal orientation. It is essential from the viewpoint of computational cost to reproduce the crystal orientation distribution of the actual material in an analytical model with a small number of grains.

In addition, the rolling texture induced by the rolling process significantly affects the mechanical properties of rolled metals, and mechanical anisotropy caused by the rolling texture appears. Numerical reproduction of the rolling texture of the actual material reproduces the mechanical anisotropy of rolled metals in a crystal plasticity FE analysis.

This study investigates a method to reproduce mechanical anisotropy by accurately reflecting the rolling texture in an analytical model with a small number of grains for crystal plasticity FE analysis. We propose a method to extract the crystal orientation representative of the rolling texture from the crystal orientation measured by EBSD and reflect it in the analytical model. Using the presented method, we perform crystal plasticity FEM analysis. Based on the analysis results, the validity of the proposed model is discussed in comparison with conventional methods.

Room-temperature deformation behavior of semiconducting crystals

Key Words: *Dislocations, Plastic deformation, Photomechanical effects, Photoindentation*

Generally, non-metallic compounds called ceramics and semiconductors are known to be brittle. This is partly due to the high Peierls potential, which cause higher force required for the motion of the dislocations responsible for plastic deformation. Recently, it has been reported that such materials can exhibit large plasticity even at room temperature by controlling the internal microstructure and/or outside external field. For example, we reported that quick room temperature deformation can be realized in strontium titanate ($SrTiO_3$) by using the internal elemental ratio close to the stoichiometric composition [1]. Also, we demonstrate a reversal of yield stress for $SrTiO_3$ crystals with different point defect concentrations and existing dislocation densities [2]. On the other hand, it was found that extraordinarily large plasticity appears in bulk compression of single-crystal ZnS in complete darkness even at room-temperature [3]. This is believed to be due to the less interactions between dislocations and photo-excited electrons and/or holes. However, methods for evaluating dislocation behavior in such materials with small dimensions under a particular light condition had not been well established. Therefore, we proposed a new nanoindentation method that incorporates well designed lighting system for exploring dislocation behavior depending on the light conditions in advanced semiconductors [4]. Then, we also used ZnS as a model material because its bulk deformation behavior has been well investigated. It is confirmed that the decrease of dislocation mobility with light observed in conventional bulk deformation tests can be understood even by the nanoindentation tests at room-temperature. It is remarkable that dislocation mobility appears to be more sensitive to light exposure than dislocation nucleation. Thus, we have investigated methods to plastically deform brittle materials and the effects of the internal microstructure and/or outside external field condition on the dislocation behavior. It is also attractive that the deformed brittle materials have a potential to exhibit unusual functional properties due to the special electronic states at around the dislocations cores [5-6].
