Key Words: *Crystalline polymers, Polylactic Acid, Spherulite, Mechanical Properties, Monte Carlo Simulation*

Thermoplastic polymers are increasingly being used in a wide range of fields because of their light weight, low cost and excellent formability. Crystalline polymers, which means thermoplastic polymers with semicrystalline phase, have a mixture of a crystalline phase with a stable folding structure of molecular chains and an amorphous phase with a disordered structure on a microscopic scale. These two layers are alternately stacked to form a structure: lamellar crystal. In addition, it is known that lamellar crystals grow radially to produce a crystalline structure, which is called a spherulite. The mechanical properties of crystalline polymers are closely related to the dimensions of the spherulite and the crystallinity, and the morphology of spherulite depends on the molding conditions such as temperature and pressure.

Evaluation of the effect of the spherulite microstructure on the mechanical properties of crystalline polymers can improve the accuracy of structural analysis. Various studies have been conducted on microstructure and crystallization models. However, since the spherulite is a complicated structure composed of amorphous and crystalline phases, the effects of actual molding conditions on spherulite microstructure formation and changes in mechanical properties depending on spherulite microstructure remain to be clarified.

This study investigates a simulation model predicting spherulite microstructure formation based on experimental observations. The crystallization process of polylactic acid is observed at different molding temperatures by in-situ observation, and the rate of spherulite formation and growth is estimated. Furthermore, according to the Turnbull-Fisher primary nucleation model and the Lauritzen-Hoffman secondary nucleation model, Monte Carlo simulations of spherulite microstructure formation are performed based on the obtained experimental results. The validity of the method is verified by a comparison of the simulated and the experimental results.

Study of Kink Strengthening of Polymer Materials with Mille-feuille Structure Based on FTMP Extended to Finsler Space

Key Words: *Field Theory, Mille-feuille Structure, Polymer Material, Kink Strengthening, Crystal Plasticity*

FTMP framework has been extended to that in Finsler space, allowing it to additionally accommodate vectorial fields to be interpreted as "network microscopic degrees of freedom" representing "free volume" for modeling amorphous polymers. By utilizing thus extended FTMP, we perform here a systematic series of parametric studies of mille-feuille structured polymeric materials with different shear strength levels to investigate the conditions for the hard layers to yield "kinking" or fold buckling. Transverse stretching are subsequently carried out to further examine whether or not thus developed kinked mille-feuille structures can contribute to the additional strengthening. Demonstrated is the positive contribution to the stress rise, provided moderately kinked layers are formed during the pre-tension process, whereas over-stretched case tends to yield sudden stress drop accompanied by accelerated strain energy release, confirmed visually on the corresponding duality diagram, as well as physically via damaged region appeared on the corresponding strain energy fluctuation contour. For further examining the distinction between the two conditions, we performed extended simulatoins focussing exclusively on the MFS areas with and without a surrounding thin layer. A severely damaged region emerges in the late stage of transverse stretching for the overstretched model w/o thin layer, manifested as sudden volumetric strain burst, affecting also the free volume distribution, bringing about steep incompatibility rise on the duality diagram, whereas thin-layered model is shown to greatly mitigate the trend. This implies that the damage produced in the MFS region has been converted to the matrix in the full model, bringing about eventual stress drop.

Key Words: *Data Assimilation, Phase-field Method, Molecular Dynamics Method, Interfacial Property Inference, Solidification*

Dendrites are a typical growing morphology for determining solidification microstructures. The phase-field method is the most accurate numerical model for expressing dendrite growth. However, there are serious issues in phase-field simulations of dendrite growth, such as the lack of solid–liquid interfacial properties of interfacial energy, interfacial mobility, and those anisotropy. Nevertheless, a conclusive prediction method of the interfacial properties has not been developed yet.

Recently, Ohno et al. [1] developed an inference method of the interfacial properties using data assimilation and phase-field method based on temporal change of solidification microstructures obtained by molecular dynamics simulation. This method can predict multiple interfacial properties simultaneously without setting special computational conditions. Nagatsuma et al. [2] also inferred the interfacial properties of a pure Ni through data assimilation.

In this study, we systematically infer the temperature-dependent interfacial properties of some pure metals through data assimilation. The temporal changes of solidification microstructures, which are used as the observation data, are obtained by molecular dynamics simulations using LAMMPS. Data assimilation is conducted based on the ensemble Kalman filter. To accelerate data assimilation with a massive number of phase-field simulations, we conduct parallel computations using multiple graphics processing units.

Key Words: *Plasticity, Nanoindentation, Pop-in, Power law, Molecular dynamics simulation*

Power laws are omnipresent and actively studied in many scientific fields, including microscale plasticity of materials. Recently, it was found that the magnitude distribution of second and subsequent pop-ins during load-controlled nanoindentation testing for body-centered cubic (BCC) iron (Fe) and face-centered cubic (FCC) copper (Cu) at room temperature obeys a power law in our previous study [1], and the obtained scaling exponent values were ≥ 3.0 and experimentally described to be much higher than those typically observed in micro-pillar plasticity, which are less than 2.0 [2][3]. Although the tendency of the exponents is partly suggested also in nanoindentation molecular dynamics (MD) simulations, systematic simulations, which are done in different temperatures and materials, have not been conducted yet. Further, although we suggested a theory of power law distribution for the pop-in size [1], the validity is still unknown.

In this study, we conduct a statistical analysis of pop-in magnitude in nanoindentation MD simulations for BCC Fe at 5, 300, 500, and 700 K and FCC Cu at 5 K. The obtained distributions of second and subsequent pop-in magnitudes follow power-law distributions. The values of scaling exponents are more than 3.0 for all the cases and decrease with temperature increases for BCC Fe cases. The results agree with the nanoindentation experiments and the suggested theory [1]. Furthermore, we discuss the validity of the theory by estimating the activation volume of dislocation migration from the equation in the theory and the simulation results. Including the previous study, we believe that the power law distribution seen in the nanoindentation pop-in magnitude provides a new insight into micro- and nanoscale plasticity in materials.

Key Words: *Rubber, foam, nonlinear viscoelasticity, model*

In order to better represent the volumetric time-dependent of foamed rubber, we examine the spherically symmetric response of a spherical shell comprised of an incompressible, hyperelastic material. The material is considered to be represented by a Parallel Rheological Framework as described by Hurtado *et al*. [1] with two networks which each have a Neo-Hookean elastic response. One of the networks has a power law viscoplastic response as well, allowing an elastic-plastic decomposition of the deformation gradient. We develop a solution algorithm to update the elastic Cauchy-Green tensors in the elasto-viscoplastic network at any given radial location based on the previous values at the point and a radial deformation applied on the outer surface of the sphere.

A numerical integration scheme is then demonstrated to update the total radial stress on the outer surface of the sphere approximately based on the internal stresses and radii at appropriate radial quadrature points. This approach is then used to describe the volumetric time-dependent response in a mechanical constitutive model for foamed rubber as an extension to the CHIPFoam model by Lewis [2]. Note that this model is appropriate for materials with moderate to high relative densities (0.3-0.99).

Influence of the Pore Structural Parameters of Thermal Barrier Coating on its Modulus and Thermal Insulation

Fan Sun[1*], Peng Jiang[1]

[1] State Key Laboratory for Strength and Vibration of Mechanical Structures, School of Aerospace Engineering, Xi'an Jiaotong University, Xi'an, China, sf2038945624@stu.xjtu.edu.cn

Key Words: *Thermal barrier coating, Modulus, Thermal insulation, Microstructure reconstruction method, Pore structural parameters*

Thermal barrier coating (TBC) is one of the key thermal protection system for high-temperature components in gas turbines and aeroengines. Modulus and thermal insulation are two vital parameters that affect the performance and durability of the TBC system, which are close relative to the pore structural parameters (porosity, pore size, pore distribution, etc.) and has gained a lot of attentions in recent ten years [1]. While, to date, the influence of TBC's pore structural parameters on its performance is mainly theoretically investigated with ideal homogeneous pore model, or using local-image-based finite-element analysis method. These researches are not sufficient to statistically catch the real TBC's microstructure characteristics and reveal the specific performance of TBC with diverse pore structural parameters. Thus, in this work, a real-pore-microstructure-reconstruction method [2] is adopted to build the TBC's microstructure models with different porosities, pore sizes and pore distributions. Then the finite element method is used to study the variation of Young's modulus and thermal conductivity with pore structural parameters. It is found that [3], the microstructure with larger porosity and smaller pore size makes TBC the lower thermal conductivity, lower Young's modulus, providing better thermal insulation and thermal mismatch resistence for TBC system. In addition, the microstructure with smaller pore angle and larger pore aspect ratio has the lower thermal conductivity, and the microstructure with larger pore angle and larger pore aspect ratio has the lower Young's modulus. The above results may provide better understanding of TBC's failure mechanism, and have certain guiding significance for its future design.

Mesoscale Modeling of Carbon-Carbon Composite Manufacturing

Peter J. Creveling*, Lincoln N. Collins, and Scott A. Roberts

Engineering Sciences Center, Sandia National Laboratories, Albuquerque, NM, USA

Key Words: Carbon-Carbon Composites, Manufacturing, Mechanical Properties, Thermal properties, Chemical Properties, Finite Element Analysis (FEA)

Spacecraft experience extreme thermal, mechanical, and chemical environments during atmospheric reentry. Some vehicles use a woven carbon-carbon (C/C) composite as a heat shield, where the carbon matrix is typically derived from pyrolized phenolic resins [1]. These composites are commonly used due to their exceptional material properties within these environments to protect and ensure survivability of the vehicle interior. However, designing new C/C based components for a wide variety of applications and atmospheric conditions is challenging. Fundamental knowledge of material properties across various length scales must be known. Additionally, understanding how manufacturing ultimately dictates performance must be well characterized.

To address the above challenges, we developed a mesoscale (tow-length scale) model of an idealized C/C composite geometry that simulates the manufacturing process. The geometry consists of woven tows impregnated with and surrounded by a resin, where the resin is modeled as a porous material. Decomposition of the resin is based on the Arrhenius equation, while pressure from pyrolysis gas formation are governed by Darcy's law and the ideal gas law for gases within open and closed pores, respectively. Mesoscale material properties are approximated using measurements of individual constituents, effective medium theory [2], and the Biot coefficient for porous solids [3].

A parametric study was performed to investigate the relationship among model input parameters and local stress concentrations. Initial results show a large increase in internal stresses during heating due to gas phase pressurization and shrinkage of the phenolic resin. While internal stresses continued to increase during cooling, they were small comparatively. Increasing the heating ramp rate had a large effect on the resulting stress, while little change occurred from varying the ratio of open to closed porosity.

Elasto-plastic evolution of single crystals driven by dislocation flow

Thomas Hudson[1*] **and Filip Rindler**[1]

[1] Mathematics Institute, University of Warwick

Key Words: Dislocations, Crystal plasticity, Topological defects.

A model for large-strain, geometrically nonlinear elasto-plastic dynamics in single crystals will be presented. The key feature of this model is that the plastic dynamics are entirely driven by the movement of dislocations, that is, 1-dimensional topological defects in the crystal lattice. It is well known that glide motion of dislocations is the dominant microscopic mechanism for plastic deformation in many crystalline materials, most notably in metals. However, a comprehensive model linking the dynamics of individual dislocations to elaso-plastic evolution has been missing to date.

A geometric language is proposed, built on the concepts of space-time "slip trajectories" and the "crystal scaffold" to describe the movement of (discrete) dislocations and to couple this movement to plastic flow. The energetics and dissipation relationships in our model are derived from first principles drawing on the theories of crystal modeling, elasticity, and thermodynamics. The resulting force balances involve a new configurational stress tensor describing the forces acting against slip. In order to place our model into context, it can be shown that several laws known in special cases before can be recovered, most notably the equation for the Peach–Koehler force (linearized configurational force) and the fact that the combination of all dislocations yields the curl of the plastic distortion field.

The mathematical framework developed has enabled existence proofs for some special cases of the model, and the development of new tools in geometric measure theory. Details of these are referenced below.

[2] Mathematics Institute, University of Warwick, Coventry CV4 7AL, United Kingdom; e-mail: F.Rindler@warwick.ac.uk; web: http://www.warwick.ac.uk/filiprindler

Key Words: Dislocations, crystal plasticity, elasto-plastic evolution, topological defects

This talk presents a novel geometric language [1, 2] to describe the movement of dislocations, which is built on the concept of space-time *slip trajectories*, that is, the 2-dimensional surfaces "traced out" by the dislocations as time progresses. This in particular allows one to compute all relevant quantities (Burgers vector, slip velocity, dislocation orientation, etc.) in a straightforward way and thus to directly couple the dislocation dynamics to plastic flow. One decisive feature of this approach is that it retains more information than the corresponding Kröner dislocation density tensor (which can be computed from the geometric description, but not the other way round).

The geometric language can furthermore be made mathematically rigorous, furnishing a "weak formulation" of the equations describing dislocation motion. This then enables a proof [3] of the well-posedness of the associated rate-independent (quasi-static) system of large-strain elasto-plastic evolution driven by dislocation flow.

Modeling Frictional Behavior in Rupture Dynamics using Field Dislocation Mechanics

Abhishek Arora[1*], Amit Acharya[2] and Jacobo Bielak [3]

[1] Carnegie Mellon University, Pittsburgh, PA 15213, aarora2@andrew.cmu.edu
[2] Carnegie Mellon University, Pittsburgh, PA 15213, acharyaamit@cmu.edu
[3] Carnegie Mellon University, Pittsburgh, PA 15213, jbielak@cmu.edu

Key Words: Rupture Dynamics, Dislocation Mechanics, Static and Dynamic Friction, Short slip

We model important physical observations in rupture dynamics including static and dynamic friction, short-slip and slip obtained via crack-like models, using field dislocation mechanics (FDM). FDM is a non-linear pde based model of the mechanics of dislocations, where individual dislocation are treated as a continuously distributed field, instead of singular lines, and the plastic deformation is accounted for due to motion, interaction and nucleation of dislocations [1].

We utilize an ansatz to produce an exact, reduced, plane model of FDM, where the dislocations are allowed to move in a planar fault layer (which is sandwiched between elastic blocks), as initially developed by Zhang et. al (2015) [1]. The model yields a non-linear Hamilton-Jacobi (H-J) equation for the evolution of plastic shear strain enabling the representation of a propagating rupture front. The plastic strain in the fault layer is assumed to damage the elastic modulus behind the rupture front. This leads to an energetic driving force contribution for evolution of plastic strain that was noted, but not accounted for, in the rupture-related simulations in [1]. Here, we account for this driving force to complete the self consistent evaluation of the rupture model. The H-J equation for front propagation is solved using an implementation of a *Central-Upwind* scheme developed by Kurganov et. al (2001) [2].

Our simulations recover static and dynamic friction laws as emergent features of our continuum model, also resembling the Mohr–Coulomb failure criterion for geomaterials, including well-defined features of cohesion and friction angle. As in earlier work [1], we are also able to recover the short-slip with lesser 'elastic damage' behind the front, as well as the square-root dependence of slip on time for the greater damage (crack like model) case with the present algorithm.

Key Words: *First Principles Calculation, Adsorption of Gas Molecules, Graphene, Strain, Electrical Resistance,*

Graphene has been suggested to be capable of detecting gas compositions in a person's breath to diagnose sickness down to the ppb-level [1,2], because of its large surface-to-volume ratio and high carrier concentration. The resistance of graphene was found to change clearly due to the adsorption of gas molecules such as CO, NO_2, and so on. When plural different molecules adsorb on graphene at the same time, however, it is impossible to identify the adsorbed molecules individually. The development of the selectivity of the adsorbed molecules, therefore, is indispensable for applying this gas-adsorption-induced resistance change of graphene to a health monitoring sensor. Since the mixed gas in a person's breath is a natural environment, understanding how to detect a target object selectively is of permanent interest to the development of novel gas sensors. Recently, it was found that the effective activation energy of chemical reactions varies drastically under the application of mechanical stress and strain [3]. This result indicates that the adhesion energy of gas molecules can be shifted from negative one to positive one under the application of appropriate strain.

In this study, the strain-induced change of adsorption behaviour of gas molecules on graphene was analyzed by using first-principles calculation to achieve selective detection of gas molecules. First, the optimal adsorption positions for each gas molecule (CO, H_2O, NH_3 and NO_2) on graphene were determined by using adsorption energy E_{ad} and Bader charge transfer ΔQ. Then, change of the E_{ad} and ΔQ was analyzed under the application of uniaxial strain to graphene from -10% to 10%. It was found that both values changed almost linearly with the applied strain. In addition, there was a critical strain of each molecule at which adsorption energy changed from negative value to positive value, in other words, adsorption behaviour changed to desorption behaviour. This result clearly indicated the possibility of the selectivity of gas molecules which adsorb on graphene by applying appropriate strain. The change of the current-voltage (I-V) relation of graphene under the adsorption of gas molecules was also analyzed using nonequilibrium green's function (NEGF) formalism. It was confirmed that the I-V curves altered obviously with the change of the adsorbed molecules and applied strain. These findings clearly showed that the adsorption behaviour on graphene can be tuned by external strain for multi-object detection, paving the path for graphene-based gas sensor in biosensing applications.

Theoretical study on strain-controllable electron transport properties of dumbbell-shape graphene nanoribbon

Ken Suzuki[1*], Qinqiang Zhang[1], Hideo Miura[1]

[1] Fracture and Reliability Research Institute, Graduate School of Engineering, Tohoku University, Sendai Japan, [1*]kn@rift.mech.tohoku.ac.jp

Key Words: *graphene nanoribbon, dumbbell-shape, strain-controlled, atomic seamless interface, first-principles*

Abstract:

When a graphene is cut into a narrow ribbon with nano-scale width, referred to as graphene nanoribbon (GNR), a GNR starts to show semiconductor properties. To employ a semiconducting GNR as the device element, a metal electrode must be attached to the GNR to form stable ohmic contact and conduct current through the GNR. In order to develop a simple and versatile method for forming ohmic contacts between metal electrodes and GNRs, we have proposed a novel structure named the dumbbell-shape GNRs (DS-GNRs) [1]. The dumbbell-shape structure consists of one narrow segment sandwiched by two wide segments. Since GNRs in the wide segments of the DS-GNR exhibit metallic electronic properties, ohmic contact with metal electrodes can be expected, and in fact, the I-V characteristics of a GNR with a width of 40 nm in the narrow segment have been successfully measured by applying the dumbbell-shape structure. On the other hand, since a DS-GNR comprises both metallic and semiconducting regions in one molecule (structure), Schottky barrier is expected to form at the junction interface between the wide and narrow segments. Therefore, the electron transport properties of DS-GNR is expected to be strongly affected by the electronic state of this junction interface. In this study, first-principles calculations based on density functional theory were performed to analyze in detail the electronic transport properties of DS-GNRs and the strain dependence of their current-voltage characteristics (I-V characteristics).

The electronic band structure of a dumbbell-shape structure consisting of a semiconducting GNR with a band gap of 1.6 eV in the narrow segment and GNRs with metallic conduction properties in the wide segments was investigated. In the longitudinal direction of the narrow segment from the junction interface betwen wide and narrow segments, the region was divided into units with the length of a six-membered ring of carbon atoms as one unit, and the density of states analysis was performed for each region. The energy barrier for electronic conduction between each region was defined by the energy difference of the lowest conduction band in each region. A clear energy difference of conduction band was observed between the junction interfaces between the wide and narrow segments, indicating the existence of a large energy barrier (Schottky barrier) near the junction interface. In the narrow segment near the junction interface, new electronic states appeared within the 1.6 eV wide forbidden band due to the exudation of a wave function from the wide segment into the narrow segment. As a result, the energy barrier in the narrow segment was not constant, but a gradient Schottky barrier appeared, in which the minimum energy of the conduction band increased monotonically from the junction interface region to the central region of the narrow segment. Furthermore, the gradient Schottky barrier changed as the band gap of the narrow segment decreased due to uniaxial tensile strain, and it was confirmed that the Schottky barrier disappeared at 8% tensile strain, and the junction interface between the wide and narrow segments became a metallic-metallic junction. Therefore, it is feasible to control the gradient Schottky barrier and switch from semiconducting to metallic conduction in the dumbbell-shape GNR by applying an appropriate range of strain.

Key Words: roofing felt, mechanical material anisotropy, microstructure of roofing felts, chemical composition of roofing felts, scalar damage; fractional calculus; damage mechanics

Due to its low cost and relatively simple installation, roofing felt is well-known material for decades and is still widely used as a waterproof insulation in commercial and residential buildings. They are available in many types and variants, differ in purpose, thickness, materials or finishing.

In presentation, we will focus on a selected representatives of this group. Research methodology, results of determination of detailed mechanical behaviour, microscopic photos of the material structure and maps of chemical composition of different types of roofing felt will be presented. The presented results will show how heterogeneous and anisotropic structure the roofing felt is.

Based on the obtained results computational modelling strategy utilizing hyperelastic fractional damage material model with memory presented by W. Sumelka and G.Z. Voyiadjis in [1] will be presented. Results of numerical analysis have been prepared with symbolic mathematical calculations software *Wolfram Mathematica* extended with *AceGen/AceFem* software in which implementation of the concept of hyperelastic fractional damage material model with memory has been prepared. The choice of *AceFem* software was dictated by its structure (the system combines symbolic and numeric approaches) and because its environment is designed to solve multi-physics and multi-field problems.

Model-order reduction of locally resonant metamaterial plates

Andrea Francesco Russillo* **and Giuseppe Failla**

Department of Civil, Environmental, Energy and Materials Engineering, University of Reggio Calabria, Via Graziella, 89124 Reggio Calabria, Italy, andreaf.russillo@unirc.it

Key Words: Model-order reduction, Modal analysis, Dynamic-stiffness method, Local resonance

A reduced-order dynamic-stiffness method is formulated in order to compute the dynamical response of locally resonant metamaterial plates, i.e. plates coupled with periodical arrays of resonant subsystems. The formulation rests on a dynamic-stiffness model obtained by exact condensation of all the degrees of freedom within the resonators. The main results are twofold: a) after having built the global dynamic-stiffness matrix, the natural frequencies and undamped modes are computed by means of the Wittrick-Williams algorithm [1, 2, 3]; b) two orthogonality conditions are derived for the modes associated to the plates only and employed to find closed analytical forms for the modal response under arbitrary loads, both in time and frequency domain, under the assumption of classical damping [4, 5]. The results are compared with finite-element solutions assessing the accuracy of the proposed formulation.

Numerical analysis of Portevin-Le Chatelier effect using regularized large strain thermo-visco-plastic model

Marzena Mucha[1*], **Balbina Wcisło**[1] **and Jerzy Pamin**[1]

[1] Cracow University of Technology,
Warszawska 24, 31-155 Cracow, email: Marzena.Mucha@pk.edu.pl

Key Words: PLC effect, large strain thermo-visco-plasticity, regularized Estrin-McCormick model

The research presented in this paper is focused on the numerical simulation of a propagative instability called Portevin-Le Chatelier (PLC) effect using large strain thermo-plasticity models. The PLC effect is attributed to dynamic strain aging and characterized by serrated response (stress-jumps) in the stress-strain plot, related to moving shear bands. It affects several material parameters like the yield stress, hardening rate (and thus material ductility) and ultimate tensile strength. The PLC effect occurs in metals, for example steel and aluminium alloys, under certain strain rate and temperature conditions [1].

A large strain thermo-visco-plastic Estrin-McCormick model [2] is employed in the analysis. The McCormick part of the model is based on [3]. The thermo-visco-plasticity formulation is an extension of the work [4]. It incorporates strain hardening, strain rate sensitivity to represent viscosity as well as the dynamic strain aging, and thermal softening. The rate-dependence is treated in the model as a regularization method, but the model is also optionally equipped with a gradient enhancement.

A parametric study for different values of strain rate, temperature, strain ageing time and, when relevant, internal length is carried out. Comparisons with experimental data from [5] are performed. All computations are executed using AceFEM and AceGen numerical packages within Wolfram Mathematica [6]. Viscosity is shown to be necessary to avoid problems with convergence. Moreover, the influence of the gradient enhancement on the simulations is evaluated. Good agreement with experimental findings in terms of global load-deformation response is obtained, but a model correction is needed to eliminate serrations in the post-peak (necking) regime.

Key Words: non-local models, plastic hinges, elastic-plastic bending, fractional calculus

The study presents recent results on nano/micro-beam modelling in the framework of space-Fractional Continuum Mechanics. According to this formulation, the scale effect is modelled using fractional derivatives and determined by parameters: α (order of fractional derivative) and ℓ_f (length scale).

The development of space-Fractional Euler-Bernoulli and Timoshenko beams theories considering elastic-plastic properties will be presented. The Huber-Mises-Henky plasticity criterion, isotropic hardening, and grain-size-dependent strengthening (described by the Hall-Petch relation) will be included. A significant result is a demonstration that the material microstructure determines the scale effect. In particular, it will be identified that the length scale ℓ_f is represented by the grain size of a microstructure. The presentation will include the effect of microstructure on the formation of plastic hinges for beams under bending.

In conclusion, consideration of the microstructure is essential in analyzing nano/micro-beams, and a direct reference to the microstructure is possible with fractional models.

ACKNOWLEDGEMENTS

Key Words: *Inverse-Isogeometric Analysis, Distributed Fiber Optic Sensing, structural monitoring, strain, stress*

Remote monitoring of structures is an important advance in modern engineering for safety, maintenance and management purposes. Recent developments in sensor technologies, fast data communication networks and Internet-of-Things enabled the prospect of smart structures which can be observed remotely for real-time changes in deformation and stress distribution.
Distributed Fiber Optic Sensing (DFOS) is an excellent sensor of choice for structural monitoring applications because of its light weight, high spatial resolution, high accuracy and resistance to harsh environments [1]. However, measured fiber strain data from DFOS must be translated to structural deformation and stress using a numerical inverse analysis method. Isogeometric Analysis (IGA) is a good candidate for this purpose since its higher efficiency and accuracy over traditional FEM has been proven [2, 3, 4].
In this work, an integrated method of inverse IGA and DFOS fiber model is proposed. This method can be used to calculate the deformation and stress distribution of a structure from measured fiber strains. In the proposed method, both structure geometry and fiber geometry are modelled using Non-Uniform Rational B-Splines (NURBS) functions which constitute the core of IGA. This integrated approach not only enables direct input from Computer-Aided Design (CAD) models for streamlined practical application but also improves the efficiency of numerical calculations. In addition, spatial resolution and sampling locations can be changed to match the measurement mode of DFOS instrument which is not possible in fixed point-sensor models.
The proposed method is first verified with a simulated example. Then, it is applied to a practical model using measured DFOS data from experiment. The results show that the inverse method is accurate, fast, robust and can accurately reproduce structure deformation and stress using the measured strain distribution in the optical fiber direction. Hence, the method shows a promising potential for industrial applications.

Ultrasonic Testing and Imaging of Out-of-plane Fiber Wrinkling in Multilayer Composites with Double-side Pulse-echo Methods

Zhuang Li[1] and Menglong Liu[2*]

Key Words: *Composites, Ultrasonic testing, Layered structure, Out-of-plane wrinkling, Imaging*

Abstract. Fiber reinforced polymers (FRPs) have been increasingly used in various fields. However, fiber wrinkling in manufacturing and service will have a great impact on the mechanical properties of composites, which requires non-destructive testing and evaluation (NDT&E) for potential structure defects[1]. Considering that a purely analytical approach relied on the assumption of plane wave, e.g. recursive stiffness matrix[2], fails to offer accurate ultrasonic Ascan signal for wavy FRP, this study builds dedicated FRP models with out-of-plane fiber winkling using the cloud-based commercial finite element simulation platform OnScale[3], in order to assess the fiber wrinkling in the layered FRP. Then the wrinkling imaging is performed in the ultrasonic Bscan imaging by information extraction from the echoed signals based on the principle of interply resonance, in which several parameters, including signal amplitude, phase, frequency, and bandwidth, are studied for improvement of imaging quality. The analysis result indicates that the single-side pulse-echo method may give false waviness imaging results at local regions attributed to the wave beam deviation from the fiber wrinkling. Hence, a double-side ultrasonic testing method is proposed, i.e. to excite ultrasound from both sides of FRP, in order to optimize the out-of-plane fiber wrinkling imaging quality. In the proposed method, two imaging results from each single-side pulse-echo are superposed with different weights at each specific imaging region, thereby improving the imaging effect. The proposed method has great potential on FRP characterization of fiber wrinkling in the manufacturing stage.

[2] University of Technology Sydney, Ultimo, NSW 2007, Australia, Gandomi@uts.edu.au

Key Words: Contact ultrasonics, Variational Mode Decomposition, Feature engineering, Instantaneous frequency, Statistical features

The contact Ultrasonic Testing (UT) technique has been widely used for Non-destructive Damage Testing of different materials such as wood. In this light, the time of flight and velocity of the ultrasonic wave in a wood section has been traditionally monitored and correlated with the wood quality. However, the results of such practice have not been satisfactory, prompting researchers to devise new strategies to tackle the problem. This study mainly focuses on the feature engineering of contact ultrasonic testing results for the quality evaluation of wooden sections. To this end, the Variational Mode Decomposition algorithm is employed to extract some informative features out of ultrasonic signals to be fed into Machine Learning (ML) algorithms. The developed ML algorithms are set to solve some supervised classification problems based on data gathered from testing specimens with different health conditions. Artificial hole defects, of various sizes, have been introduced to the specimens to simulate different severity of the defect in the specimens. The study focuses mainly on the effectiveness of different types of features in solving the classification problem of wooden specimens based on their health state. To this end, different features are obtained out of the extracted modes of the ultrasonic testing result, including the centre frequency of the extracted modes, the root mean square value of the instantaneous frequency of the modes, as well as some statistical features such as mean, median, skewness and kurtosis of the instantaneous frequency of the modes. A comprehensive comparison of the obtained classification results is made when different types of features were fed into the classification problem.

Varying-pitch comb-shape DW sensor for UGW based SHM

Key Words: *Ultrasonic Guided Wave (UGW), Direct-Write (DW) Sensor, Comb-Shape, Wave Mode Match/Mismatch*

The low profile, lightweight and flexibility of direct-write (DW) sensors made of piezoelectric coatings have great advantages in ultrasonic structural health monitoring (SHM) applications. The DW sensors can be printed on the surface of the structure or embedded into the structure through scalable processing with improved consistency and lowered implementation cost. To selectively excite and receive the ultrasonic guided wave (UGW) signal, a comb-shape DW sensor is usually designed with element pitch same as the mode wavelength. A good match between the element's pitch and the wavelength of the designed mode is crucial for accurately and efficiently recording the arrival signal. In real situations, the structural and material properties may not be uniform or degraded during in service. Changes in these properties may alter the UGW wavelength, causing a deviation in the match between the comb-shape sensor and the pre-selected wave mode. As a consequence, the designed comb-shape sensor may fail due to an inaccurate evaluation of wave received.

In this paper, we first examine the effect of mismatch of comb-shape sensors on the wave arrival time in an adhesive structure (Al-Epoxy-Al). To simulate the mismatch phenomenon, the degradation of adhesive material properties and the variation of adhesive thickness in actual adhesive structures are taken into account when modeling the adhesive layer. By selecting an appropriate UGW mode, it can be determined whether disbond has occurred in the adhesive layer based on the differential arrival time of the wave. However, the wave arrival time in the disbond case may be completely different from the design stage when the mismatch occurs. This mismatch prevents the comb-sensor from detecting disbonds in adhesive structures. To solve this challenging mismatch problem, we present a new comb sensor design that can adapt to the mode wavelength. In the new design, the pitch and width of the elements can vary with the length of the elements. Pitch variations are tuned to correspond the changes in mode wavelength. Simulation results showed that the high-amplitude wave packet can correlate to the designed mode packet. Accordingly, the varying-pitch comb-shaped sensor provides a more reliable evaluation of structural health by adapting to the mode wavelength.

* shg@hhu.edu.cn

Key Words: *Anomalous diffusion, Fractional derivative, Complex media, Non-locality*

Heterogeneity embedded in natural media and flow field challenge the application of Fick's 1st Law in anomalous diffusion well documented in many disciplines. Anomalous diffusion is one of the major topics in theoretical physics and statistical mechanics, and it is also the fundamental physical process with good potential application in environmental and hydrologic sciences and engineering. As a novel modeling tool in mathematics and physics, the fractional-order derivative diffusion equation models characterize anomalous diffusion with history-dependence and spatial non-locality, accurately describe the tailing in breakthrough curves of solute transport. We summarize the recent progresses and discuss the key challenges of fractional derivative diffusion equation models including the existed research and current development, fractional derivative modeling, numerical algorithms, and related applications in the field of environmental fluid mechanics. Here also made some preliminary discussions on issues of fractional derivative diffusion equation model, such as statistical description, model parameter determination and dimensional analysis, which may contribute to the further study of anomalous diffusion.

[3] Computational Science and Analysis, Sandia National Laboratories, CA, USA, mdelia@sandia.gov

Key Words: Nonlocal equations, domain decomposition, FETI

We present a domain decomposition method for the efficient simulation of nonlocal problems. Our approach is based on a multi-domain formulation of a nonlocal diffusion problem where the subdomains share "nonlocal' interfaces of the size of the nonlocal horizon. This system of nonlocal equations is first rewritten in terms of minimization of a nonlocal energy, then discretized with a meshfree approximation and finally solved via a Lagrange multiplier approach in a way that resembles the finite element tearing and interconnect method. Specifically, we propose a distributed projected gradient algorithm for the solution of the Lagrange multiplier system, whose unknowns determine the nonlocal interface conditions between subdomains. Several two-dimensional numerical tests on problems as large as 191 million unknowns illustrate the strong and weak scalability of our algorithm, which outperforms the standard approach to the distributed numerical solution of the problem. This work is the first rigorous numerical study in a two-dimensional multi-domain setting for nonlocal operators with finite horizon and, as such, it is a fundamental step towards increasing the use of nonlocal models in large scale simulations.

Extended Bond-based Peridynamics with Plasticity

Qi-Zhi Zhu[1*] and Wei-Jian Li[1]

[1] College of Civil and Transportation Engineering, Hohai University, Nanjing 210098, China , qzhu@hhu.edu.cn

Key Words: *Bond-based peridynamics, Plasticity, FEM/XPDM coupling, Numerical modelling, Quasi brittle materials*

Cohesive-frictional materials usually experience inelastic deformations during their progressive damage. In constitutive modeling, the classical peridynamic theory has gained increasing interests in describing elastic damage and failure of brittle materials essentially by means of bond breakage. In order to remove the limitation of the Poisson's ratio, the bond-based peridynamics has been recently enriched with bond rotation effects.

In order to enlarge its application particularly for geomaterials which presents material damage and inelastic deformation under compressive loading, the present paper aims at integrating the description of plastic strains into the extended bond-based peridynamic model (XPDM). For that, the total strain approximated locally is decomposed into an elastic part and a plastic part. The evolution of plastic strains is determined in the classical plasticity theory. In other words, commonly used elastoplastic models can be incorporated directly in the proposed framework.

For validation, the von Mises type yield function without hardening effect and the Drucker-Prager type yield function with an isotropic plastic hardening are taken into account for validation purpose. On numerical aspects, the XPDM with plasticity is implemented by following a peridynamic/finite element coupling procedure. Numerical predictions by the XPDM with plasticity are compared with those from finite element analyses and experimental data. In that process, numerical accuracy and computational efficiency of the proposed method are assessed.

Key Words: *peridynamics, fatigue crack propagation, non-local methods*

Fatigue crack propagation in structural materials is one of the most common problems in aeronautical applications where cracks are closely monitored on the field with very limited attempts to simulate their evolution. In this study Peridynamics (PD) [1,2] a nonlocal continuum theory formulated with integral equations, is adopted to simulate the crack propagation due to fatigue phenomena. Inspired by [3] the peridynamic formulation has been enriched introducing a damaging effect due to the high cycle fatigue phenomena applied to a bilinear constitutive law [4]. Consequently, the fatigue degradation of the bond stiffness can be evaluated. The total load is composed by blocks of cycles, each block is characterized by a fixed load amplitude and a given number of cycles. Two components of damage increment are considered: the static damage, and the fatigue damage, both of which contribute to defining the damage state of the material.
Furthermore, combining the capability of Peridynamics in modelling crack propagation with a FEM-PD coupled method [5] the computational effort can be reduced. Peridynamics is adopted in the region of the model where the crack is expected to propagate while the remaining part of the specimen is discretized by using FEM.
The proposed approach is applied to model 2D structures in presence of voids and inclusions under fatigue load conditions considering isotropic homogeneous and heterogenous materials. Results are evaluated taking into account different mesh sizes, horizon dimensions, crack initial lengths and crack orientations to demonstrate the capabilities of the proposed method.

Fully anisotropic peridynamics with pair-potentials

Vito Diana

Department of Civil, Chemical and Environmental Engineering, University of Genova,
via Montallegro 1, 16145 Genova, Italy

vito.diana@unige.it

Key Words: Peridynamics, Multiphysics Problems, Anisotropy, Fracture

We present an in-plane anisotropic continuum-molecular formulation for elasticity, fracture and diffusion-based problems in the peridynamic theoretical framework. Following a mechanistic approach, we define constitutive laws for long-range interactions such that the macroscopic behavior of the material is the result of the assigned micro-interactions properties. Elastic and inelastic pair potentials act on interacting oriented material points within a cutoff distance and enable to derive pairwise actions as energetic conjugates to specific pairwise deformation measures. The non-central force assumption, together with the definition of specific direction-dependent micro-moduli functions respecting material symmetries, allow to obtain a continuum formulation for anisotropic media using a purely pairwise descriptions of deformation and general constitutive properties. Non-uniform material toughness is modeled adopting an anisotropic energetic failure criterion related to direction-dependent fracture energy functionals. This is the first two-dimensional fully anisotropic bond-based type model without restrictions affecting the number of independent material moduli. Applications proposed include comparison against analytical solutions and fracture and damage sensing in conductive tissues.

Key Words: *Nonlocal problems, Bi-material system, Conservation laws, Wave reflection*

ABSTRACT:

In this talk, we explore the theory and implementation of wave propagation in a one-dimensional bi-material system using the local and nonlocal models, respectively. The local description is based on a coupling of two local continuum mechanics and the nonlocal description is based on a coupling of two nonlocal peridynamics with different constants. To study the physical reflection coefficients and diminish the artificial reflection rising from the simulation, one need to maintain the conservation laws across the material interface on a discrete level. We study the conservation laws of linear momentum and total energy for both local and nonlocal models in a continuous setting and then propose the numerical discretization accordingly to preserve those quantities. We test various propagating waves to study the reflection coefficients in a one-dimensional bi-material system. Several numerical tests are performed to confirm our theoretical findings.

[2] Missouri University of Science and Technology, Rolla, MO 65409
[3] Missouri University of Science and Technology, Rolla, MO 65409

Key Words: Radial basis functions, meshfree methods, fractional PDEs, nonlocal models

There has been a growing interest in the study of nonlocal models and fractional PDEs as more general and sometimes more realistic alternatives to the conventional PDE models. However, high computational cost could be induced by numerical approximations of integral formulations of nonlocal derivatives. Meshfree methods based on radial basis functions (RBF) provides an alternative to solve fractional PDEs without the use of numerical quadratures. Although computationally convenient, there is little understanding of the properties of meshfree methods for fractional PDEs based on RBF. For example, stability of the numerical methods is not guaranteed theoretically and the way to choose the RBF shape parameter is ad-hoc. In this talk, we will introduce a stable RBF meshfree method for fractional PDEs using Gaussian kernels where the RBF shape parameter is correlated with the mesh parameter. We study the convergence of the proposed method and provide numerical examples for practical guidance.

Key Words: *Additive manufacturing, spall, shockwave, peridynamic, crystal plasticity, impact*

Because nonlocal methods do not assume or require continuous displacement fields, they allow a computational model to capture the nucleation and progression of damage with potentially great generality. In this work, the effect of microstructure on the high-rate tensile failure (spall) of additively manufactured 304L stainless steel is studied. The simulation method uses state-based peridynamics with a new model for the time dependence of high-rate failure within grains. A crystal plasticity model incorporates anisotropy in the elastic and plastic response of the grains. The grain shapes and lattice orientations are initialized directly from Electron Backscatter Diffraction (EBSD) images.

The model results are compared with test data from plate impact experiments over a range of impact velocities. Although it takes place within a very short time interval, the process of dynamic failure has an observable effect in the measured data. This effect is, to a large extent, reproduced by the model.

Simulations with different realizations of the microstructure reveal the sensitivity of the failure process to the random nature of the grains. This is important with additively manufactured steel because of the wide variations in sizes and shapes of grains at different positions within the sample.

[2] Oak Ridge National Laboratory, One Bethel Valley Road, P.O. Box 2008, MS-6085, Oak Ridge, TN, 37831-6085, United States, reevest@ornl.gov

Key Words: *Peridynamics, Large-Scale Fracture Simulations, GPUs, Performance Portability, Exascale Computing*

Peridynamics is a nonlocal reformulation of classical continuum mechanics suitable for material failure and damage simulation, which has been successfully demonstrated as an effective tool for the simulation of complex fracture phenomena in many applications. However, the nonlocal nature of peridynamics makes it highly computationally expensive, compared to classical continuum mechanics, which often hinders large-scale fracture simulations. In this talk, we will present ongoing efforts to develop a GPU-enabled, performance portable, and exascale-capable peridynamics code designed to run on U.S. Department of Energy supercomputers, in particular Summit (currently ranked #2 in the TOP500 list) and Frontier (to be deployed later this year), both at Oak Ridge National Laboratory.

Combined finite-discrete element simulations for multi-body dynamics and fracture mechanics

Ado Farsi[1*]

[1] Imperial College London, UK, ado.farsi@imperial.ac.uk

Key Words: *FEM, DEM, FDEM, Fragmentation, Multi-body Systems, Industrial Processes*

The key features of the combined finite-discrete element method (FDEM) [1] are the following: (a) compute the contact interaction and motion of bodies, (b) calculate the stresses and deformations and (c) compute the transition from continua to discontinua when fragmentation occurs.
This talk will cover some of the most recent applications of FDEM for multi-body dynamics and fracture mechanics. This includes applications to the packing and breakage of catalyst pellets, fibre-reinforced concrete tunnels, armour units for coastal defence, and the simulation of breakouts and solid production in drilled rock formations [2, 3, 4, 5]. Some of the discussion will focus on open problems and on the challenging aspects of FDEM in fracture simulations, such as the joint-element induced artificial compliance, element size constraints due to the discretisation of the process zone, dynamic effects induced by the application of boundary conditions (e.g. in-situ stresses), and others.

Creating Digital Twins for Human/Society and System/Service with Uncertainty and Complexity

Tohru Hirano

Daikin Information Systems Co., Ltd.,
2-3-18 Nakanoshima, Kita-ku, Osaka, Japan,
tohru.hirano@daikin.co.jp

Key Words: *CPS, Digital Twin, Surrogate Model, Complex Network, SCM, Society5.0*

In VUCA (Volatility, Uncertainty, Complexity, Ambiguity) era such as COVID-19 pandemic, global manufacturing industry should be transformed into the new paradigm of smart manufacturing based on Cyber Physical Systems (CPS) with Digital Twins including uncertainty and complexity of human/society and systems/services. Especially concerning to the global supply chain management (SCM) network which is heavily damaged under COVID-19 pandemic, the complexity of the network structure should be considered and modeled properly for the inclusion to the Digital Twins.

In MS196 of WCCM2020, we have introduced the foundation of "Computational Information Science" in order to incorporate the human and the society into the Digital Twin models for the implementation of the smart services in Society5.0[1)]. On the uncertainty quantification of the CPS process, the human and the society have quite wide range of uncertainty for the modeling of human behavior and social decision making. We have defined Uncertainty of Things as the uncertainty in data from devices and uncertainty in Digital Twin models which are created as Surrogate Models from CAE analyses and Machine Learning regressions. Also, we have defined Uncertainty of Subject as the uncertainty of the human and the society, which are the beneficiaries receiving services and have bounded rationality of human based upon Prospect Theory[2)]. Then, we will introduce Digital Twin model for SCM process having complexity and fragility based upon Complex Network theory[3)].

Finally, Digital Twins for design process, production process, global SCM process and service delivery process are introduced and discussed in view of realizing human centered Society5.0. Furthermore, we will consider the crisis recognition of the global manufacturing industry and the global supply chain logistics from a new perspective, including uncertainty and complexity. In order to promote business transformation (DX) under new-normal condition, we will create Digital Twins with CPS including SCM and value chain networks.

Digital Triplet for Recording and Reusing Engineering Processes Executed by Human Intelligence

Yasushi Umeda[1*]

[1] The University of Tokyo, Hongo 7-3-1, Bunkyo, Tokyo 113-8656, Japan, umeda@race.t.u-tokyo.ac.jp

Key Words: *Digital Twin, Digital Triplet, Cyber Physical Production System*

The rapid digitalization is changing the manufacturing paradigm as Industrie4.0 exemplifies. Japanese manufacturing industry seems to be falling behind this digitalization. We should transplant the strength of Japanese manufacturing industry, if there is, to the new vessel (namely, digitalization). Perhaps the strength is high-quality in manufacturing, which results in high-quality products and cost down and no defect in production. For transplanting the strength of Japanese manufacturing industry or to a new vessel, we are proposing *Digital Triple*. Since Industrie4.0 takes rather a top-down approach, it is difficult to make full use of field experts' knowledge and skill, which are typical strongest points of Japanese manufacturing industry. For solving this issue, Digital Triplet aims to support engineers and technicians to solve problems and to crate various values throughout a product life cycle, which leads to human centered digital manufacturing.

While CPS or digital twin consists of physical world and cyber world, Digital Triplet consists of physical world, cyber world, and intelligent activity world done by human so as to create values from data and information by employing human knowledge. Digital Triplet integrates these three worlds to realize the integrated support of engineering activities throughout a product life cycle.

Specifically, we propose a novel method for structurally describing decision-making processes by mapping intention and judgment of engineers to actions on CPPS. Digital Triplet aims at recording various engineering processes executed by engineers on cyber physical systems and supporting other engineers by reusing the recorded engineering processes.

Finally, this study illustrates an experiment for performance improvement by engineers on the prototype system of a learning factory. The experiment verified that the Digital Triplet concept is successfully realized, and the proposed method is effective to represent the engineering processes of engineers.

Modelling Cognitive Bias in Safety using Bayesian Inference

Hideyoshi Yanagisawa[1*]

[1] The University of Tokyo
7-3-1 Hongo, Bunkyo, Tokyo, JAPAN, hide@mech.t.u-tokyo.ac.jp

Key Words: *Safety, Perception, Cognitive Bias, Bayes, Covid-19*

In a human centred society, sense of safety perceived by people is important to consider as well as actual safety. The gap between expectations and reality in safety causes social problems. Overestimation of safety provokes dangerous behaviours, while underestimation of safety causes excessive behavioural restraint. For example, in COVID 19 pandemic, the overestimation may lead to the spread of infection due to dangerous behaviours, and the underestimation may lead to slow consumption due to excessive self-control.

In this talk, I propose a mathematical framework to model sense of safety using Bayesian inference. Recent neuroscience studies suggest that human brain activities can be explained as a Bayes' model(Knill & Pouget, 2004). Here, based on Helmholtz's epistemology, I assume that safety x is inferred as the cause of observation (data: y) and define the sense of safety as Bayesian posterior $p(x|y)$ that is proportional to a product of a prior $p(x)$ and likelihood $p(y|x)$. The prior and the likelihood represent the expectation of safety and the safety based solely on the data (observed safety), respectively. In this model, the prior (safety belief) is updated to the posterior (perception of safety).

The difference between the posterior mean and the peak of likelihood represents the gap between perceived and observed safety. This gap is regarded as a cognitive bias termed *expectation effect* (Yanagisawa, 2016). In our previous study, we modelled the expectation effect as a function of three parameters: a prediction error (difference between prior mean and peak of likelihood), prior precision (inverse variance of the prior), and observation precision (inverse variance of the likelihood). We found that there are two types: assimilation and contrast. Assimilation diminishes the prediction error, and contrast exaggerates the prediction error. The expectation effect explains several psychological biases that lead to abnormal behaviours, such as normalcy bias, excessive anxiety, and overconfidence. Based on the expectation effect model, I discuss the condition of each psychological bias in safety. In addition, I discuss how to model emotions such as anxious and fear in a mathematical manner by applying information theoretic quantities such as surprisal and free energy (Yanagisawa, Kawamata, & Ueda, 2019).

Key Words: *Digital Twin, Smart Manufacturing, High-Fidelity Simulation, IoT, Data Science*

Recently, there are more opportunities to hear the term Digital Twin (DT). In particular, it is often used as one of the elements to realize the "super-smart society" set forth in Society 5.0 described in the 6th Science and Technology Basic Plan (2021-2025). While DT used to be mainly discussed in the manufacturing context as for Industry 4.0, recent DT is extensively even focused on the social phenomena (weather, earthquakes, etc.) and the social activities (smart city, healthcare, etc.). In October 2019, Hexagon M.I. and Tokyo University of Science (TUS) signed a joint research to promote research on DT and smart manufacturing, infiltrate the core competency into Japanese manufacturing industries and develop human resources thereof. In April 2020, in order to increase the opportunities for interaction between academia and industry, Hexagon/TUS Digital Twin Laboratory (DTlab) was established at the Katsushika Campus of TUS [1].

As is well known, DT consists of three elements, *i.e.* a physical entity, a virtual counterpart, and the data connections in between. A widespread definition and extensive concepts about DT have been employed so far, and DT is conceived as a major tool in the manufacturing industry to carry out smart manufacturing, fault diagnosis, robotic assembly, quality monitoring, job shop scheduling, and decision making. The main enabling technologies for DT [2] can, in our recognition, be categorized into: (1) elemental level (*e.g.* physics-based modelling, data-driven modelling, big data cybernetics), (2) system level (*e.g.* infrastructure and platforms, human-machine interface.) Also DT can be divided depending on their applications: product DT, production DT, and performance DT. At the DTlab, the research of elemental level technologies was started initially particularly focused on the production DT phase where computational simulation is no doubt one of the keys, and high-fidelity physics-based simulation, multi-objective optimisation, design space exploration and data science approach including PCA, machine learning are being studied [1].

In this paper, the basic idea and background, and the aim of a strategic effort launched at the TUS DTlab in 2020 to infiltrate DT competency into Japanese manufacturing industries are first summarized. Next, some preliminary research results at DTlab are presented, for example, the numerical evaluation of the compression after impact strength for CFRP laminate with the help of X-ray CT image information, the numerical prediction of warpage in additive manufacturing, the indoor airflow analysis by CFD with a 3D as-built model based on the point cloud data obtained from 3D laser scanning, and the acoustic anomaly detection for predictive maintenance using machine learning. Finally, the future perspective on the DT joint research and the DTlab activities will be discussed including the idea of establishing a smart factory research centre which provides a place for practice of DT between TUS and the joint research companies.

Real World Modelling beyond the Paradigm of Industrie4.0 and Society5.0

Teruaki Ito[1*]

[1] Okayama Prefectural University,
Kuboki 111, Soja, Okayama 719-1197, JAPAN
tito@ss.oka-pu.ac.jp

Key Words: *Digital transformation, IoT, Industrie 4.0, Society 5.0, beyond the paradigm*

The digital transformation is one of the key challenges of, not only global product development and production, but also all areas of business processes. In addition to that, it also has a significant impact on every society and even each individual. Depending on the cultural and industrial background, this transformation has diverse effects on the different economic systems and areas, where the penetration of IT changes manufacturing systems, business processes and even people's lives for the better in every aspect.

For this digital transformation, there are two major paradigms which are on-going in the name of Industrie 4.0 and Society 5.0. Industrie 4.0 represents the forth industrial revolution that has occurred especially in manufacturing industries originally initiated by Germany. Industries 4.0 application includes wide areas, such as logistics, supply chain, autonomous equipment and vehicles, robots, additive manufacturing, IoT and cloud, opportunity identification, and so on. In the meantime, Society 5.0 covers human life activities as opposed to Industrie 4.0 covers manufacturing activities. Society 5.0 was proposed in the 5th Science and Technology Basic Plan as a future society that Japan should aspire to. It follows the hunting society (Society 1.0), agricultural society (Society 2.0), industrial society (Society 3.0), and information society (Society 4.0) [1].

These two paradigms seem to have differences in the focus of digital transformation: one targets industries while the other targets societies. However, when looking at these digital transformations from the viewpoint of interdisciplinary, connectivity, and network, there are many common issues where both countries are facing. Japan-Germany Symposium on IoT design, systems and applications, or JGIoT-DSA[2] is one of the academic platforms organized by the volunteers, where researchers from both countries discuss the issue from the different perspectives in terms of design, systems, and applications. As a result, this platform offers an meaningful and significant opportunity to discuss these issues and to propose a common solution to these two paradigms. This talk shares ideas regarding what is expected beyond the paradigm of Industrie 4.0 and Society 5.0, which has been discussed in this platform, and it also discusses real world modelling of cyber-physical systems beyond these paradigms.

[3] Osaka University, 2-1 Yamadaoka, Suita, Osaka, Japan, kaito@ga.eng.osaka-u.ac.jp

Key Words: *Railway Bridge, Image Displacement Measurement, Multipoint Measurement*

Displacement of a railway bridge due to the passage of a train is one of the typical performance indicators, and various measurement methods have been developed to realize efficient and quantitative maintenance. Displacement measurement with a video camera can measure multiple points at the same time, and there is a possibility that the curvature of bridge deflection, which is highly sensitive to damage, can be easily calculated. In previous studies, the accuracy of non-target multipoint displacement measurement of bridges by a video camera was verified, and it was shown that the displacement responses in the mid-span of a bridge can be measured with constant accuracy as the existing method [1]. However, there were some measurement points in the image where the displacement response could not be obtained due to overexposure points and so on [1]. For determining the curvature of bridge deflection, it was necessary to establish a method for pre-extracting such points. In this study, a new method to pre-extract measurement points suitable for displacement estimation is proposed.

The displacement estimation was premised on the use of the digital image correlation method, which calculates the amount of pixel movement by normalized cross-correlation (ZNCC). In addition, the sub-pixel estimation is based on the fitting of a quadric surface to 9 points composed of the maximum ZNCC pixel and the surrounding 8 pixels [1]. The purpose of this study is to make a simple evaluation as to whether such sub-pixel estimation is possible based on this premise. Authors focus on the second-order differential value at the maximum quadratic surface point used for subpixel estimation, and extract information on displacement estimation accuracy from the determinant of the Hessian matrix at each measurement point. To calculate the displacement response, multiple images that make up the captured video are required, however this method only uses the values calculated by sub-pixel estimation between the first and second frame images, which are the reference images.

As a result of applying the proposed method by continuously setting measurement points in the longitudinal direction of a main girder of a steel railway bridge, higher index values are taken at the position where the stiffener exists, and displacement response can be obtained at these higher index points. On the other hand, it was confirmed that displacement response could not be obtained at most of the measurement points where the determinant of the Hessian matrix had a value close to 0. In addition, the positions of these higher values have almost the same as those of the higher values of the variance of the luminance in the vicinity of the measurement point. This fact can indicate that displacement response can be easily obtained at a measurement point where the change in texture is large. By projecting obtained image information on measurement accuracy onto an image scheduled for video recording, it is possible to understand the points that can be used as measurement points before displacement estimation. This method can also be used to adjust the camera position, which is suitable for measurements with many displacement estimation points.

Drive-By Bridge Quasistatic Deflection Estimation Using Track Irregularities Measured on a Passing Train

Kodai Matsuoka[1*]

[1] Railway technical research institute, 2-8-38 Kokubunji, Tokyo, Japan, matsuoka.kodai.13@rtri.or.jp

Key Words: *Drive-by bridge inspection, bridge deflection, track irregularity*

Methods to estimate bridge frequencies and modal shapes using sensors installed on traveling vehicles are proposed as efficient bridge-monitoring methods [1] and have gained much attention as they enable drive-by bridge inspection [2]. One of the typical performance indexes of railway bridges is the deflection under train passage. If bridge deflections can be measured by the traveling vehicles, the time- and cost-intensive ground measurements can be avoided. In addition, measurement by traveling vehicles can greatly contribute to realizing quantitative and high-frequency condition evaluations. However, not much progress has been made in the field of bridge deflection evaluation based on on-board measurement data (acceleration of each vehicle part or track irregularity) in theoretical or experimental works.

This study aims to contribute to establishing this innovative drive-by bridge deflection estimation method. As the first step, a drive-by Bridge quasiStatic Deflection (BSD) estimation method was developed in this study. This method is based on the track irregularities of the first and last vehicle positions that are actually measured on a daily basis. Based on the measurement of the track irregularity of the front and rear bogie positions of one vehicle, theoretical examination revealed that the difference between these irregularities and the BSD are in a proportional relationship, and the proportionality coefficient depends only on the bridge span length and the load interval. In addition, it is clarified that this relationship can be extended to the track irregularities measured by the first and the last vehicles of a train with multiple vehicles. Thereafter, a method of estimating easily the maximum BSD when the train travels is proposed. This estimation is based on the maximum value of the difference between the track irregularities measured by first and last vehicles using a conversion coefficient corresponding to the span length.

The effectiveness of the proposed method was verified by numerical simulation. Thereafter, a correction coefficient was added according to the measurement method, such as string or chord length, of the track irregularity required for application to actual railways. Thereafter, the proposed method was applied to the track irregularities measured for the first and the last vehicles of an actual train traveling at a speed of about 100 km/h, and the BSDs on the railway line were estimated. Furthermore, the estimated values of six of these bridges were compared with the deflection measured from the ground during the passage of trains at a low speed. The results demonstrate that the proposed method measured the BSD with good accuracy within 10% error. This method was developed considering special conditions in which the dynamic response of bridges was ignored; hence, the applicable conditions are limited when the traveling train speed is low. Despite such drawbacks, this work makes a remarkable scientific contribution by paving the way for advances in drive-by BSD estimation via original theoretical and field studies.

Key Words: *Rail Bridge, Modal Identification, High-Order Local Mode*

The local member vibration of steel railway bridges that occurs under train passages can lead to fatigue and structural noise. Existing research indicates that structural noise, in particular, adds to ambient noise in a wide frequency band from 100 to 2,000 Hz in I-girder open steel railway bridges with directly connected tracks. However, the mode shapes of the higher-order vibration mode that is the source of such structural sound are more complicated than those of the lower order and have several nodes in the same member. Therefore, to evaluate the predominance of high-order local vibration modes and this contribution to structural noise under train passages, the mode shapes of the local vibration mode in the actual bridge must be identified. Nevertheless, a large-scale multipoint measurement that can identify complex vibration mode shapes cannot be applied to field tests with high temporal and spatial constraints. Thus far, few examples have been given concerning the identification of high-order local vibration mode shape of railway bridges that exceed 100 Hz.

The present research proposes a new method for identifying the frequencies and mode shapes of the local vibration modes of steel railway bridges using field tests. This method significantly reduces the time and labor required to install a sensor using multipoint excitation with an impulse hammer instead of multipoint measurement. Furthermore, by exchanging the relationship between the input and the output points that are obtained as transfer functions based on Maxwell's reciprocity theorem, the vibration mode can be identified based on a simulated large-scale multipoint measurement. In addition, the method includes an entirely original phase-referenced procedure that corrects for the slightest phase synchronization error between the hammer and sensor, which is crucial in the reciprocity theorem.

The proposed method was applied to a steel I-girder bridge with a span length of 20 m. The frequencies and mode shapes up to around 1,000 Hz of the steel bridge main members such as the upper flange, web, lower flange, and stiffener for one panel (approximately 1,000 mm in the longitudinal direction) separated by the stiffeners were identified using a multipoint hammering test. In particular, on the web, it was found that high-order complex vibration modes, such as vertical 7th order and horizontal 3rd order, which had previously only been identified using theoretical analysis, also exist in actual bridges. Moreover, a comparison with an existing identification method based on multipoint measurement and theoretical calculations confirmed that the proposed method could identify the frequencies and mode shapes of the members with a high level of accuracy. Subsequently, the identification result was compared against the measurement spectrum when trains passed; the local member vibration modes, which can be the source of the structural noise, were identified. Furthermore, it was suggested that the specified vibration modes vibrate significantly when a train passes owing to the coincidence with an excitation frequency that is caused by periodical track irregularity.

Key Words: *Steel Railway Bridge, High-order Local Vibration Mode, Modal Identification*

The local member vibration of steel railway bridges that occurs when a train passes can cause fatigue damage and structural noise. In particular, rail joints on steel bridges may cause fatigue damage due to the introduction of impact forces with high frequencies and the corresponding Higher-order Local Vibration Modes (HLVMs) of steel bridges [1]. However, mode shapes of HLVM are more complicated than those of the low order modes, and have many nodes in the same member. Therefore, in order to evaluate the effect of HLVM, it is necessary to identify the mode shape of the HLVM in an actual bridge. However, large-scale multipoint measurement that can identify complex vibration mode shapes cannot be applied to field tests with large temporal and spatial constraints. So far, there have been few HLVM identification results of railway bridges exceeding 100 Hz [2]. In addition, the modal damping ratio, which greatly affects the repetition of HLVM, is an open problem that has not yet been clarified.

In this study, a novel identification method for frequencies, mode shapes and the modal damping ratio of the HLVMs of steel railway bridges was developed. The proposed method consists of the following four contents: 1) multi-point excitation with impulse hammers instead of multi-point measurement, 2) Maxwell's reciprocity theorem [2] for exchanging input points and output points, 3) estimation of multipoint free vibration by back calculation from transfer functions and 4) modal identification by ERA method from estimated multipoint free vibrations.

The proposed method is applied to a steel I-girder bridge with a span length of 10 m, and the HLVMs up to about 1000 Hz of upper flange, web, lower flange, and stiffener for a panel (about 600 mm in the longitudinal direction) separated by a stiffener have been identified. Since the number of measurement points has increased significantly due to multi-point excitation compared to the conventional measurement method, it is clearly shown that the mode shapes of HLVM with a complicated shape can be precisely identified. In addition, the modal damping ratio of the identified HLVMs indicated low values of around 1% in many modes. This means that the vibration duration of the HLVMs can be long. In other words, it is suggested that it may have a great effect on repetition in fatigue damage. The obtained results provided important basic information in the fatigue evaluation of steel railway bridges considering the influence of HLVMs.

Key Words: *Steel truss bridge, railway bridge, structural health monitoring, direct monitoring, vibration-based monitoring.*

Viaducts and bridges enable daily transportation of goods and passengers throughout the entire country. Railway network is subject to increasing travelling loads and traffic frequency. In addition, most of the bridges were built in the last century: they are subject to ageing and degradation [1], as an unavoidable phenomenon. It is therefore necessary to develop proper structural health monitoring systems that can support periodical visual inspections. That is why infrastructure managers are always looking for new technologies to assess in an almost continuous way the health status of their network components. Direct monitoring systems consist of mounting a set of different sensors on the structure under analysis, whose measurements are then used in order to assess structure mechanical performances and status. Given the nature of the bridge/viaduct to monitor and the kind of damage to detect, it is important to choose the proper typologies of sensing devices. Moreover, the following step is represented by the choice of an adequate damage-sensitive index (or set of them), that is able to capture and reflect eventual changes in structure performances during time. This paper is the result of a numerical study performed on a 3D FE model based on an existing structure: the studied bridge is a Warren truss railway bridge, located in Northern Italy, built few year after the second world war. The authors investigated the performances of different vibration-based methods [2]-[3], namely two modal-parameters based approaches and a non-modal ones. The former, based on the use of modal parameters (natural frequencies and mode shapes) as damage-sensitive indexes, was shown to be slightly sensitive to damage, also applying important flaw intensities. Instead, the latter, that do not imply the computation of any modal parameter, showed better results, both in terms of damage identification and localization. In particular, exploiting the RMS values of the signals recorded by a mesh of velocimeters placed along the span can represent a possibility to detect damage presence and its approximate location. This analysis has been performed for a set of different damage scenarios, suggested by the infrastructure managers. The simulations were run adopting a complete multi-body train model. Furthermore, in the attempt to get closer to real operating conditions, the actual track profile featuring the considered line portion was inserted in the simulation program.

Key Words: *Mutual interference of wind turbine wakes; Reynolds-Averaged Navier-Stokes (RANS); Doppler beam swinging (DBS) Light Detection and Ranging (LiDAR)*

In order to promote introduction of a large-scale offshore wind power generation system, it is necessary to accurately evaluate the wind conditions at sea and optimize the wind turbine layout in a wind farm. In a wind farm consisting of multiple wind turbines, the effects of upstream wind turbines cause wake where spatial and temporal variations of wind speed occur. Therefore, it is essential to correctly evaluate the influence of upstream wind turbines on the wind conditions in the wake and to determine the separation distance between wind turbines. We have been conducting joint research with the Institute of Applied Mechanics, Kyushu University and Hitachi Zosen Corporation since 2018 to develop a versatile wake model [1].

In the wind turbine wake region, there are velocity distributions in both horizontal and vertical directions. It is important to understand this characteristic, and in this study, we used computational fluid dynamics (CFD) to clarify the three-dimensional wind speed distribution in the wake region. The CFD simulation base on the unsteady Reynolds-averaged Navier-Stokes (RANS) equations was performed. The simulation indicates that wind speed vector in a wake region shows complex changes.

In order to verify the accuracy of the simulation, we carried out measurements of the wake at a wind power plant site by using Doppler beam swinging (DBS) Light Detection and Ranging (LiDAR). The single LiDAR unit measures the wind speed distribution in the vertical direction at the LiDAR placement location and cannot evaluate the wind speed distribution in the horizontal direction. To measure the wind speed distribution in the horizontal direction, simultaneous measurements using two LiDAR units were performed. One of them was set along the inflow direction and another one was set with 45 degrees rotation. From the results of the comparison between the simulation and the measurement, it was confirmed that the simulation do not agree with the trend of the measured results for sea wind. On the other hand, the simulation agreed with the trend of the measured results for the land wind.

Key Words: *Wind turbine wakes, Large-eddy simulation (LES), Actuator line model, Wind direction fluctuations*

During a wind turbine is in operation, a wake is created behind the wind turbine and it reduces the power generation and lifetime of a wind turbine located downwind. Therefore, it is important to accurately predict the effects of wake in order to assess the feasibility of a wind farm. Hitachi Zosen Corporation has been conducting joint research with the Institute of Applied Mechanics, Kyushu University and Toshiba Energy Systems & Solutions Corporation since 2018 to develop a versatile wake model [1]. In this paper, we report the three-dimensional structure of the unsteady wind turbine wake and the behaviour of the wake when wind direction variation is given to the inflow wind, obtained by numerical simulation of the Omonogawa wind power plant conducted during the development process.

We conducted numerical simulations to reproduce wind turbine wake using the "RIAM‐COMPACT" real urban version [3]. The following findings were obtained from the simulation results. Inside the wake in 1D downstream of a wind turbine, a flow field that rotates in the direction opposite to the blade rotation direction occurs. There is no significant difference in the flow field of the wind turbine wake between the up-wind type and the down-wind type. In 5D downstream of a wind turbine, the vertical distribution of the mainstream velocity component is almost the same regardless of the power of the inflow profile in the swept area of the wind turbine. When the inflow wind has a wind direction variation defined by a sinusoidal function with a maximum value of 10 degrees, the wind turbine wake is quite diffuse and the results of its vertical profile are in good agreement with the field measurement results by a vertical profiling lidar.

Key Words: Industrial Applications, Multiphysics Problems, Fluid-Structure Interaction, Wind Turbine

The construction of offshore wind farms where it is easy to obtain stable winds in large areas is becoming more and more active. Since the efficiency of a wind turbine is proportional to the cube of the wind speed and the square of the blade length, wind turbine blades built in the farms have been getting enormous in recent years. In order to realize larger wind turbine blades in the future, it is necessary to design lighter and stronger wind turbine blades. This study performed fluid structure interaction (FSI) analysis [1] combining a multiscale structural analysis, a three-dimensional unsteady fluid analysis around the wind turbine blade, and structural sizing based on the FSI analysis result. We investigated the influence of the material properties of CFRP reinforced fiber types on the design solution in terms of the thickness and weight of the wind turbine blade.

Key Words: *Wind Turbine Wake, Machine Learning, CFD, Lidar, Wind-tunnel*

This study provides a development of a new wind turbine(wake) modelling method based on machine learning for precise wind prediction by numerical simulation. (wake: Area where the wind speed generated on the downstream side of the wind turbine is low, and the airflow is complicated and turbulent.) Evaluation of site-specific wind conditions is required in wind power since turbulence is cause of wind turbine failure, although wind is source of energy. In a large-scale wind farm consisting of multiple wind turbine groups, the interaction of "wake" between wind turbines causes a decrease in the total power generation and an increase in the risk of failure. Therefore, in the wind power generation business, it is important to select the optimal installation site taking into account the effects of wakes, the optimal design of the wind turbine layout, and the operation of the power plant with minimal risk of failure.

Wind simulation has been utilized in the design and operation of wind farms. These simulations enable highly accurate prediction of power generation and evaluation of the risk of wind turbine failure by precisely reproducing the reduction in wind speed and wind turbulence caused by wakes, together with meteorological and oceanographic characteristics and topographic turbulence. In the field of wind simulation, a number of physical models (wake models) have been proposed and validated to reproduce wakes with high accuracy. Uchida et al. [1] succeeded in developing a CFD porous disk model, which simulates a part of a wind turbine rotor with a resistive element, and demonstrated its effectiveness by comparing it with actual measured data of wind farms in coastal areas. In recent years, however, expectations for new modeling methods based on machine learning have been rising. Machine learning has the potential to accurately model complex nonlinear phenomena that are difficult to formulate, such as wakes. In this study, we constructed and verified the accuracy of a new wake model using machine learning, which is different from the conventional fluid dynamics viewpoint, in order to realize a wake model with high robustness and versatility that does not require complicated parameter adjustments. For the supervisory data of the machine learning model, we used wind tunnel tests, LiDAR measurements for coastal wind turbines, and time series data during the inflow wind speed and wake region from the CFD analysis (without modeling the wake). These measurements and analyses produce a variety of wind data sets at different wind turbine outputs (blade lengths) and wind conditions.

Key Words: *Offshore Wind Power, Topography, CFD, LES, Atmospheric stability*

In recent years, there have been calls for the expansion of renewable energy both in Japan and abroad, and bidding for offshore wind farms has begun in Japan. In Europe, many offshore wind farms have already been installed, but in order to accelerate the introduction of offshore wind power in Japan, Japan's unique problems must be solved. In Europe, offshore wind farms are more than 10 km from the coast, whereas in Japan, offshore wind farms will be only a few km from the coast because the water depths deepen near the coast. As a result, the site will be strongly influenced by the onshore topography, and the wind speed distribution in the site may not be uniform and the turbulence intensity may be high. In addition, it is known that airflow separation due to topography is affected by atmospheric stability [1], but there are very few studies on how atmospheric stability affects offshore sites in Japan, since atmospheric stability varies with region and season. In order to solve these problems unique to Japan, it is essential to verify the accuracy of wind flow simulations that can reproduce the effects of topography and can be set to any atmospheric stability level, rather than just the conventional atmospheric stability neutral.

In this study, the annual frequency of atmospheric stability and the effect of topography were investigated using ERA5 data and observation data from wind observation masts installed at four locations on the island for a site under development where bidding will soon begin. As a result, it was found that a variety of atmospheric stabilities appeared at the site and that the annual average events were not neutral but unstable, and the deviation from neutral varied depending on the season and wind direction. The turbulence intensity varies greatly depending on the mast position and wind direction, and it is necessary to reproduce the wind flow separation due to topography in order to predict the wind conditions of wind turbines located close to the island. The accuracy of the wind flow simulation by LES was verified using the mast-to-mast wind speed ratio. As the simulation software, we used the commercial Riam-Compact [2], which is widely used in Japan, based on which the atmospheric stability can be arbitrarily set. As a result, it was found that the accuracy could be improved by refining the analytical wind direction classification and taking the average of the results calculated with several atmospheric stability levels.

A Particle-Based Simulation for Friction Prediction of Rubber on Snow

Hiroyuki Minaki[1*]

[1] Bridgestone Corporation,
3-1-1 Ogawahigashi-cho, Kodaira-shi, Tokyo 187-8531, Japan,
hiroyuki.minaki@bridgestone.com

Key Words: *Material Point Method, Coupling Methods, Snow Simulation*

In order to develop tires that can run safely even on snowy road, it is necessary to elucidate the complex frictional phenomena between tires and snow. Since it is difficult to elucidate this mechanism through experiments alone, it is necessary to apply prediction technology. Since the properties of snow vary depending on a variety of factors, prediction technology that can reproduce the differences in snow behavior is needed. Finite Element Method (FEM) [1] based on the Lagrangian formulation is commonly applied for deformation analysis of tires. However, if FEM is applied to snow, large deformation of snow distorts elements. Therefore, in order to solve the complex interaction between snow and tires, Material Point Method (MPM) [2] is applied to predict snow deformation in this research.

MPM is a particle method based on continuum mechanics. Physical quantities such as stress and strain are placed in the particles, and the equations of motion are solved by a grid placed in the background. MPM is suitable for large deformation analysis, and there are examples of its application to snow simulation [3].

FEM can change the resolution of the analysis by changing the size of the elements, but MPM is difficult to change the resolution of the analysis. Therefore, modeling both tires and snow with MPM requires a huge amount of calculation time. Therefore, FEM is applied to tires, and MPM is applied to snow.

Tires have designed grooves called a tread pattern, which affect the traction performance of the tire on snow. As a fundamental research for the development of tread patterns with higher traction performance, the coupled MPM-FEM method was applied to predict the friction prediction on snow of rubber blocks. The prediction analysis was performed under different conditions of snow properties and rubber block shapes, and was verified by comparing with experiments.

A study on Prediction of Water Discharge Performance for Showerhead Product Design

Chiaki Miyazawa[1*]

[1] LIXIL Corporation ,2-2-2,Ojima,Koto-ku,Tokyo,JAPAN, E-mail:chiaki.miyazawa@lixil.com

Key Words: *Showerhead, finite volume method, MPS particle method, fluid splash, droplet, mixing, product design*

LIXIL Co. handles a wide range of water-related products such as toilets, baths, and kitchens. The fluid behaviour control is a key technology for developing of these products. Therefore, the numerical simulation with CFD plays an important role in product and technical development.
The flow of water in a toilet has been simulated with the finite volume method (FVM). However, the simulation with a large number of fine droplets such as in a shower needs a lot of computational cost. To deal with this problem, MPS particle method[1] has been introduced to take advantages of enabling for simulating such as liquid splashing, and mixing. In this paper, the application of the simulation to the design of a showerhead is discussed.
The discussed shower has high water-saving performance. The impeller inside the showerhead rotates at high speed while half blocking the holes in the showerhead. By increasing the pressure in the blocked area, strong water flows can be released even with a small amount of water. This enables a bathing experience with a sense of water volume while maintaining high water-saving performance. The possibility with the MPS for product development was investigated for this shower, too.
The major subjects to be studied are as follows;

(1) Prediction of impeller rotation speed and transition
(2) Prediction of water behaviour and droplet size
(3) Prediction of internal pressure of the showerhead

In conventional MPS particle method, the accurate prediction is difficult because an only constant rotational velocity can be applied to the impeller. To improve the accuracy, it is necessary to solve the problem by coupling the water flow and the motion of the impeller. Therefore, in this research, a coupling technique of MPS and rigid body dynamics are applied. As a result, the simulated results show a good agreement with the experimental one.
This paper focuses on the application of the MPS particle method to the showerhead design. Since computational efficiency is also an important factor for the product development, the computational performance of multi-GPU for the MPS particle method is also discussed.

Key Words: *Fine particle dispersion system, Shear flow, Moving particle semi-implicit*

It is industrially important to understand the flow properties of materials containing multiple components such as particle dispersion in liquids and droplets. For example, controlling the rheological properties of the slurry solution is effective in battery development and clarifying the evaporation mechanism of ink droplets improves image quality of the inkjet printer.

In these fine particle dispersion system, the experimental study is difficult because the size of particles is so small (ranged from nm to μm) and particles interact intricately with each other. In these situation, simulation methods for such systems have been studied recently. SPM(Smoothed Profile Method) has been developed and applied to analyse the motion of dispersed colloidal particles in a shear flow [1] and SPH(Smoothed Particle Hydrodynamics) with lubrication force model has been studied for shear-thinning phenomenon [2].

We develop a method based on MPS (Moving Particle Semi-implicit) [3] to analyse the rheology of the fluid with dispersed particles in a shear flow. The algorithm and some applications to the fine particle dispersion system will be discussed in our presentation.

Particle Accretion Simulation Using Particle/Grid Hybrid Approach

Eiji Ishii[1*] and Tomoyuki Hosaka[2]

Key Words: *Multiphysics Phenomena, Particle Method, Accretion, Industrial Application*

In manufacturing processes and in the operation and maintenance of industrial products, the accretion of foreign matter in products affects performance, the creation of defects, maintenance periods, etc. Therefore, it is necessary to have techniques to predict where accretion will occur and the amount. There are various examples of accretion phenomena such as dust in inspection apparatuses, carbon accretion in automobile engines, frost on the heat exchangers of air conditioners, and snow on the bogies of high-speed trains. In this study, a simulation for predicting snow accretion on high-speed trains was developed as a common technique for the above problems. Allain et al. [1] developed a snow-accretion simulation for high-speed trains. Snow was modeled as spherical particles, and an Euler-Lagrange approach was applied to simulate the interaction between snow and air. The snow concentration in the air was assumed to be small enough to have no significant influence on the solution of the flow field. The ratio between the mass flux of the simulated particles and the real mass flux was used to estimate the actual snow-accretion mass. Murotani et al. [2] developed a snow-accretion analysis method that reproduced snow-accretion growth processes. Snow was also modeled as a sphere, and the boundary shape, modified by the snow-accretion form, was reflected in the boundary shape of an air flow simulation. The approach was validated with a snow-accretion experiment on a cubic model, and the results agreed well with the snow accretion in the experiment. These two studies demonstrated excellent approaches that are highly accurate and practical. However, a lot of particles are needed to obtain statistical homogeneity, so this factor increases the computational load. In this study, we developed a particle-accretion simulation with a small number of particles in order to reduce the computational load. A particle/grid hybrid approach that was previously developed [3] was applied. In the simulation with grids, a two phase flow that consisted of dry air without snow and wet air with snow was simulated. Snow behavior was simulated by using parcel particles containing snow particles with the same diameter and same velocity. The parcel particles were uniformly generated only in the wet air around observation areas, so it was possible to significantly reduce the number of particles. The wall accretion of the parcel particles was controlled on the basis of the velocity and angle between the velocity and normal vectors at the wall surface. The developed simulation approach was first validated with snow accretion on a cubic model [2], and the simulated accretion shape agreed well with the measured one. Furthermore, the simulation approach was applied to snow accretion on bogies of a high-speed train with three bogies. Qualitative and reasonable results regarding the location of snow accretion were obtained.

Key Words: *MPS method, Impinging Jet Cooling, Heat Transfer Coefficient, Rotating Machinery*

The realization of high cooling performance for oil-cooling electric vehicle (EV) motors is energetically promoted. It is very important to comprehend the characteristics of oil flows and the impingement cooling in the development. It is promising to utilize the MPS method [1], which is one of particle-based methods and suitable for free-surface flows with moving walls, for oil-impingement cooling analysis in EV motor development. However, it is difficult for the particle-based method to increase the resolution near the component surface as in the conventional mesh-based method. In the MPS method, this makes it difficult to evaluate the heat transfer between the component and the fluid, that is, to utilize it for the thermal design of EV motors.

In the present study, the heat transfer coefficient model suitable for the impinging jet flow, which is important in the thermal evaluation of oil-cooling EV motors, is constructed [2]. The local heat transfer coefficient is obtained by the model corresponding to the stagnation area of the impinging jet flow and substituting the flow velocity and length scale near the component surface into the heat transfer coefficient correlation. The parameters included in the model are determined by comparison with the impinging jet flow experimental correlation.

The oil-cooling rotor calculations are conducted using the MPS method and model parameters, in order to simulate the local heat transfer coefficient of the rotor surface. The numerical results are compared with the experiment, and it is confirmed the heat transfer is satisfactorily reproduced with the present method.

Key Words: *Traffic Simulation, Parallel Computing, Multi-Agent System*

Traffic policies, such as changes in the road environment, are costly to implement. Therefore, it is necessary to evaluate the traffic policies quantitatively in advance. For this purpose, it is appropriate to test the policies virtually using a traffic simulator. On the other hand, since traffic phenomena are complex systems, their prediction requires a high computational cost. Therefore, it is desirable that the simulator is not only accurate and scalable, but also optimized to be handled by a large-scale parallel computer.

In this research, we have attempted a hybrid parallelization of a multi-agent-based traffic simulator [1] using MPI/OpenMP. In this simulator, cars are modelled as autonomous agents. Each car's agent obtains information about its surroundings (position of other cars and traffic signals), makes autonomous decisions, and acts accordingly. In previous research, MPI parallelization has been achieved by dividing the road network so that the load is approximately equal and assigning it to each processor [2].

However, when using SMP clusters, hybrid parallelization can perform better than pure MPI parallelization in some cases [3]. Additionally, when using supercomputers, the number of MPI parallels may be limited. Therefore, in order to run a traffic simulator on a large-scale parallel computer, the authors perform hybrid parallelization of the simulator. The results will be presented at the conference.

Our approach contributes to the introduction of methods that have been used in the field of computational mechanics to the new field of social simulation.

Key Words: *Traffic simulation, Hybrid model, Cell transmission model, Intelligent driver model, Traffic Forecasting*

Traffic congestion is causing economic and environmental problems. Recently in Japan, road maintenances for roads used for a long time have been required in many places. Thus, a maintenance schedule that can minimize the effect of a traffic jam or any other social problems is necessary. Traffic simulation is useful for testing many scenarios at a low cost and finding a good maintenance plan.

In order to achieve both precision and low computational cost simultaneously, Takahashi et al. [1] proposed a dynamic hybrid traffic simulation model that uses different simulation models of different granularity, depending on the traffic condition and properties of road networks. In this approach, the Cell Transmission Model (CTM) [2] is employed as a macroscopic model regarding traffic flow as continuum fluid, while the Intelligent Driver Model [3] and MOBIL [4] are employed as microscopic models simulating the individual behaviors, are employed. The models are switched to each other dynamically during a simulation.

The main target area of this hybrid model is a highway, and the validation was conducted using real traffic data on highways. The results show that the model can perform accurate simulations with low computational costs. However, this model still has some limitations in the accuracy under certain situations and cannot model merge and diverge sections. To overcome limitations in the previous dynamic hybrid traffic simulation model, the authors in this study propose an improved model with higher accuracy and wider applicability. The concrete results of the study are to be reported at the conference.

Key Words: *Electric vehicle, charging, coupled simulation, OpenDSS, MATES*

There is a worldwide demand for a sustainable carbon-neutral society, and the reduction of energy consumption derived from fossil fuels is an urgent issue. In the transportation sector, which accounts for a large percentage of energy consumption, the use of EVs (Electric Vehicles) with high environmental performance has been rapidly increasing in recent years. EVs are expected to play a major role in realizing a carbon-neutral society.

In this study, we proposed a coupled simulation framework that can represent the interaction between the transportation system and the power system. This will enable us to evaluate the impact of the introduction of EVs into society and to study the appropriate charging control policy. The framework is verified in a simple numerical environment, and it is shown that the two-way coupling can be executed correctly. In the proposed simulation framework, OpenDss [1] is used to simulate the power distribution mechanism, and MATES [2] (Multi-Agent Traffic and Environment Simulator) is used to simulate the road traffic mechanism. These two simulators run independently, but exchange information with each other through two-way coupling. MATES can link not only EV charging events but also congestion estimates and reservation status of charging facilities to OpenDSS. After power flow calculation, OpenDSS can link the rated output of chargers, rate settings, and other information to MATES.

Key Words: Air Traffic Management, Air Traffic Flow, Simulation Evaluation, Modeling Fidelity

Modeling the air traffic flow and evaluating the operational impacts have been widely conducted for the enhancement in the efficiency of Air Traffic Management. This paper investigates the effect of the fidelity of the simulation models on flight delay at a microscopic scale by comparing AirTOp commercial simulator and our proposed Cellular Automaton(CA)-based simulator; both are utilized in our previous studies [1, 2]. Our CA-based simulator[2] has been modeled to assess airport and airspace complexity at a macroscopic scale. On the other hand, AirTOp[1] can take into account the microscopic behavior of the aircraft by the new sequencing and spacing operation, so-called Point-Merge (PM) operation, started from 2019 at Tokyo International Airport (RJTT). In this study, both simulators model 578 arrivals at RJTT, consisting of 435 flights coming from south-west direction and 143 flights coming from the north direction. The actual data including radar track, and flight plans (FP) during the 6 months between September 2019 and February 2020 are analyzed to make 39-days traffic scenarios. Each agent (flight) departs reference points located in 200 NM from RJTT in south-west direction and 120 NM from RJTT in north direction and flies along the designated FP. The main difference exists in the spacing adjustment algorithms. AirTOp realizes the spacing adjustments by ”vectoring (taking a detour)” following the actual PM-operation. In contrast, the CA-based model implements spacing adjustments following 3 simple rules regardless of the area. As the result, the comparison reveals that AirTOp simulator captures the characteristics of the delay originated from PM-operation better than SBCA owing to the configuration of vectoring zones and the implementation of the actual speed and altitude restriction at PM-operation area. However, the results show that the calculated macroscopic metrics such as descent and speed profile, total flight time, total traveling distance, and separation at the runway threshold are well fitted to the actual operational data in both simulators. These findings suggest that air traffic simulators could deal with the delay area and amount in detail by considering the constraints of the location, speed, and altitude of sequencing and spacing.

Key Words: *Asymptotic solution; finite element method; logistic function; nonlinear least squares method; statistical analysis; uncertainty estimation; verification.*

By considering every finite element method (FEM) solution [1] as the result of a numerical experiment for a fixed model, a purely mathematical problem, i.e., solution verification, can be addressed by first quantifying the errors and uncertainties due to their sources, and then developing numerical algorithms to assess the solution accuracy of all candidate solutions. In a recent paper [2], we presented a new approach to FEM verification by applying two mathematical methods, namely, (1) a 4-parameter logistic function to represent the behavior of an asymptotic solution of a specific FEM model, and (2) the nonlinear least squares method [3], to find the asymptotic solution and its 95 % confidence bounds. Using the two methods, we developed a numerical algorithm, to be known as "Asymptotic-FEM Algorithm (AFA)," we estimated an asymptotic FEM solution and its uncertainty at some very large degree of freedom such as one billion or more, based on the availability of a sequence of increasingly-dense-meshed solutions of a specific FEM model. Since a full logistic function has four parameters, we needed a minimum of 5 FEM candidates in the first sequence of increasingly-dense-meshed solutions to get one convergent asymptotic estimate. As the size of the sequence increases, we get more asymptotic estimates until when the size reaches 9, we get a total of five asymptotic estimates. In this paper, we develop a doubly-asymptotic FEM algorithm (DAFA) by applying the AFA again to the sequence of 5 asymptotic estimates in order to obtain an ultimate estimate of the solution of a specific FEM model. Our results include calibration of this DAFA method using problems of known analytical solutions and the application of the method to sample problems, of which no theoretical solution exists.

Development of Efficient FEM Analysis Method using Equivalent 2D Model for Linear Friction Welding Analysis

Tomohiko Ariyoshi

ATORI CAE Inc., 3-18-19 Futaba, Shinagawa, Tokyo 142-0043, Japan, ariyoshitom@gmail.com

Key Words: *2D Model, Linear Friction Welding, High-Tension Steel, Solid Phase Bonding*

Linear friction welding(LFW) is one of the methods in accordance with the SDGs in machine-parts production processes. Lately the method has been used for not only airplane production but also automobile production owing to its rationality.

In the LFW process two machine-parts are bonded with their surfaces in solid phase with the friction-heat brought by lateral oscillation with each other. It needs neither big facilities like large electric energy sources nor other materials as in the arc welding.

But when the LFW analysis are planned the analysis models are usually prepared in 3D models. That is because LFW processes include 3D loads and 3D deformations. And accordingly the model becomes so big that it takes much calculation time and long development period.

We intended to develop 2D model for this analysis with the following method. In the LFW process small pressures normal to the friction surface are occurred through the lateral oscillating motions of the blanks. These pressures are important but lost in the 2D model.

We introduced the body-force field representing the upper-mentioned pressures in the 2D model. And the body-force field is generated by the centrifugal force on the blank considering that the pressure-forces are independent of the push force of the blanks.

Key Words: *Particle Method, SPH, Die Casting, Air Entrainment, Mold Filling, OpenMP*

Die-casting is a casting method suitable for mass production because it can accurately form complicated shapes. However, when the mold is filled with the molten metal, there is unsatisfactory performance that casting cavities (gas porosity) are generated due to air entrainment, and the strength of the product varies.

Recently, with the aim of improving the quality and production efficiency of castings including this air entrainment, there has been many studies of simulating the behavior of molten metal during filling and visualizing the state of gas entrainment using CAE.

In this study, the mold filling process considering air entrainment in the die cast are simulated using the two-phase flow SPH method, that can be applied to the mold flow including gas entrainment[1], [2]. Then, the behavior of air entrainment due to the filling of molten metal (Aluminum alloy), especially the efect of injection speeds are investigated.

The particle model (number of particles: 270,000) that simplifies the 3D die-casting shape in the field is used in this simulation. And particles with a specified speed flow in continuously at the molten metal inflow gate. At the outlet (vent part), particles flowing out of the mold are erased.

In concluson, it is possible to investigate/visualize the air entrainment behavior at the time of filling the molten metal and the flow behavior due to different filling speeds, which is considered to be effective for improving the gas porosity of the cast product.
In addition, to speed up the two-phase flow program by SPH method, a parallel algorithm using OpenMP, which enables parallel calculation on a shared memory type machine, has been implemented. As the result of parallel calculation, we were able to achieve more than 3 times faster computational speed on a PC with 4 cores.

Key Words: *two-phase flow, SPH, foundry filling process, air entrainment*

Gas entrainment is one of the major defects caused in the foundry filling process. Since the smoothed particle hydrodynamics (SPH) is a Lagrangian method that does not use a lattice, large deformations and movements can be easily analyzed, so it has the potential to be applied to such gas defect prediction as a methodology. However, numerical simulation of the two-phase flow, in particular those with large density ratio, has been challenging. It is because the discontinuities of the density and the sharp pressure gradient exist over the interface. Authors have developed a two-phase flow SPH methodology that can be applied to the foundry filling process containing gas [1].

The weak compressible SPH(WCSPH) was used as the analysis method. Strictly speaking, water has a slight compressibility. The weak compressible SPH is solved by using NS equations and equations of state (EOS) alternately. The Tait equation was used for EOS.

The methodology developed in this study is applied to bubble rising in water, which is a typical problem of gas-liquid two-phase flow. The bubble / water density ratio is 1/1000. In the 2D as well as 3D calculation results for the bubble radius 20 mm, the bubble shape became a spherical cap as shown by Grace [2]. The water tests regarding the gas entrainment in the inclined part of the rectangular cavity and air exhaust from backstep part were also analized. Good agreement between the water tests and simulation results demonstrates the success of the SPH methodology development.

The methodology in this study is applied to the 3D mold filling process simulation considering air entrainment [3].

A New Forest Evapotranspiration Model Accounting for the Spatial Variability of Rain-snow Fraction and Forest Conditions

Chen-Wei Chiu[1*], Takashi Gomi[1], Yuichi Onda[2], Shodai Inokoshi[1], Yupan Zhang[2] and Asahi Hashimoto[2]

[1] Tokyo University of Agriculture and Technology, 3-5-8 Saiwaicho, Fuchu, Tokyo 183-8509
[2] University of Tsukuba, 1-1-1, Tennoudai, Tsukuba, Ibaraki 305-8572

Key Words: *Evapotranspiration, Rain-snow fraction, Forest conditions,*

Evapotranspiration (ET) is one of the most important hydrological processes in forested catchments and is essential in terms of water resource management. ET differs depending on the precipitation type (rainfall or snowfall) and forest conditions, such as, species, stand density, and tree height. For example, rainfall interception ranged 10–20 % of the rainfall, while snowfall interception ranged 30–50 % of the snowfall in evergreen coniferous forests. In addition, rainfall and snowfall interception ranged 10–40 % and 0–10% of the rainfall and snowfall in deciduous broadleaved forests, respectively. Thus, our objective in this study is to estimate catchment ET based on the new practical model which accounting for precipitation types and forest conditions.

Our new model was based on the model developed by Komatsu (2020). In particular, the part of interception loss (Ei) needed to be improved in terms of different precipitation input (rainfall and snowfall). Ei was estimated by species, stand density, and tree height as Ei rate to precipitation based on the review of 77 published studies all over the world. Transpiration (Et) and forest floor evaporation (Ef) were estimated by species, stand density, tree height, and climatic data. We further applied the model to three forested catchments located in Ymanashi Prefecture, central Japan (area: 21km^2, elevation: 680 to 2200 m a.s.l.).

Estimated annual rainfall Ei ranged from 64 to 460 mm with a mean of 282 $\pm$ 100 mm and snowfall Ei from 18 to 241 mm with a mean of 47 $\pm$ 42 mm. Annual evaporation from dry canopy (i.e., Et and Ef) ranged from 190 to 1034 mm with a mean of 507 $\pm$ 186 mm. The total ET ranged from 412 to 1195 mm with a mean of 809 $\pm$ 206 mm. We found the different distribution of ET in each of the catchments and which was caused by the forests and meteorological conditions depending on altitude and management history. Incorporating our model with LiDAR remote sensing, we can estimate the distribution of ET within catchments and thus it can be effective for future catchment management.

Integrated Study on Groundwater Utilization System at Water Outage/shortage during post-Disasters and or Draughts: Watershed Modeling and Scenario Analysis

Taikan OKI [1*], Yukiko HIRABAYASHI[2], Hiroyuki TOSAKA[3]

[1] The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, oki@civil.t.u-tokyo.ac.jp

Key Words: *Integrated Watershed Model, Water Outage, Groundwater Utilization System*

In emergencies such as large-scale earthquakes, floods, and accidents, "water outage" is still the most familiar and urgent problem. In the questionnaire "Problems after the disaster", "Securing sufficient water" always ranks high. In the event of a large-scale earthquake in the past, not only will it have a major impact on domestic water, but it will also become a bottleneck for resuming operations due to the total water outage of industrial water, and it hinders rapid recovery and rebuilding of life. In the report of the National Land Council in May 2017, "About the ideal water resource development basic plan for the stable supply of risk-managed water," the promotion of demand-led water resource development up to now has been changed to risk-managed. With the aim of shifting to a stable supply of water, the use of alternative water sources such as groundwater has been proposed as a flexible response in the event of a crisis.

On the other hand, since the quantitative impact assessment of the flow status of groundwater has been delayed, ground subsidence due to excessive pumping may occur due to improper regulation, on the contrary, it cannot be used effectively due to regulations.

Based on this situation, as one of the issues "Strengthening of National Resilience Against Natural Disasters" in the second phase of the Cross-ministerial Strategic Innovation Program (SIP) implemented by the Cabinet Office, "Integrated Study on Groundwater Utilization System at Water Outage/shortage during post-Disasters and/or Draughts" was adopted, and research began in 2018.

This system consists of "Development of social implementation interface" and "Integrated Watershed Model", and will be implemented and operated by the government, local governments and the basin council.

Multiple disaster scenarios are set in "Development of social implementation interface" to enable governments and local governments to understand the availability of water sources, including water demand and the water supply of surface water and groundwater as a whole in the affected areas, and to identify the amount and location of available groundwater.

In " Integrated Watershed Model ", we will develop a model that combines three advanced technologies: Integrated Watershed Model, New Forest Evapotranspration Model and Land Subsidence combined Watershed Hydrogeological Model.

Assuming the scenario set in the "social implementation interface" in the model area (Kanto Plain, Nobi Plain), the amount of groundwater that can be supplied is estimated under the standard of maintaining the land subsidence below a certain level.

In this presentation, we will introduce three advanced technologies and scenario analysis results.

Integrated Watershed Modelling for Groundwater Use at Emergency in the Kanto Plain, Japan

Soki Fukazawa[1*], Kazuhiro Tada[1], Takafumi Yoshida[1], Junichi Aoki[1] and Hiroyuki Tosaka[1]

[1] Geosphere Environmental Technology, Inc., 2-1 Awajicho, Kanda,Chiyoda ward, Tokyo, 101-0063, Japan, NCO Kanda Awajicho 3rd Floor, sfukazawa@getc.co.jp (https://www.getc.co.jp/)

Key Words: *Emergency use of groundwater, Watershed surface/subsurface coupled modelling, Hydrogeologic parameter identification, Groundwater potential*

For the purpose of mitigating water shortage/outage caused by possible natural disasters such as earthquakes or drought in the Kanto Plain which contains the Tokyo Metropolitan area of Japan, we have been working on numerical hydrologic modelling to investigate possibility of emergency water supply from groundwater wells.

For modelling the watershed which covers around 35,000km^2, a general-purpose hydrologic simulator GETFLOWS[1] was used, in which the interactions of the surface water and groundwater are treated in a fully coupled manner.

We collected necessary field data for numerical modelling as follows;

- DEM with 5m resolution
- Digital maps of vegetation and land use
- Hydrogeological information such as boring data, published maps and related bibliographies
- Records of surface/subsurface water use (location and rate with time)
- Climate records regarding precipitation distribution over the watershed
- Observation records of river flow (rate or water level), and groundwater level at wells.

The Kanto Plain is discretized with 250m horizontal resolution, and 60 variable thickness layers in subsurface down to -6500m. The final grid system was formed in around 46 million grid blocks.

For depicting the 3-D geological structure of the watershed, around 200 borings and other geological information/expertise were used to estimate geological structure of the whole watershed. Intensive calibration was made through comparison between the observed and calculated groundwater levels at over 100 wells, as well as the observed and calculated runoff rate for large rivers. The calibration processes were done by changing hydraulic parameters for the period of drought around 1994, and for the period from 1920 to present including the time when a large amount of groundwater was used for lives/industries from 1945 to 1970s.

In the presentation, we will introduce the tentatively obtained hydrogeological information such as

- Groundwater potential distribution (maps of permeability x thickness) ,
- Estimated cumulative thickness of muddy layers for estimating subsidence potential,
- Historical change of contours of groundwater level, and
- Flow lines from the past to the recent by graphics.

These hydrogeological information was transferred to the analysis of land subsidence.

Key Words: *Watershed Modeling, wide-area land subsidence, groundwater pumping, alluvial fan, unconfined aquifer.*

In the event of a disaster such as a large-scale earthquake, the function of water supply facilities may stop, and the water supply that is essential for people's lives may stop. The use of groundwater is effective as a water resource in such an emergency. On the other hand, unplanned use of groundwater may cause wide-area land subsidence and may cause various problems such as an increase in the risk of subsequent inundation.

We are constructing an integrated watershed model for identifying hydrogeological condition and groundwater potential in the Nobi Plain with the aim of quantitatively understanding when, where, and how much water can be pumped within the range that does not cause land subsidence. In constructing the watershed model, we keep in mind that 1) it is a model that matches the purpose, and 2) it is a model that captures the characteristics of the area related to the purpose.

The Pleistocene gravel layer distributed in the Nobi Plain is rich in groundwater recharged by the alluvial fan formed by the Kiso, Nagara, and Ibi rivers. In the Nobi Plain, which is rich in groundwater, wide-area land subsidence occurs due to the pumping of a large amount of groundwater during the period of high economic growth, and groundwater management including regulations is carried out to prevent this. As a result, wide-area land subsidence has subsided over time in recent years, but during the drought in 1994, although the annual pumping amount was below the control value, temporary groundwater pumping in the summer was progressed. As a result, ground subsidence has occurred. In an emergency such as a disaster, excessive pumping of groundwater may occur in the terms of time and space. This is considered to be exactly similar to the phenomenon of 1994.

In this report, we introduce that in order to construct a watershed model that satisfies the above requirements 1) and 2), we modeled an alluvial fan as a recharge source area, unconfined aquifer which is rich in groundwater and confining layer based on various information on topography and geology, and then simulated seasonal fluctuation trends in groundwater levels in 1994.

Modeling of Line-Sources for Seepage Flow Analysis Allowing Arbitrary Finite Element Meshing

Hideyuki Sakurai[1*] and Toshiko Yamada[2]

[2] Shimizu Corporation, Kyobashi 2-16-1, Chuo-ku, Tokyo 104-8370, Japan, toshiko_y@shimz.co.jp

Key Words: *finite element, seepage flow, line source, point source, unstructured grid*

A new model of line-source is proposed for the finite element method (FEM) of groundwater seepage flow. In the FEM, considering the pumping or injection (hereafter referred to as pumping) well, it is necessary to divide the pumping well and its vicinity into a very fine mesh to obtain accurate results. Because the diameter of the well is very small compared to the that of the analysis area, the well is often modeled as a line-source that is represented by a sequence of nodal points with given pressures or flow rates.

When modeling a pumping well with a sequence of point sources, each point source is considered as a well with a certain diameter according to the size of connecting-elements that connect to the point sources. Theoretically, the size of connecting-elements can be only approximately seven times the actual radius of the well, imposing significant restrictions on mesh division for large three-dimensional (3D) regions with planes of ten thousand of square meters or more.

Extensive research has been conducted earlier in the field of petroleum engineering to address this problem. Most of them are organized in the commemorative paper [1]. However, for 3D mesh, existing studies are only valid for the structured or the semi-structured grids. In this study, a new model of line-source for FEM accepting arbitrary 3D mesh is proposed to address this problem.

The proposed line-source allows the use of mesh that is divided by 3D finite elements of arbitrary shape. Because this model corrects only the permeability of the connecting-element based on the theoretical solution, its implementation into the existing programs involves creating only two subroutines. One corrects for permeability before constructing the FEM equations, and the other reversely corrects the velocity vectors and other factors related to the permeability after the solution. In addition, by making these subroutines as external programs, this model can be used as pre/post-processing of the existing programs or commercial software.

Analysis results of two simple problems are shown as code verifications for this line-source model after explaining the formulations and algorithm of the model in detail. One is the problem of a well pumping groundwater from the confined aquifer sandwiched between parallel impermeable layers, and the other is the problem of a well pumping groundwater from sections partitioned by packers for shielding groundwater. From these results, it was verified that the proposed line-source model provided considerably high accurate solutions even in arbitrary meshes.

Key Words: *groundwater, urgent usage, earthquake, drought, land subsidence*

Owing to the emergent situation under earthquake, flood and so on, the water outage is serious and grave damage to the suffers. Main countermeasure for water outages is emergency water-supply by a water tender. When the wide-area is damaged, the capacity of the water tender is not enough for water demand of suffers. Groundwater has the potential to support a part of water demand. On the other hand, groundwater intake has been limited to avoid land subsidence so far. Recently, the wise usage of groundwater for a risk-managed reliable supply of water is now considered. Here, we try to develop a scenario for the safe use of groundwater during the post-disaster period over the Kanto Plain including Tokyo, the capital of Japan, and Nobi Plain, including Nagoya, Japan. Those plains are at risk of earthquakes and drought.

The shortage of water resources was calculated as the amount of demand minus the supply. The amount of water outage after a disaster was estimated as the time series of water supply interruption rate based on past earthquake cases. This water supply interruption rate is high in areas at risk of liquefaction, where the risk of water pipe breakage is high, so the calculation was made separately from other regions. The demand for domestic water use was based on the demand for water for domestic use in each time series assumed in the disaster prevention plan by the Japanese government. Specifically, only drinking water (~3 liters per person per day) would be needed for the first three days after the earthquake, and that demand for washing and bathing (~250 liters per person per day) would increase as the days went by. These calculations were conducted for each municipality category and finally weighted and allocated regarding land use to create a 250m mesh of water shortage.

The developed scenario allows us to show the hot spots where the water demand is not met after the earthquake occurrence, depending on the season, climate condition, and distribution of seismic intensity of the earthquake. For example, in the downtown area, where urban development is not yet advanced, and wooden houses are densely built, there is a shortage of water to fight fires caused by earthquakes in many areas for the first day. In contrast, while outage of municipal water reaches its maximum around two weeks after the disaster event. The estimated time series of water outages at 250m mesh can be used as input data of the 3-D groundwater model to investigate the potential of groundwater safe of use without land subsidence.

Study of groundwater flow in Minami-soma City, Fukushima Prefecture, Japan

Key Words: *Great East Japan earthquake, Groundwater Flow Simulation, Radioactive Cesium*

Due to the accident at TEPCO's Fukushima Dai-ichi Nuclear Power Station, radioactive materials were released over a wide area, and relatively high concentrations of radioactive cesium (hereinafter Cs) were deposited in the Abukuma Mountains. Although it has been clarified in previous studies that most Cs are strongly adsorbed on the surface soil, the possibility of Cs transport into the bedrock cannot be ignored in areas where the soil layer is relatively thin or where the basement granitic rocks are exposed at the surface.

Therefore, groundwater flow simulation with particle tracking analysis has been conducted in the area from the Abukuma Mountains (topographic high) to the lower coastal plain at the southern part of Minami-soma City, Fukushima Prefecture. The geological model has been constructed based on published topographical and geological information[1]. The geological model consists of Mesozoic granite in the west, Neogene sedimentary layers consisting of alternating beds of sandstone and mudstone in the east, and the NS-trend Futaba fault zone between them. The hydrogeological model was constructed by utilizing published hydraulic conductivity values[2] to geological zones of the geological model.

Regarding boundary conditions, constant head boundaries have been set for the side boundaries, while a no flow boundary has been set for the bottom boundary. Since actual measurements of hydraulic conductivity values are limited, sensitivity analysis has been conducted by changing the hydraulic conductivity of the Futaba faults zone and mudstone in the sedimentary formations.

As a result of the particle tracking analysis, most of the particles recharged from the mountainside discharge to three areas within a few years to several tens of years in the eastern plains regardless of differences in hydrogeological models. A groundwater reservoir exists within the discharge area above mentioned. This suggests that if Cs migrates with groundwater, Cs concentration may increase around the reservoir in near future. Therefore, it is important to conduct continuous monitoring of Cs concentrations around the reservoir.

A study on the effects of Cs in groundwater is expected to provide important information to citizens who are considering returning to this area.

Key Words: *Land Subsidence, Inverse Modeling, Uncertainty, Evolutionary Multimodal Optimization*

This study tried an uncertainty analysis for numerical land subsidence modeling with multiple sets of subsurface properties which make comparable reproducibility of observed land subsidence by using an evolutionary algorithm for multimodal problems. Subsurface properties are often uncertain and multiple sets of subsurface properties can explain observed subsidence in numerical modeling, causing the reliability of a single "best" set to be questionable. Existing studies have attempted to solve this reliability problem through the ensemble Kalman filter or ensemble smoother, but these were not straightforward for highly nonlinear problems, such as a clay compaction process. It has also been reported that these methods can only deal with problems which have a small dimensionality in parameter space. This study aims to construct multiple sets by an inversion procedure of an evolutionary algorithm for the vertically 1D coupled simulator of groundwater flow and subsurface deformation with a modified Cam-clay model. The evolutionary algorithm has shown to be efficient and applicable for nonlinear problems, but it easily loses model diversity during the modeling process. We solved this problem by employing fitness sharing, which modifies the evaluation of a model according to its distance and similarity to neighboring models. As a result, we succeeded in obtaining diverse sets of subsurface properties with comparable reproducibility of observed land subsidence. Furthermore, the test of different thresholds for determining the size of the neighborhoods showed how the threshold controls the diversity of the obtained sets. Through an application to a synthetic problem, it was found that the hydraulic conductivity, specific storage, compression index, and the initial preconsolidation stress in clay and compression index in the aquifer are well-constrained, while the hydraulic conductivity and specific storage in the aquifer and initial void ratio in both clay and aquifer are uncertain. Finally, we demonstrate our method of visualizing the predictive uncertainty in land subsidence by applying it to an actual field problem and conducting the scenario analysis.

A Detailed Simulation Model to Evaluate the Crash Safety of a Li-Ion Pouch Battery Cell

Key Words: *Electromobility, Crash Safety, Battery Modelling, Layered Cell Structure, Failure Analysis*

In crash situations with an electric vehicle, the integrity of the battery cells is critical for the consequences of the crash. A short circuit triggered by deformation and damage of the internal cell structure can cause overheating of the battery (thermal runaway) and may result in a vehicle fire or even an explosion. Thus, for assessing the crashworthiness of electric vehicles evaluating the deformation states of potential crash situations with respect to the occurrence of a short circuit is crucial. A particular challenge for building a cell model with acceptable computational time lies in the very different spatial scales regarding the overall cell size and the thickness of individual layers. Cells installed in vehicles have dimensions of several centimetres, whereas the thickness of the individual layers is in the micrometre range. Much research has already been conducted based on homogenized cell models that do not explicitly account for the internal layer structure, and existing material models calibrated to experimental data (e.g. [1]-[3]), while explicitly considering the layered structure is just pursued more recently (e.g. [4]-[7]).

Within our contribution we introduce a detailed numerical model which, as a part of a multilevel simulation approach, can be used to evaluate the criticality of a deformation state. The model mimics the layered structure of the cell, whereby the constitutive properties were determined by in-house experiments on the respective materials. For validation, bending tests and indentation tests with different punch geometries along with CT-scans at selected indentation depths are available. Comparing the simulation results with the failure sequence and the force-displacement curve from the experiment, a closer view on critical deformations and on their respective stress states is obtained. The results indicate that in-depth understanding and modelling of the failure behaviour is crucial for correctly modelling battery cells under crash loading scenarios.

Acknowledgments

This research was partially funded by the State Ministry of Economic Affairs, Labour and Tourism Baden-Württemberg (Ministerium für Wirtschaft, Arbeit und Tourismus Baden-Württemberg) through the project BATTmobil, grant number 3-4332.62-EMI/3. Thanks to financial support by the Federal Ministry of Education and Research Germany (Bundesministerium für Bildung und Forschung, BMBF) the work could be continued in BATTmobil-2. The project is part of the research platform Tech Center i-protect.

We are thankful to Ralph Langkemper for the CT-scans and to André Töpel and Jürgen Kuder for performing experiments.

In the early stage of vehicle planning phase, feasible designs based on the vehicle plan should be derived to meet the lower development cost and working hours.
Conventional finite element analysis from CAD drawings can't find the feasible area in the design space without long hours of CPU.

To conduct feasibility study in the early stages of vehicle planning phase for vehicle body deformation and occupant safety, the database was constructed from large number of frontal crash FE analysis using parametric FE models.

Machine learning(ML) models were created from the database. Coupling analysis using ML models between vehicle body deformation and occupant safety enables occupant injury value predictions from design variables for the vehicle body frames.

Artificial Intelligence with Dimension Reduction Methods for Applications in Shape Recognition

Key Words: *3D-objects, 1D-like Features, Artificial Intelligence, Automatic Shape Recognition, Mesh Generation*

In recent years, a wide range of different approaches have been proposed as shape recognition techniques for 3D objects. The important key for efficient and practical operation in real world is proper engineering of the data representation [1-2]. Vast majority of data representation for 3D objects is based on image-processing methods. Meanwhile, the algorithm to effectively extract data representation (high-level representation) from the raw 3D data is still under study. In this paper, an attempt to define high-level representation is proposed, where the raw 3D data can be extracted into a simplified 1D-like data. Besides data simplification and dimension reduction, the experimental results show no significant loss of accuracy. This 1D-like data is then used as an input into machine-learning system to be manipulated for shape recognition.

3D objects are basically made up of multiple surfaces that can be split separately. Here, data representation of each surface is calculated using our proposed methods to obtain 1D-like features information [3]. The extraction of 1D-like data from surface properties is proposed in [4], which consists of geometrical descriptors, face angle, point angle, etc. Therefore the real 3D objects can be simply modeled as 1D-like data arrays collected from the overall surfaces. This method is able to construct data representation with less computation power and time respectively.

An experiment was carried out to evaluate the performance of dimension reduction methods implemented in machine learning (deep-learning algorithms) for use in 3D shape recognition with a task to predict the label for each surface. The proposed method has achieved satisfactory result with accuracy > 90%. The advantage of this proposed method is the computation speed of data extration, which makes it attractive as a potential candidate for high-speed shape recognition in real practice. Further works are under going to improve the recognition accuracy and robustness.

Generation of abuse simulation models of battery cells and battery packs

Robert Kießling[1*], Martin Schwab[1]

[1] 4a engineering GmbH, Industriepark 1, 8700 Traboch, Austria, robert.kiessling@4a.at, www.4a-engineering.at

Key Words: Multi-phyiscal Model, Battery Cell and Pack, Abuse Testing and Simulation

In accordance to several safety requirements, battery packs have to pass certain tests defined by international standards and regulations. Particularly, the avoidance of the effect of thermal propagation, induced by a single cell and resulting in a catastrophic failure of the whole pack, has to be addressed within the design process. Aiming for an efficient optimization of the overall safety behavior, multi-physical models of the battery pack as well as of the applied battery cells are required. This contribution introduces a standardized and automatable generation methodology of the required simulation models. Aiming for the initial characterization of the single battery cell, specific experimental investigations are performed. In addition to an electrical and thermal characterization, electrical as well as thermal abuse tests are carried out. Based on the experimental results, the relevant model parameters are identified. To this end, specific multi-physical models are created and evaluated in the commercial finite element code LS DYNA. Here, a self-developed tool is utilized, which allows for the automatic generation of these models. Note, that various modeling approaches ranging from homogenized scale models down to layer level models can be considered with respect to the desired discretization. To validate the resulting model of a single battery cell, some tests are exemplary simulated and the results are compared to the experimental data. In addition, the arise of the thermal runaway is analyzed with respect to the location of the initial short circuit and the state of charge. Next, a model of one investigated battery cell is integrated in an abuse simulation of a whole battery pack. Finally, the simulation results allow for a study and discussion of the influence of specific design measures on the avoidance of thermal propagation. Consequently, the full range from experimental characterization and abuse testing of single battery cells to abuse simulation of whole battery packs is covered by this contribution.

Investigation of Internal Deformation of Lithium-ion Battery and Simulation Model for Internal Short Circuit

Key Words: *Lithium-ion battery, Internal short circuit, Digital microscope, SEM image, Shear band, FEM, DEM, Simulation, Ansys LS-DYNA*

A fire accident caused by the thermal runaway of the Lithium Ion Batteries is one of the important issues of practical electric vehicles. As a safety testing for electric vehicle, thermal runaway and white smoke generation due to impact and crush tests is often evaluated. Basically, though the short-circuit is considered to be caused by the contact between the positive and negative electrodes[1], it is difficult to confirm what kind of deformation occurs inside the battery, because the battery explodes by a short circuit and thermal runaway. The purpose of this research is to elucidate the mechanism of the internal short circuit by visualize the internal deformation state when an internal short circuit occurs. First of all, in order to investigate the inside of Lithium Ion battery during large deformation, the battery was held and solidified in its deformed state, and the internal deformation is observed by digital microscope. In according to the observation in section plane of deformation state, the aluminum and copper of the current collector foil were broken in the upper layer. Furthemore, a shear band could be confirmed by connecting the points of the broken collector foil. It is presumed that this internal deformation state is the cause of the contact between the active materials of the positive and negative electrodes and the contact with the foil, which causes an internal short circuit. This result is important to explain why battery cells cause internal short circuits when large deformation has occurred. In addition, in order to elucidate the mechanism of this shear band, we will introduce a proposal to elucidate the internal short-circuit generation mechanism by constructing a simulation model that can reproduce the shear band by compression by using the commercial finite element method code Ansys LS-DYNA.

Simulation of Stretching Deformation of Films for Electronic Devices in Automotive Applications

Jihong Liu[1*], Akio Higaki[1], Nobuyuki Komatsu[1] and Satoru Takanezawa[1]

[1] Daikin Industries, Ltd., 1-1 Nishi-Hitotsuya, Settsu, Osaka 566-8585, Japan
jihong.liu@daikin.co.jp, https://www.daikin.com/

Key Words: *Finite Element Method, Orthogonal Anisotropic Plasticity, Fluoropolymer, Film, Biaxial Stretching, Transverse Stretching, Deformation, Kink Band*

Fluoropolymers have excellent weather resistance, heat resistance, electrical insulation properties, etc., and are used in a wide range of fields such as semicondutcors and automobiles [1]. Recently, it has been clarified that the electrical properties such as relative permittivity, volume resistivity and dielectric breakdown strength of the fluoropolymers are significantly improved by controlling their crystal structure with biaxial stretching [2]. As a result, biaxially stretched fluorine films are increasingly expected to be used in automobile-related electronic devices such as high-frequency substrate films, motor insulating papers, and film capacitors to improve their performances and reduce their sizes and weights. For example, the size of the film capacitors can be reduced to less than half with the fluorine films compared to polypropylene (PP) films. As automobiles become CASE (Connectivity, Autonomous, Sharing/Subscription, Electrification), various devices are required to be smaller and lighter. The downsizing of the film capacitors will greatly contribute to the miniaturization and performance improvement of the electronic devices for electric vehicles. However, it is difficult to continuously manufacture the fluorine films because kink bands and stretching tears are easily to occur during successive biaxial stretching with a tenter.

In this study, we proposed a simulation method for film transverse stretching based on the finite element method using the orthogonal anisotropy plastic model [3]. The simulation method can not only analyse the large stretching deformation up to the orientation hardening region, but also predict the kink band phenomenon that occurs during the film transverse stretching. The validity of the simulation method was confirmed by the film transverse stretching tests performed on the fluorine film sheets with different longitudinal stretching ratios. Using the simulation method, we clarified that the anisotropy index of the fluorine film sheets has a great influence on the presence or absence of the kink band phenomenon during the film transverse stretching. The anisotropy index of the film sheets after longitudinal stretching can be related to their orientation, and the two are approximately in a linear relationship for the fluorine film sheets. Moreover, we revealed the change in film stretching deformation due to difference in tenter shape. The main conclusions drawn by the simulations are as follows.

(1) The presence or absence of the kink band phenomenon during transverse stretching largely depends on the anisotropy of the film sheets after longitudinal stretching.
(2) The ratio of length to width of the stretching zone is desired to be 2.0 or more.
(3) The protective layer attached to the edge of the film sheet has the effect of preventing the film from tearing during the transverse stretching.

The UPSCALE project. Physics informed machine learning turbulence modelling applied to vehicle aerodynamics

Bhanu Prakash*, Sergio Illera and Enric Aramburu

IDIADA Automotive Technology SA, Po Box 20 L'Albornar Santa Oliva (Spain),
idiada@idiada.com

Key Words: *CFD, PIML, turbulence modelling, aerodynamics, machine learning*

The UPSCALE project is the first EU funded project intended to integrate Machine Learning (ML) algorithms with CAE tools to foster the development of Electric Vehicles. Within the frame of the UPSCALE project several innovative solutions that apply this premise have been implemented and tested on real vehicle designs. Examples of this new approach to simulate key automotive load-cases include surrogate models of aerodynamic CFD simulations, reduced order models of battery cells in crash simulations or machine learning physics informed (PIML) turbulence models.

In this work, we present the application of machine learning to find a correlation between Reynolds (Re) stresses and the main flow variables in high fidelity flow fields, with the aim to set an iterative process to progress through RANS solutions with realistic flowfields including, pressure, velocity and Re stresses.

Following the approach proposed by *Xiao* [1],the authors implemented a framework that extracts up to 10 variables (inputs in our ML model) and 8 responses (outputs ion our ML model) in RANS and DNS flowfields and tried different strategies to improve the RANS solution accuracy and trying to be closer to DNS flowfield.

Framework 1 is focussed on computing the discrepancy between RANS Re stresses and the would be Re stresses in the DNS solution. So, we use RANS flowfield variables as inputs and the difference between RANS and DNS Re stresses as output to train the ML algorithm. This approach proved to be promising for similar flowfield, with same geometry and Re number, showing its limitations when moving to complete different flowfields**.**

In framework 2, we use high fidelity data only as inputs and the DNS Re stresses as outputs for the training phase and we apply this rule on the RANS inputs to get a new Re stress field. The direct application of this approach on converged RANS flow-fields proved to be unsatisfactory, and the authors deem this is due to inaccuracy of the converged flowfield, so further investigation needs to be performed, for instance a coupled procedure between the Navier Stokes equations solver and the PIML Re computation.

The presentation will include the description of the different investigated frameworks, the main results, conclusions and the foresight of the application Physics informed strategies in turbulence modelling.

Key Words: *Image-based simulation, uncertainty quantification*

Image-based simulations are a key enabler of digital twins and can represent a digital engineering workflow for the analysis of as-built materials and components. In this talk, we detail the development of key enabler technologies for credible and automated image-based simulation workflows. Machine learning techniques are created for 3D image segmentation with uncertainty, which we show to be more robust and accurate than human segmentations. We also extend the conformal decomposition finite element method to automatically generate high quality meshes for numerical simulation. This entire workflow is subjected to rigorous uncertainty quantification. Our processes are demonstrated on three key exemplar applications, thermal protection system materials, electrodes for lithium-ion batteries, and exploding bridge wire detonators.

Additionally, we have fully automated this image-based simulation workflow with a cloud-computing-based web interface. We demonstrate this automation on the exploding bridge wire detonator exemplar.

Key Words: *Nonlinear Finite Element Analysis, Deformation Analysis, Point Cloud, Laser Scanning*

Abstract

In recent years, with the advancement of technology in shape measurement and geometry processing of structures using terrestrial laser scanners (TLS), it becomes possible to create finite element analysis models from the point cloud measured by TLS.[1,2] In the methods presented in the previous studies, the shape of the structure at the time of point cloud measurement is used to generate the analysis model before deformation. However, the actual structure is already deformed at the time of point cloud measurement even when it was constructed just the moment. The existing studies ignore the deformation until the shape is measured.

To perform structural analysis including deformation before measurement, an analysis method that considers the point cloud data as a deformed partial shape of the structure was proposed in this study. In this method, it is assumed that drawings or CAD data of the structure exist. The deformation analysis is performed so that the finite element analysis model obtained from these data matches the partial point cloud data after deformation.

Beams, which are basic structural mechanics problems, were analyzed to investigate the performance of the proposed method. Point cloud data created virtually were used in these analyses before applying this method to real structures. In the presentation, we will present a numerical analysis of a more complex and realistic structure by using point cloud data.

Key Words: *Co-creative design; Adhesive; Shape optimization; Failure criterion; Multiaxial stress state*

An important technical trend in the automotive industry in recent years has been a reduction in the weight of structures in an effort to reduce the emission of carbon dioxide and energy consumption. One strategy adopted to lighten structures is multi-material design. [1] Among various methods of joining dissimilar materials, adhesive bonding has the advantage of being low weight. The problem of adhesive bonding is complicated that both material factors and structural factors affect the strength and design process. As a result, a co-creative design process is necessary to involve all those factors into the application of adhesive bonding.

For material factors, experiments using pipe specimens with inclined surfaces bonded by epoxy adhesive were performed, whereby multiaxial stress states were realized simply by conducting a uniaxial tensile test. The failure function of the epoxy adhesive, expressed by the mean stress and octahedral shear stress, was then obtained from the experimental data and compared with that of acrylic adhesive previously reported in the literature. [2] For material factors, the obtained failure functions of both adhesives were then applied to the shape optimization of the adhesive layer under different loading conditions. The optimization object is the strengthening of jointed structures. The optimal shape for different loading conditions differed for the different adhesives because of the driving force generated by the applied stress. [3]

The final shapes were thus optimized numerically and found to be strongly dependent on the initial shapes before optimization. We found that these final shapes are numerically optimized to realize a higher mechanical integrity of the adhesive layer. The patterns of the shape changes during the optimization process differed according to different loading condition as well as different adhesives which could be indicated by the shape gradient function inducing the geometric change of the adhesive layer. The research is expected to provide a procedure of co-creative design of multi-materials using adhesives. The observation of the shape optimization could be used as an indicator of whether the initial model is appropriate for multi-material design.

Key Words: *Seismically isolated structure, High-damping rubber bearing, Finite element analysis, Elastic-plastic constitutive law*

New elastic-plastic constitutive law for rubber material of high-damping rubber bearing was developed. High-damping rubber bearing is one of the seismic isolation bearings which are important members of seismically isolated structure. In design of the seismic isolation bearings, finite element analysis (FEA) is widely used as a method of numerical simulation. Generally, in design of rubber-like material based on FEA, selection of a constitutive law is particularly important. There are many types of seismic isolation bearings, however, high-damping rubber bearing shows complex behaviour compared with other seismic isolation devices. It is one of the feature of rubber bearing that magnitude of deformation is much larger than other rubber products and the maximum shear strain of rubber is about 400%. In the past, many constitutive laws for FEA of high-damping rubber were proposed. However, they could not represent the complex behavior of restoring force characteristics of high-damping rubber bearing with high accuracy. Thus, authors developed new elastic-plastic constitutive law for rubber material of high-damping rubber bearing. The constitutive law is called deformation history integral type model (DHI model). The model was developed as elastic-plastic constitutive law by modifying Simo's viscoelastic constitutive law [1]. The model is defined by the relationship between second Piola-Kirchhoff stress and right Cauchy Green tensor. Features of proposed constitutive law are as follows;

A. DHI model can represent the horizontal creep behavior when strong wind such as hurricane, cyclone and typhoon hits seismically isolated structure using high-damping rubber bearings.
B. DHI model can represent the complex behavior of high-damping rubber bearing for wide range of shear strain including horizontal bi-directional loading.
C. Calculation algorithm of DHI model is very simple and calculation cost is low.

Accuracy of the proposed constitutive law was confirmed by comparing various test result of high-damping rubber bearing. While new constitutive law was developed for high-damping rubber bearings, the model has the potential to apply to other materials and products.

Key Words: *Homogeneous finite element analysis, Kelvin unit cell, Polyurethane foam*

In this study, the homogeneous finite element analysis using the Kelvin unit cells was performed to evaluate the macroscopic mechanical properties of the polyurethane foams considering their microscopic structures.

The mechanical properties of foam materials have been evaluated by the homogeneous finite element analysis with unit cells [1][2]. The unit cells were required to represent the geometric feature of the microscopic structure from the engineering point of view.

The Kelvin unit cell was introduced to represent the microscopic structure of the polyurethane foams. In this study, the Kelvin unit cell consisting of 6 squares and 8 hexagons was applied to the numerical simulation. There are 36 beams and 24 edges in one unit-cell. Three-dimensional CT scanning images were observed to create the Kelvin unit cell considering the microstructure of the polyurethane foams. The beams of the polyurethane foams have a non-uniform distribution of cross-sectional areas along their length. The non-uniformity of beam cross-sectional areas was given to the Kelvin unit cell to reproduce the microstructural geometry of the polyurethane foams.

The hyperelastic material was applied to the matrix of the Kelvin unit cell. The higher order Yeoh model was adopted to the potential energy function of the hyperelastic material. The original homogeneous finite element analysis code of the Kelvin unit cell was developed. The mechanical properties of the polyurethane foams in the uniaxial compressive deformation were evaluated by the analysis code. From the analysis, the non-uniformity of beam cross-sectional areas is an important factor for the mechanical properties of the polyurethane foams.

Key Words: *UMMDr, hyperelastic, damage, viscoelastic*

With the diffusion of commercial finite element software, practical problems have been solved by numerical simulations in a wide range of fields. However, for more advanced problems, we require material models that are not prepared using the default analysis options. For this reason, computer aided engineering (CAE) engineers need to customize the options available in finite element programs themselves and consider the material model appropriate for the problem, but these technical processes require specialized knowledge and skills.

The Japan Association for Nonlinear Computer Aided Engineering (JANCAE)[1] offers information and learning opportunities to CAE engineers in various positions. Since 2011, participants have developed and verified two user subroutine libraries: the Unified Material Model Driver for Plasticity (UMMDp) for anisotropic yield functions, and the Unified Material Model Driver for Rubber (UMMDr) for modeling rubber materials. We announced the release of the UMMDp[2] at the 2018 WCCM, and will announce the UMMDr this year.

In the UMMDr, a subroutine library combines the hyperelastic models (e.g., stretch-based models such as Ogden and Shariff, and invariants-based models such as Mooney Rivlin.), damage models (e.g., Simo, Miehe, Ogden-Roxburgh[3]), and visco-elastic models (e.g., Simo, Holzapfel,[4] Reese-Govindjee[5]). Using these models, the stress and consistent tangent stiffness for a given deformation gradient are calculated, and converted to the stress rate or the alternative stress that is suitable for each commercial finite element software, such as Abaqus, ADINA, Ansys, Ansys LS-DYNA, Marc, and Simcenter Nastran. Therefore, new constitutive models can be added to the UMMDr just by creating a new subroutine.

In this presentation, we will explain the structure of the UMMDr and how to introduce a hyperelastic model, a damage model, and a viscoelastic model into the UMMDr. We will also demonstrate verification using some simple tests.

Key Words: *Multi-scale analysis, Filled rubber, Molecular dynamics, Finite Element Method, the K computer*

In order to establish a sustainable society, superior rubber materials for tires are required so that both the rolling resistance and wear performance can be improved. It is known that visco-elastic characteristics of rubber material plays an important role for these performances. Filled rubber is a nano-scale composite made of matrix polymer such as natural or synthetic rubber, and filler particles such as carbon black or silica. Precise study in mechanical behaviour of matrix polymer, filler particles, and their interactions is expected to explore the origin of visco-elastic properties. However, it is very difficult to do it by experiments.

This study aims to develop a simulation technology which can predict the visco-elastic response of nano-composite by numerical simulations. A multi-scale computational modelling method is proposed. Both molecular dynamics (MD) and large scale Finite Element Method (FEM) are utilized to include molecular level properties into continuum level analyses. MD resolves the matrix-filler interaction in the molecular scale to obtain the thickness of the interphase region and the mobility of molecules of the matrix polymer within the region. These results are passed to the FEM analyses where nano-scale filler structures are precisely modelled from the images measured by 3-dimensional transmission electron microscope tomography (3D-TEMT). The FEM computations are done by 6144 cores of the K computer since the numerical model becomes around 200 Million degree of freedoms.

The effects of filler-matrix interaction intensity and filler dispersion are analysed, and the differences in relaxation modulus are presented to show the effectiveness of the proposed method.

Key Words: *UMMDr, rubber, damage, finite viscoelasticity*

The Japan Association for Nonlinear Computer Aided Engineering (JANCAE)[1] provides information and learning opportunities for CAE engineers in various positions. As part of the activities of the subcommittee for non-linear material modeling, since 2011 we have been developing a material model driver, the Unified Material Model Driver for Rubber (UMMDr), to handle the constitutive laws of rubber like materials in a unified manner. The model consists of a hyperelasticity branch with damage and finite strain viscoelasticity branches in parallel. The user selects hyperelastic models, such as Ogden, Mooney-Rivlin and Extended-tube,[2] and can also select damage models, such as Ogden-Roxburgh,[3] or finite strain viscoelastic models, such as Holzapfel[4] and Reese.[5] It is possible to consider the damage model and the viscoelastic model at the same time. One can also add their own new constitutive model to the UMMDr.

In this presentation, we report on two practical examples of using the UMMDr in the following codes: Abaqus, ADINA, Ansys, Ansys LS-DYNA, Marc, and Simcenter Nastran (with Samcef Mecano as the solver behind the solution). In the first example, we evaluate hyperelastic-viscoelastic properties by repeatedly performing simple shear deformation of a cube. In the second example, we evaluate hyperelastic-viscoelastic properties by repeatedly performing compression of a rubber bushing. Normal outputs were obtained for each code.

Key Words: *Tire rubber, Friction, Wear, Surface roughness, Power spectral density*

A full understanding of the wear phenomenon of frictional tire rubber on a road surface plays an important role at predicting the tire life with high accuracy. Although the multiple analyses including adhesion, hysteresis and ploughing friction may be required for elucidating the wear mechanism, such a comprehensive analysis needs a high-cost performance because various contact and fiction mechanics at the corresponding scales should be implemented. Therefore, the present tire-life prediction is to use the stationary equation of wear volume, estimated by tire wear tests with a belt-type or drum-type machine. It is not efficient in the terms of intensifying the development cycle of a tire.

In this study, we focus on the initial wear process of tire rubber, in which the abrasive wear severely proceeds along with the change in a statistical nature of surface topography. We demonstrated the reciprocating friction tests with carbon black-filled rubber specimens and a vitrified grindstone plate. Measuring the pre- and post-sliding surfaces of the rubber specimens, we carried out the spectral analysis on the measured surface height data to compare with that of the grindstone substrate using a correction method of the areal 2D power spectral densities (PSDs) [1]. To convert the 2D PSDs to the isotropic PSDs and fitting them with the K-correlation model [2, 3], we revealed that the average Hurst exponent (H) of the rubber surfaces approaches asymptotically to that of the substrate with the increase of sliding distance (d). We also calculated the relative wear volume (V_{rel}) using H within the high wavenumber range and clarified that the curve of $V_{\mathrm{rel}}(d)$ can be expressed by the logistic equation, which is the model of population growth in the field of ecology. Our findings open the elemental wear mechanism of soft matter on a rough and hard substrate, which could link to the stationary wear process of our practical interest.

Key Words: *Polymer foam, Microstructure, Voxel FEM, Microscopic CT-scan*

In this study, voxel finite element analysis(FEA) of microscopic structure of polymer foam were performed to reproduce its viscoelastic behavior.

Finite element models were created from 3-dimentional microscopic CT-scan data of the polymer foam material. A polyurethane foam for automobile seats was applied to the polymer foam in this study. The tensile loading test specimens of polymer matrix without air-bubbles were created by original defoaming-process. The viscoelastic properties were obtained from tensile loading test results of polyurethane matrix.

Viscoelastic hyperelastic model was applied to reproduce the stress-strain relationships of the polymer-matrix. The polyurethane-matrix was confirmed as nonlinear elastic and weak viscous material. Compression loading tests of the polymer foam materials were conducted under some relative density. The effect of relative density on the mechanical properties was evaluated by the loading test results.

Effects of microstructure were simulated by the voxel FE analysis with 3-dimentional microscopic CT-scan data. The analysis results were compared with stress-strain relationships obtained from compression tests of the polymer foam materials.

Three-FE models were applied to the voxel FE analysis. The number of elements in each models was 1,194, 1,254, and 1,263, respectively. Effect of microstructure on the macroscopic mechanical behavior of foam material were appeared in plateau-area. Location of stress concentration in microstructure of the foam materials was shown to be consistent at different strain rates by the simulation results. Viscous effect of the polymer matrix on the macroscopic mechanical behavior of foam material were shown in the simulation results.

Key Words: *Chemical Vapor Deposition, Computational Fluid Dynamics, Alumina deposition, Industrial-scale Reactor*

This work presents a two-dimensional, time-dependent, computational fluid dynamics (CFD) model of an industrial-scale Chemical Vapor Deposition (CVD) reactor, used for the coating of cutting tool inserts. In CVD processes, a gas reactant mixture enters the reactor chamber and through a series of homogeneous and surface reactions, leads to the deposition of a thin film on a heated surface. The developed CFD model accounts for the transport of mass, momentum, and chemical species inside the reactor while including a simple reaction scheme for the deposition of alumina.

The reactor used for the production of the alumina coatings consists of around 45 perforated trays, stacked one on top of the other. The cutting tool inserts are placed on each tray on appropriately sized structures. The gas reactants enter through perforations which are carefully placed on a central rotating tube. This ensures the uniform distribution of the gas reactants around the inserts. The simulations aim to capture the effect of the gas flow field on the coating thickness and, in extension, on the coating thickness uniformity. Providing accurate thickness predictions will enable the implementation of the model as an optimization tool for the production setup. However, implementing such a model in everyday production is not feasible unless the model is efficient in terms of the required computational resources. This consecutively leads to several challenges, such as simplifying the three-dimensional geometry coupled with the physically meaningful incorporation of the rotating gas feed tube in the model.

The model's predictions are compared with α-Al_2O_3 coating thickness measurements available for different locations inside the reactor. The model can accurately predict the coating thickness with an average relative error of 5%. The model allows for simulations of several different reactor configurations and process parameters and can therefore be used to study the effect of these factors on the resulting coating thickness.

Development of a hybrid model for large-scale plant RUL prediction based on data and physical models

Elif Öztürk [1*]

[1] inspire AG, Technoparkstrasse 1, 8005 Zurich, Switzerland, oeztuerk@inspire.ethz.ch
(https://www.inspire.ethz.ch/ and https://www.iwf.mavt.ethz.ch/)

Key Words: *Predictive maintenance, Machine Learning, Industrial Applications, Optimizing maintenance intervals, Remaining Useful Life*

Large plants in the process industry are monitored and maintained at regular intervals, and repeatedly maintenance is either too early or too late. This causes unnecessary costs due to technicians, spare parts procurement as well as delivery issues and to high downtime costs due to unexpected shutdowns. In this context, the Remaining Useful Life (RUL) plays a major role, as it is an indicator of how long a machine or component can run without breakdown, repair or replacement. By predicting RUL using predictive maintenance, maintenance can be better planned, operational efficiency optimized, and unplanned downtime avoided. Optimizing the prediction accuracy should therefore always be in the foreground and is therefore the topic of this abstract.

Lei et al. [1], in a review on data acquisition to RUL prediction, emphasize that predicting the operational behavior of machinery and equipment is one of the major challenges in condition-based maintenance. According to the authors, such a prediction program consists of the following four technical processes: 1. data acquisition; 2. construction of the Health Indicator (HI) of machinery and equipment; 3. subdivision into different stages of the Health Stage (HS); and 4. RUL prediction. The relevance of RUL prediction is also supported by Jimenez-Cortadi et al. [2]. Analogous to Lei et al. [1], Jimenez-Cortadi et al. [2] list different approaches and techniques, but the main contribution is finding a solution to the prediction problem in real machine processes. The results show that preventive maintenance can be transformed into predictive maintenance. In this context, the goal of predictive maintenance is to extend the life of machines and equipment. Jimenez-Cortadi et al. [2] used a CNC milling machine as a real example and used machine-learning techniques to predict the RUL. However, the authors emphasize that the complexity of the model made it difficult to implement in the production machine. Another approach would be a hybrid modeling; this is also emphasized by the authors in Arias Chao et. al [3]. To combine the advantages of both models physical and data-driven, which on the one hand draws on the information of physical models and on the other hand uses deep learning algorithms. The results from the experiment [3] show that the hybrid model outperforms purely data-driven models in terms of predictive power - the prediction horizon could be extended by about 127%.

The hybrid model is enhanced by the physical model to evaluate and prioritize the wear of the plant condition under the given operating conditions and influences. The hybrid model is applied to a real process gas industry. The basic questions are: What was defective and what was repaired? Which components fail most frequently? Which components have to be replaced or repaired at high cost? The prerequisite for this is service and repair data. The physical model describes a functional relationship between operational stress and service life. The remaining service life is finally predicted by determining whether and when the predicted parameters meet the failure criteria from the failure description. The task is to elaborate the technically essential aspects from the point of view of the modeling of mechanical components under the consideration of dynamic quantities and simulation of a large industrial plant. The goal is to correlate the anomalies found by the hybrid model as well as possible with future faults. Such a trained model can be of great importance for industrial real-time applications; after all, the anomalies identified by the model can enable predictive maintenance for complex large-scale plants.

Key Words: *Wind loading, Machine learning, Computational fluid dynamics, RANS, LES*

Computation fluid dynamics (CFD) represents an attractive possibility to be used for the design of structures. Nevertheless, routine use of the CFD for design purposes still requires significant progress to guarantee the right balance between accuracy of the results and computational efficiency [1].

On the one hand, Reynolds-averaged Navier-Stokes (RANS) simulations are widely employed in wind engineering applications due to their low computational cost. However, their inability to accurately predict complex features of the flow, such as separation and reattachment is limiting their application to qualitative analysis [2, 3]. Thus, RANS-based calculation of the wind loads is generally considered as insufficiently accurate [1], as it is even challenging to obtain a quantitatively accurate prediction of the mean pressure field. On the other hand, Large Eddy Simulation (LES) can provide more accurate prediction of wind loads, but with significantly higher computational costs. In this specific case, wind loads on the the building, these computational costs are even more emphasized as different wind directions of approaching flow needs to be considered.

Therefore, the aim of this study is to propose an optimal machine learning framework that combines computationally efficient RANS, for several wind directions, with more expensive LES for fewer wind directions to provide accurate predictions and lower the computational cost. The developed model takes the RANS mean flow variables, such as mean pressures, coordinates, angle of attack and others as an input and predicts LES obtained mean and rms pressure coefficients. Those LES results are validated with the wind tunnel results. Feature selection techniques are used to explore the optimal combination in terms of accuracy, but as well to reduce the computational cost of modelling. Different machine learning algorithms such as support vector machine, gradient boosting, random forest, and artificial neural networks are adopted and hyperparameter optimization is done to increase the accuracy. Optimal set-up for each of the output parameters, mean and rms pressure coefficient on the building surfaces is presented.

Key Words: *Computational Fluid Dynamics, Autonomous Underwater Vehicle (AUV), energy-saving formation, multi-level CFD, optimization, engineering application, potential flow*

Swimming and flying animals can improve their energetic efficiency by moving through fluids in formation (e.g. [1]). It is reasonable to expect that Autonomous Underwater Vehicle (AUV) Group may also adopt specific formation to optimize energetic efficiency, which may significantly benefit our future AUV-group-based exploration, development, and cleaning in ocean.

This challenging hydrodynamic problem is solved by a multi-level numerical approach, which consists of individual- and group-level solutions.

The individual-level simulation provides accurate propellor power at cruising speed, the gradient of power with respect to speed around cruising condition, as well as the flow field around the AUV. We modelled a full scale AUV, and perform simulation by commercial software STAR-CCM+ (SIEMENS, Germany [2]) with Reynolds averaged Navier-Stokes (RANS) turbulence model. The result is then input as source information for the group-level solution. Unsteady flow field is time-averaged into a steady axisymmetric flow.

The group-level simulation is based on an analytical potential-flow model, we approximate the velocity field far from an individual AUV by the velocity field of a vortex ring and a momentumless wake. This allows us to investigate equilibrium formations for groups of AUVs and evaluate the perspective of energy saving through their far-field interference.

By solving the flow system that consists of the superposed elements and constraints set on the relative position of the AUVs, we formulate an optimization problem for minimizing the power at a given speed, and find optimal formations using numerical methods of global optimization. Our result reveals optimal formation formed by several to tens of AUVs.

A Comparison Study between Isogeometric Analysis and Finite Element Analysis for Nonlinear Inelastic Dynamic Problems with Geomiso DNL Software

Panagiotis Karakitsios[1], Ioannis Prentzas[1]*, Athanasios Leontaris[1], Alexandros Papakonstantinou[1]

[1] Geomiso Company, pkarakitsios@geomiso.com, geomiso.prentzas@gmail.com, aleontaris@geomiso.com, geomiso.papakonstantinou@gmail.com
www.geomiso.com

Key Words: *Isogeometric analysis, Finite element analysis, Computational structural dynamics, Inelastic analysis, T-splines, NURBS, Accuracy, Convergence, Computational cost, Cloud*

This research aims to compare the efficiency of isogeometric analysis and finite element analysis for nonlinear inelastic dynamic applications with the recently developed Geomiso DNL program. Geomiso DNL is a hybrid software solution, which combines isogeometric analysis and 3D design with NURBS and T-splines. The isogeometric method satisfies the rising industrial need for unification of the fields of computer-aided design and computer-aided analysis, while modern T-splines overcome limitations inherent to NURBS, permit local refinement, ensure higher-order continuity across patches, and provide great superiority of modeling irregular geometries with hole features. Therefore, this powerful generalization of the classical finite element method has attracted growing interest in both scientific community and industry.

Geomiso DNL is not just a plug-in, but a both on-premises and cloud-based software, which enables engineers to simulate dynamic phenomena, whose impact on products and structures in real-world environments can be more efficiently evaluated. This new software fully integrates the industrial design of any geometry with its computational real-time testing by facilitating the geometry modeling within analysis. A key feature is that this hybrid program provides parameterized geometries in the design, as it weaves the mesh generation process within CAD, while its comprehensible modern graphical user interface offers an innovative way to preserve the exact geometry at all refinement levels in contrast with finite element programs.

Applications to nonlinear plane stress, plain strain, and three-dimensional dynamic problems are demonstrated with a comparison between Geomiso DNL and finite element software packages. We compare the matrix assembly and solver time, as well as the accuracy of the numerical results, such as displacement, strain and stress fields, for typical examples arisen in structural dynamics. We also perform parametric tests on the effects of polynomial order of shape functions and the number of patches, elements, control points, and quadrature points. This program appears to be preferable to finite element software packages, as it represents major improvements, such as higher accuracy, robustness, and stability level, combined with significantly shortened computational cost. This research has been co-financed by the European Union and Greek national funds through the Operational Program Competitiveness, Entrepreneurship and Innovation, under the call «RESEARCH–CREATE–INNOVATE» (project code: T2EDK-00338).

An Alternative Approach for Inelastic Static Isogeometric Analysis and 3D Design with Advanced Spline Techniques with Geomiso TNL: a New Hybrid Cloud-based CAD/CAE Software

Panagiotis Karakitsios[1]*, Panagiotis Kolios[1], Athanasios Leontaris[1], George Karaiskos[1]

[1] Geomiso Company, pkarakitsios@geomiso.com, pkolios@geomiso.com, aleontaris@geomiso.com, gkaraiskos@geomiso.com
www.geomiso.com

Key Words: *Isogeometric analysis, Finite element analysis, Computational structural mechanics, CAD, T-splines, NURBS, Patch, Material nonlinearity, Cloud-based software, Industry applications*

In this paper a recently developed cloud-based simulation platform (www.geomiso.cloud) is proposed to help engineers and industries make more effective use of 3D design and isogeometric analysis with advanced spline techniques. Geomiso TNL fully integrates the industrial design of any product with its computational real-time testing by facilitating the geometry modeling within analysis, thus it can solve demanding structural engineering problems subjected to static loading conditions otherwise very challenging. Users can easily test performance, predict behavior, optimize durability, and improve efficiency of their products. This is the first time ever such a cloud-based software has been developed.

This online solution provides inelastic static isogeometric analysis and 3D design of complex multipatch structures with NURBS and T-splines. Material nonlinearity in combination with the isogeometric method has attracted increasing attention. Modern T-splines can accurately represent any geometry with their local refinement properties and overcome limitations inherent to NURBS by ensuring higher-order continuity across patches, while in practical circumstances, it is often necessary to describe domains with multiple patches, especially them with parts in which different material or physical models are to be used. Geomiso TNL directly utilizes the CAD file in its solver to perform a structural analysis without any intermediate steps of geometry clean-up or further mesh generation by using the same shape functions, namely splines, for both describing the domain geometry and building the numerical approximation of the solution. Thus, it maintains the exact representation of the geometry at any stage of the design process and eliminates geometric errors. This hybrid software provides parameterized geometries in the design, while its modern graphical user interface offers an innovative way to preserve the exact geometry at all refinement levels. As it is demonstrated in this paper with several industry applications, the developed platform is seen to handle these situations remarkably well.

Geomiso TNL is considered to be a comprehensive answer to today's simulation challenges and a viable alternative to finite element software packages, as it removes the barriers between design and analysis and represents major improvements, such as higher accuracy, robustness, and stability level, combined with cost-efficiency and instant access from a web browser. This research has been co-financed by the European Union and Greek national funds through the Operational Program Competitiveness, Entrepreneurship, and Innovation, under the call «RESEARCH–CREATE–INNOVATE» (project code: T1EDK-04288).

Isogeometric analysis of monoclinic 3D concrete printing Timoshenko beam

Huaikun Chen[1*], Yu-Ching Wu[1]

[1]Tongji University, Shanghai, 200092, PR China
2032654@tongji.edu.cn

Key Words: *Isogeometric analysis, monoclinic, 3D concrete printing, Timoshenko beam*

3D printable concrete construction techniques have been well developed in the past decade. 3D printable concrete can be used to build free forms and shapes of structural components. In this paper, the isogeometric analysis (IGA) of 3D concrete printing monoclinic curved beam is made. Timoshenko curved beam theory in three dimensions is investigated. Definitions, properties, formula, and algorithms of Non-Uniform Rational B-Spline (NURBS) curves are reviewed. Corresponding finite element weak forms, discretization, and IGA formulations are derived and developed. Several numerical experiments are carried out and results are in a good agreement with experimental data in literature. It is indicated that the proposed isogeometric approach is feasible, accurate, and efficient to conduct an in-depth analysis of 3D concrete printing monoclinic Timoshenko beam.

Seismic isolation is a technique that has been used worldwide to protect not only building structures and their non-structural components, but also their content from the damaging effects of a strong earthquake. The use of expanded polystyrene geofoam fills for foundation in areas with intense seismic activity, such as Greece, has seen growing use around the world in urban environments. This geosynthetic product, which is manufactured into large lightweight blocks, can be used as a fill material for seismic isolation of buildings against combined static and seismic activity. The mitigation of seismic-induced dynamic earth forces by placing geofoam buffer is a recent geotechnical innovation. This paper studies this novel seismic isolation technique implemented on a real-world project, where geofoam was placed at a depth below the raft foundation of multi-storey apartment buildings in Greece. The behaviour of this integrated soil isolation-building system and the influence of the buffer on the reduction of dynamic forces has been investigated. Numerical simulations of transient response were carried out using both the Geomiso software and FEA programs on models of these buildings resting on raft foundation in sand beds of different stiffnesses, with and without soil isolation mechanism. Parametric investigations were also carried out to study the effect of EPS density and thickness on the buildings' seismic response. The numerical results indicate that geofoam compressible inclusions significantly reduce the total applied pressure on the ground and drastically increases the bearing capacity of the buildings in static and seismic condition. With the increasing time, the compression of geofoam increases, while softer EPS blocks produce more compression which takes more vibration energy by their deformation. Better results were obtained with NURBS-based isogeometric analysis with Geomiso software (www.geomiso.com), as it achieves higher accuracy and efficiency as far as the calculation of load carrying capacity and stress fields inside the layered soil body are concerned. EPS geofoam seismic buffer is proved to be a new more efficient alternative soil isolation medium for buildings, as it substantially reduces the earthquake energy transmission to the structure and its dynamic response during earthquake ground shaking, thus it improves the building damage from severe to slight with lesser deformation. This is a novel technique for improving the building's earthquake resistance, which combines speed, cost saving and safety, and leads to more efficient seismic isolation. This research and specifically the first author has been supported by the Alexander S. Onassis Foundation (G ZG 017/ 2010-2011).

Key Words: *Isogeometric analysis, Plate Theory, Kirchhoff-Love, Mindlin-Reissner, Splines, Patch, Slab, Industry applications, Software, Cloud*

In this paper, we propose Geomiso ISA (www.geomiso.com), a new software for applications on static isogeometric analysis with plate elements and advanced spline techniques. It is based on the isogeometric method, the powerful generalization of the traditional finite element method, which, in combination with the plate theory, has attracted increasing attention in construction industry over the last decade, as it achieves efficient design-through-analysis procedures and shows superior performance. Although NURBS are ubiquitous in CAD industry, the most promising spline technology is T-splines, which overcome limitations inherent to NURBS, ensure higher-order continuity across patches and permit local refinement.

The recently developed Geomiso ISA program is not just a plug-in, but a both on-premises and cloud-based software solution, applicable to real world and industry applications, which provides static isogeometric analysis with plate elements. It is used to simulate spline models of slabs and analyze their strength and behavior, while it has many features in common with both FEA software and design programs. This solution addresses the rising industrial need for seamless integration of computer-aided design and computer-aided analysis, while it appears to be more efficient to FEA software packages, as it facilitates the geometry modeling within analysis, eliminates geometric errors and achieves superior accuracy per degree-of-freedom with shortened computational cost. It offers an innovative way to merge geometric design with mesh generation into a single procedure by designing, with its modern user interface, slabs as tensor product grids in contrast to design programs.

Real world and industry applications on thin (Kirchhoff-Love) and thick (Mindlin-Reissner) plates are demonstrated with a comparison between Geomiso ISA and FEA programs, and between plate and hexahedral elements. We compare the accuracy of the numerical results, such as displacement, strain and stress fields, and the stiffness matrix assembly and solver time for analysis of typical slab types widely used in construction. We carry out parametric investigations on the effects of polynomial order, multiplicity and continuity of basis and shape functions, as well as on the number of control points and knot spans. This hybrid software represents improvements over finite element software packages, as higher accuracy, robustness, and stability level are accomplished.

This research has been co-financed by the European Union and Greek national funds through the Operational Program Competitiveness, Entrepreneurship, and Innovation, under the call «RESEARCH–CREATE–INNOVATE» (project code: T2EDK-00703).

Modeling and Analysis of Real World and Industry Applications with Geomiso SEA: a New Hybrid CAD/CAE Software for Inelastic Static Isogeometric Shell Analysis and 3D Design with Advanced Spline Techniques

Panagiotis Karakitsios[1], Vasiliki Tsotoulidi[1]*, Panagiotis Kolios[1], George Mprellas[1]

[1] Geomiso Company, pkarakitsios@geomiso.com, geomiso.tsotoulidi@gmail.com, pkolios@geomiso.com, geomiso.gmprellas@gmail.com
www.geomiso.com

Key Words: *Isogeometric analysis, Shell Theory, Kirchhoff-Love, Mindlin-Reissner, Splines, Patch, Complex geometries, Industry applications, Software, Cloud*

In this paper the new Geomiso SEA software (www.geomiso.com) is proposed for applications on inelastic static isogeometric analysis with shell elements and advanced spline techniques. This hybrid program is applicable to real world and industry applications, while it satisfies the rising need for technical software of dual CAD/CAA nature. It is based on the isogeometric method, which has attracted a lot of attention for solving boundary value problems, as a result of using the same shape functions, means splines, for both describing the domain geometry and building the numerical approximation of the solution. T-spline-based isogeometric shell analysis has attracted increasing attention in automotive and aerospace industries, as it efficiently handles geometries with patches, discontinuities, and irregularities, while T-splines can design any geometry no matter how complex it is. Geomiso SEA is not just a plug-in, but a both on-premises and cloud-based software solution, which is used to simulate spline models of complex structures, or machine components, for analyzing their strength and behavior. This hybrid program, used for both design and analysis, has many features in common with both FEA software and design programs. It offers an innovative way to merge geometric design with mesh generation, by creating, with its modern graphical user interface, 3D models as tensor product grids. The utilization of the exact mesh for analysis eliminates geometric errors, while there is no need of repeating the geometry design for refinement purposes. In contrast, the standard finite element technique of remeshing with more and smaller elements, not only cannot fully utilize the available data of the exact mesh, but also makes engineers unable to benefit from advanced spline techniques, which are proved a mighty tool for IGA. Real world and industry applications on both thick (Mindlin-Reissner) and thin (Kirchhoff–Love) shells are demonstrated with a comparison between Geomiso SEA and FEA programs, and a comparison between shell and hexahedral elements. We compare the matrix assembly and solver time, as well as the accuracy of the numerical results. Parametric tests were also performed on the effects of the polynomial degree of the basis functions, and the number of patches, knot spans, control points, and integration points. This unique solution for seamless integration of the industrial design of shell geometries with its computational real-time testing, appears to be preferable to FEA programs, representing major improvements, such as higher accuracy, and considerably reduced computational time.
This research has been co-financed by the European Union and Greek national funds through the Operational Program Competitiveness, Entrepreneurship, and Innovation, under the call «RESEARCH–CREATE–INNOVATE» (project code: T2EDK-00328).

Key Words: Robustness, Multi-objective optimization, Iso-geometric formulation, Brake system

Robust shape optimization is a method to generate optimal geometries of mechanical parts with respect to performance objectives which depend on the application, while taking into account uncertainties linked to their manufacturing process or material properties. Such uncertainties can be understood as small perturbations of the design variables. Previous works have investigated approaches based on Efficient Global Optimization (EGO) with Expected Improvement (EI) criteria calculated using the worst case in terms of uncertainties [1], but these do not enable exploration of the entire Pareto front. Other studies have aimed to describe robustness as an additional theoretical optimization objective [2, 3].

Based on this approach, the presented work exposes an efficient way to thoroughly quantify robustness as an objective function. We apply such robustness criteria to a disc brake system under dynamical performance criteria, in order to determine a set of Pareto solutions which are the least sensitive to the design parameters' uncertainties.

The main optimization goal is minimization of squeal noise generated by the brake system which is expressed through Complex Eigenvalue Analysis (CEA) of the the dynamical model. A simplified model of the disc brake is advantageously constructed with the Isogeometric Analysis (IGA) formulation which is well-suited for optimization problems where numerous evaluations of the objective function are needed, leading to extensive use of numerical model calls.

A robustness criteria established on precise evaluation of the local variance of the output in the neighborhood of a solution is proposed and its effectiveness is discussed. In light of high computational cost, this robustness objective is coupled with a Kriging meta-model optimization scheme. The efficiency of IGA in the framework of robust multi-objective shape optimization under dynamical criteria is also inspected.

Key Words: *Carbide-free bainite, Multiphase, Plasticity, Martensite transformation, Ratchetting deformation*

Carbide-free bainite (CFB) rail is a new generation rail for heavy-haul railways. Under the stress-controlled cyclic loading, the deformation mechanisms of CFB rail steel are mainly dominated by the bainite ferrite, martensite, and retained austenite. A microscopic cyclic plastic model that incorporates the plasticity of each phase and martensite transformation of retained austenite is proposed to describe the ratchetting deformation of CFB rail steel. Since the film-like retained austenite is located between laths (bainitic ferrite lath and martensitic lath), it is assumed that the strain of retained austenite and surrounding laths is the same. The Olson-Cohen model [1] is used to consider the strain-induced martensite transformation. The Mori-Tanaka mean-field theory is used to consider the interaction between bainitic ferrite laths and martensitic laths. The evolution equations of internal variables controlling the evolution of the hysteresis loop are dependent on the current dislocation density. The dislocation-based lath model [2] is introduced, and the strength difference between bainite ferrite laths and martensitic laths is considered. The comparison between the simulated and experimental results demonstrates that the proposed model can reasonably describe the ratchetting deformation of CFB rail steel.

A unified constitutive model coupled with a continuum damage model for simulation of a broad set of elevated temperature responses

Tasnim Hassan[1*] and **Nazrul Islam**[2]
[1] North Carolina State University, Raleigh, North Carolina, USA
[2]Bangladesh University of Engineering and Technology, Dhaka, Bangladesh

Keywords: *Unified constitutive model, continuum damage model, Isotropic damage, creep-fatigue interaction, long-term creep, stress triaxiality*

A unified constitutive model[1,2] (UCM) coupled with continuum damage models (CDMs) is developed for simulation of a broad set of high-temperature responses, including fatigue, long-term creep, short-term stress relaxation, creep-fatigue, and thermomechanical fatigue. The model development was motivated primarily by the fact that available constitutive models were unable to predict all these responses using a single set of model parameters. Two CDMs, Kachanov[3] and the isotropic damage[4], are evaluated by coupling these with a Chaboche type UCM to achieve the objective. Based on the strengths and limitations of the continuum damage models studied in predicting the elevated temperature responses, a modified Isotropic damage model is proposed. The parameter determination of such a complex UCM-CDM manually is difficult, hence a hybrid and automated parameter determination tool implementing gradient and genetic algorithm approaches is developed. The modified UCM is experimentally validated against a large set of high-temperature alloy responses. The modified UCM in simulating creep responses of a notched specimen is also demonstrated. Finally, the proposed UCM is evaluated by analyzing a thick cylinder under thermal transient loading[5] to demonstrate the modified UCM's applicability for the design and evaluation of high-temperature components.

Key Words: *Digital Twin, Nonlinear FEM, Elastoplastic material modelling, Spring-back.*

Digital Twin technology that predicts deformation, material change and other behavior occurring production process is highly demanded since reduction of physical prototype with virtual prototype enables the cost reduction in addition to the shortening die design cycle. The key technology is the prediction accuracy of spring-back mode and amount. However this aspect of technology was not sufficient in case of high strength steel stamping cases in particular.

The conventional elastoplastic constitutive equation assuming perfect elasticity inside of the yield surface has been used for elastoplastic analysis by nonlinear finite element method. On the other hand, the subloading surface elastoplastic constitutive equation has the basic structure that the plastic strain rate is always induced even in a low stress state.

With the elasto-plastic traditional constitutive equation, it was difficult to precisely predict the spring back behavior after deep drawing metal forming process, in which material behavior during re-yielding in the reverse loading state is important. In particular, the amount of spring back of high tensile strength steels with initial yield stress of over 1 GPa, which are being used as automobile parts for weight reduction purpose in recent years, is bigger than conventional sheet metal and hard to predict.

Data calibration technology is also important for the accuracy. We developed the system that calibrates material constant and other parameters for the Digital Twin with CADLM system by learning data and internally generates ROM system for the simulation input parameter calibration in order to minimize the deviation between simulation result and nominal value of physically measured shape.

In this paper, we discuss on the implementation of subloading surface elasto-plasticity model into Marc implicit nonlinear finite element code and the effectiveness of sheet metal forming analysis using the subloading surface model in Marc which describes elasto-plastic material behavior even in reverse loading state accurately. This base Digital Twin model is subjected to optimization process for the accurate prediction performance enhancement.

An Efficient Parameter Estimation Method for Elastic-Plastic-Creep Simulation of Aluminum Alloys

Key Words: *Elastic-Plastic-Creep Simulation, Aluminum Alloy, Constitutive Model, Parameter Estimation, Cyclic Loading, Strain Rate Effect, Temperature Effect, Thermo-Mechanical Fatigue*

Automotive engine components made of aluminum alloys are often subjected to loading in a high-temperature range that exceeds 1/2 of the melting temperature T_m of aluminum alloys. Therefore, the strength reliability of the aluminum alloy components should be evaluated by conducting elastic-plastic-creep finite element analysis (FEA). However, in fact, elastic-plastic FEAs have been conducted for the evaluation to avoid long-term product development time, because the elastic-plastic-creep FEA requires long-time creep tests under at least three stress levels at several temperatures to determine material constants. This is not a favorable situation to ensure the strength reliability of the aluminum alloy engine components. In this study, we propose an estimation method for the material constants used in a creep model for an aluminum alloy without conducting any creep test. The method utilizes stored heat cycle test data that are closely related to the strength reliability evaluation for aluminum-alloy engine components. The research and development departments of car companies often have stored a lot of test data related to practical use even though they do not have enough time to carry out creep tests. In addition, we introduce the "plasticity-creep separation method" [1], [2] which employs the estimated creep material constants to obtain time-independent stress-elastoplastic strain relations. Using these relations, the material constants for the plastic model considering the kinematic hardening can be estimated systematically. The elastic-plastic-creep simulations of time and temperature dependent cyclic deformations of the aluminum alloy are conducted using the estimated material constants. The simulations successfully predict both the time and temperature dependent deformations.

Various plasticity models, i.e. the Choboche model[1], the multi-surface model[2], the two surface model[3] and the subloading surface model[4], etc. have been proposed hitherto. In this presentation, the mathematical-physical structures of these models are classified from the aspects of the yild surface, the existence of elastic domain, and their mechanical features are classified first. Then, the advantages and disadvantages of these models are analyzed comprehensively from the aspects of the description of monotonic-cyclic loading behavior, the mechanical ratchetting behavior, the stress amplitude, the unloading behavior, the efficiency of computation, etc. Consequently, the overall assessment of these models will be provided for the valuable information when the industrial engineers choose the suitable plasticity model for their mechancal design.

Constitutive behaviour of viscoplastic materials under a wide range of strain rates and elevated temperatures

Xu Long[1*], Tianxiong Su[1] and Yuntao Hu[1]

[1] School of Mechanics, Civil Engineering and Architecture, Northwestern Polytechnical University, Xi'an 710072, People's Republic of China
[*]E-mail address: xulong@nwpu.edu.cn

Key Words: *Mechanical Behaviour, Constitutive Model, Strain Rate, Working Temperature.*

Thermal cycling reliability tests, as well as cyclic temperature changes caused by switching on and off and changes in ambient temperature during service, impose typical thermomechanical coupled physical fields on the solder joints, which significantly affects the mechanical reliability of the solder joint and the performance of the electronic device under the service conditions. To address the dwelling stages at low and high temperatures, an improved constitutive model is proposed in this study based on the unified creep and plasticity theory to describe the uniaxial mechanical behaviour of viscoplastic materials subjected to a wide range of strain rates and elevated temperatures. In the usual service condition of electronic devices, the strain rates of Sn3.0Ag0.5Cu (SAC305) solder material are far less than 1.0 s^{-1} at which the creep deformation is dominant, especially at higher working temperatures. However, the strain rate could range from 1.0 s^{-1} to 300 s^{-1} under drop impact in electronic packaging structures. The working temperature of solder materials is elevated above the room temperature up to 125°C as requried by the reliability standard for electronic packaing structrures. This is drawing more attention due to lack of experimental data, especially on dynamic mechanical properties of lead−free solder alloys. In extreme impact conditions, the solder material may experience even higher strain rates. As different mechanisms dominate the respective regime of strain rates, the developed constitutive model is calibrated to be applicable to most of the strain rate regimes by properly considering the coupled effect of creep and plasticity. Moreover, the parameters in the proposed model are defined with clear physical meanings and reasonably determined by regression to the published experimental studies. Lastly, the developed model is validated against experimental results at different elevated temperatures and also compared with other constitutive models, including the power-law equation for creep deformation at low strain rates and the Johnson-Cook model for plastic deformation at high strain rates. It is concluded that the proposed model is more generalized and capable of predicting uniaxial mechanical behaviour of SAC305 solder at low, medium and high strain rates from room temperature up to 125°C with reasonable accuracy.

Energy-Based Thermo-Mechanical Fatigue Life Prediction of Ferritic Stainless Steel for Exhaust Manifold

Key Words: *Thermo-mechanical fatigue, ferritic stainless steel, energy-based life prediction model, plastic strain energy density*

In this work, thermo-mechanical life prediction of ferritic stainless is conducted using the energy-based method. As ferritic stainless steel is commonly used to high-temperature structures such as the exhaust manifold in automotive, it is apt to be exposed to thermal cycles[1]. Under that condition, thermo-mechanical fatigue can cause the failure of the structure induced by constrained boundary conditions. To evaluate the thermo-mechanical fatigue life appropriately, the accurate cyclic material property and life prediction model are required. Chaboche unified visco-plasticity model is established as the cyclic material property to incorporate the time-dependent behaviour in high-temperature[2, 3]. The isothermal tensile, low cycle fatigue tests are conducted to validate the determined cyclic material property. Thermo-mechanical life is evaluated using the energy-based life prediction model that the plastic strain energy density is used as the damage factor. It shows good agreements by comparing the predicted life and results of the thermo-mechanical tests using the V-shaped specimen.

Key Words: *Sample size effect; Grain size effect; Strain gradient; Stress relaxation; Cyclic plasticity*

Size effects of both the sample and the grain on the cyclic torsion of micro-scale copper wires have attracted extensive attention. We constructed a high-order strain gradient cyclic plastic model to consider the coupling effect of microstructure and strain gradient. With a 3D element that separates the gradient field solution and the description of mechanical behavior, the simulation of cyclic torsional experiments of copper micro-wires was implemented into ABAQUS to reveal the change of strain gradient distribution with the cycle numbers in different working conditions. By introducing the intrinsic length of material and the average characteristic length of microstructure that evolves with the cumulative plastic strain, the anomalous Bauschinger effect, and the cyclic hardening characteristics[1-3] in symmetric cyclic torsional experiments were simulated. In addition, the internal stress conjugated to strain gradient was introduced into the back stress evolution, and the increase of mean stress relaxation with decreasing the sample size and grain size in the asymmetric cyclic torsional experiments[3] was simulated reasonably. This proposed model explains the influence of the material characteristic length evolution and strain gradient distribution on the cyclic torsion of micro-scale copper wires.

Key Words: *CFRP, Interlaminar, Delamination, Fatigue, Multiscale*

Carbon fiber-reinforced plastics (CFRPs) are used in various fields because of their high specific strength, high specific stiffness and high corrosion resistance compared to general metallic materials. Since CFRPs are composite materials in which unidirectionally reinforced resin sheets (laminae) are laminated multidirectionally, delamination can occur between laminae while they experience cyclic loads. Such delamination should be considered when designing CFRP structures because it can cause significant decrease of strength and stiffness of CFRPs.

In order to evaluate the delamination of CFRPs due to cyclic loads, it is important to know the interlaminar fatigue strength. For this, two kinds of testing methods have been conducted [1]. One is the four-point-bending fatigue test using L-shaped specimens, and the other is the flatwise tension fatigue test. However, the analysis method to predict interlaminar fatigue strength of CFRPs has not been established yet.

In this study, a prediction method for interlaminar fatigue strength of CFRPs is proposed based on an inelastic two-scale analysis method [2] combined with the Coffin-Manson law [3, 4]. First, the flatwise tension test of a CFRP is simulated using the two-scale analysis method, and the distributions of microscopic viscoplastic strain occurring at resin parts in micro-structures (unit cells) are examined. Then, the maximum value of microscopic viscoplastic strain is applied to the Coffin-Manson law for the resin to predict interlaminar fatigue life of the CFRP. It is shown that the proposed method is successful in predicting the interlaminar fatigue strength of the CFRP.

Key Words: *Cyclic Plasticity, Constitutive Model, Cyclic Hardening, Pre-loading, Ratcheting*

An extended evolution equation of cyclic hardening was proposed to include the effect of the maximum plastic strain induced by pre-loading and ratcheting. A set of evolution equations was also proposed for a plastic strain surface to properly evaluate the cyclic plastic strain range in the presence of pre-loading and ratcheting. The extensions were made by decomposing the plastic strain rate into the maximum and cyclic plastic strain rates.

The extensions were verified by performing uniaxial cyclic tests of 316 stainless steel at 600ºC, in which cyclic loading with a constant strain range was accompanied by either pre-loading or strain-controlled ratcheting. These experiments noticeably exhibited the effect of maximum plastic strain on the evolution of cyclic hardening.

The experiments were simulated using a constituive model with the extensions in addition to the resetting scheme proposed recently [1, 2]. Strain-range variable tests of 316 stainless steel at 600ºC [2] were also simulated. All the tests were accurately simulated. The extended equations were further used to discuss the effect of maximum plastic strain in light of experiments in previous studies.

Key Words: *Soil, Subloading Surface Model, Cyclic plasticity, General Purpose CAE Code, User subroutine*

The history of plasticity started in the study of deformation behavior of soils by Coulomb when he proposed the yield (failure) condition of soils by applying the friction law proposed by himself. Thereafter, the leadership of soil plasticity was superseded by the metal plasticity. One of the reasons would be caused by the fact that soils exhibit various complex plastic deformation behavior. For example, the bulk modulus of soil increases upon pressing. Also, when the preconsolidation stress is exceeded, the stiffness reduces dramatically while the stiffness increases upon unloading. At failure, there is no resistance to shear, and stiff clays or dense sands are dilatant.

Over the years, many formulations have been used, including linear elastic, nonlinear elastic, Drucker-Prager or Mohr-Coulomb, and Cam-Clay and variations thereof. Take general purpose CAE code Marc (MSC Software [1]) as an example, the material models available for soil modeling are linear elasticity, nonlinear elasticity, the Cam-Clay model, von Mises, linear Mohr-Coulomb, parabolic Mohr-Coulomb, orthotropic elastic, and exponential cap model.

The incorporation of the subloading surface model is of crucial importance for the constitutive equation of soils because the remarkable softening behavior occurs in soils and thus the excessively high peak stress is described by the conventional plasticity model in soils. Explicit constitutive equations of soils will be described in this study, based on the elastoplastic constitutive equations.

In this study, a user subroutine of subloading surface soil model is implemented into Marc, and several fundamental problems are analysed to confirm its validity. Also, footing settlement problem is analysed to show the applicability of this model is verified by comparison with the test data for sand grounds with high friction property.

Key Words: *Circumferential cracked pipe, very low cycle fatigue crack growth simulation, 3-D FE debonding technique, Chaboche combined hardening model*

The fracture behaviour for cracked pipes under seismic loading is an important part of the structural integrity for nuclear power plant. Seismic loading consists of the dynamic loading (strain rate effect) and large-amplitude cyclic loading (very low cycle fatigue loading). For the pipe material, the large-amplitude cyclic loading was more dominant effect on reduced fracture resistance than dynamic loading [1]. Many institutions performed the full-scale pipe under very low cycle fatigue loading [2]. The full-scale pipe test could accurately observe complicated pipe fracture behaviour, but had limitations of time and cost. The finite element (FE) damage analysis is numerical method that can simulate the crack growth under very low cycle fatigue loading using minimal experimental data [3]. As for the reliable predicted results, the cyclic hardening model should be appropriately applied by FE analysis [4]. In the previous studies [5], the cyclic hardening model, such as the Chaboche model, was mainly applied to the non-cracked structures, and the parameters were determined from hysteresis loop under low strain range. However, the crack exhibits the wide strain range depending on the distance and high strain near the crack tip. The cyclic hardening model parameters could not be determined from the specific and high strain range hysteresis loop. In this study, the simplified cyclic hardening modeling was proposed by considering the characteristic of cracked structure. The proposed hardenig modeling was developed to simulate the crack growth for cracked pipe under very low cycle fatigue loading. The FE debonding analysis was introduced to verify cyclic hardening model. The test materials were SA508 Gr.1a low alloy steel (non-cylic hardenig material) and TP 316 stainless steel (cyclic hardening material) at room temperature. The cyclic hardening model verified applicability to C(T) specimen and through-wall cracked pipe using FE debonding analysis.

Key Words: *Circumferential cracked pipe, very low cycle fatigue crack growth simulation, multi-axial fracture strain energy density damage model, FE damage analysis*

In this study, ductile tearing of circumferential through-wall cracked pipes under very low cycle cyclic loading was simulated by using multiaxial fracture strain energy damage model [1], and simulation results were compared with the pipe fracture test under four-point load-controlled cyclic load condition [2]. Two parameters in the damage model, multiaxial fracture strain energy and critical damage value, are determined by analyzing standard tensile test and monotonic pipe test using FE analyses. The load amplitude and load ratio effect on the plastic strain energy under low cycle fatigue loading was incorporated by the multiaxial fracture strain energy density. The load amplitude effect (failure cycle) was included from the relationship between the plastic strain energy per cycle and the failure cycle [3]. The load ratio effect was included from the Coffin-mason fatigue curve considering the mean stress correction factor based on the Walker model [4]. The proposed damage model was applied by simulating the crack growth for through-wall cracked pipe under very low cycle fatigue loading with different load amplitudes and load ratios. The cyclic hardening model used the Chaboche combined hardening model verified by FE debonding analysis in Part I [5]. The predicted results compared with the experimental crack growth and fracture surface data and were in good agreements.

Key Words: *Thermal Radiation, Urban District, Large Eddy Simulation, Inflow Turbulence, Weather Disturbance*

As an extreme weather event, recently heatwaves often occur in various regions in the world. Elucidation of real state and mechanism of the resulting heat stress becomes more important in order to keep comfort living space. In the temperature and flow fields, not only the steady characteristics but also unsteady change should be clarified because temperature and turbulent fields vary intermittently and locally. The formation of the outdoor thermal environment in urban districts is related to various factors such as solar radiation, long-wave radiation, airflow, and heat conduction. Therefore, in order to comprehensively simulate such outdoor thermal environment, it is necessary to consider the related physical phenomena such as air and heat transport, and radiation. For the method grasping the unsteady change of turbulent field in the actual urban districts, some researchers show the method using Large Eddy Simulation (LES). However, it isn't considered interaction between turbulent field and heat transfer from urban surface. Also, many researchers show the estimation of convective heat transfer coefficient (CHTC) as the analysis of heat transfer from cooled and heated urban surface, but the obtained characteristics are limited for very simple shape. On the other hand, turbulent and thermal fluctuations at the meteorological scale such as foehn wind and sea breeze also have a significant impact on the thermal environment in the urban canopy. Therefore, the generation of inflow turbulence that considered the velocity and temperature fluctuations in the actual meteorological field is an issue. In the previous study, Kawai and Tamura [1] proposed a method of adding high-frequency fluctuation of velocity in the driver region to the results of a mesoscale meteorological model.

This study shows complicated turbulent flows including fine structures around urban surface and heat transfer process in urban canopy by LES coupling with radiation model, and evaluates the thermal environment in urban districts. As the inflow boundary condition including a fluctuation of temperature for actual urban district in summer, we investigated the generation of inflow turbulence with weather disturbance and time-averaged temperature by mesoscale meteorological model.

Key Words: Negative peak pressure, Trailing-edge vortex, Proper orthogonal decomposition, Square cylinder

In the wind-resistant design of cladding system in the façade of buildings, local peak pressures have received a great deal of attention from both safety and economic point of view. Many techniques for estimating the peak wind pressure have been proposed. However, it seems that no consensus is reached about which method should be used for determining peak pressure for the design purpose of cladding components. The main reason may be the lack of full understanding of the space-time characteristics of peak pressures [1]. This study used the high-performance computer to obtain the high-resolution flow and pressure fields around a square cylinder at Reynolds number of 22,000 [2]. The local severe suction immediately upstream of the trailing edges is particularly emphasized. The minimum trailing-edge pressure coefficients have a close correlation in a streamwise length of approximately $0.1D$ (D is the width of the cylinder). On the basis of high-resolution simulation, the occurrence of small trailing-edge vortex is observed, which has highly concentrated vorticity and is responsible for the trailing-edge peak pressures. The trailing-edge peak pressure occurs immediately before the shear layer moves far from the cylinder and recovers to the symmetric state. Standard proper orthogonal decomposition (POD) is applied to discover the inherent spatial modes with sharp peak pressures upstream of the trailing edges. Instead of the 1st mode (corresponding to vortex shedding), the higher-order modes contribute significantly to the trailing-edge peak pressures, whose mode coefficients have harmonics of vortex-shedding frequency. As a variant of POD proposed recently, conditional space-time POD is valid in studying the average evolution of wind peak pressures. It further provides the relative phase and frequency ratio between the trailing-edge peak pressure and vortex shedding.

Key Words: *Large Eddy Simulation, Fluid Structure Interaction, High-Rise Building*

The application of Computational Fluid Dynamics on the evaluation of wind load on actual building is investigated in some research [1]. The wind load simulation results conducted by Tamura et al. show pretty good agreement with the corresponding wind tunnel test results. In the design of high-rise buildings especially with the height over 300m such as high-rise buildings being planned in Tokyo, not only wind load but also wind-induced vibration of building are quite important factors to be investigated. They should be evaluated simultaneously through a series of simulations, but the accuracy of evaluation of the wind-induced vibration amplitude using Computational Fluid Dynamics has not been investigated well yet. Therefore, the accuracy of evaluation of the wind-induced vibration amplitude using Computational Fluid Dynamics is investigated in this study.

The target model building is the rectangular building with the side ratio D/B=2 and the aspect ratio $H/\sqrt{BD} = 5$ where D and B is the long and short side length of the rectangular section respectively and H is the height of the building. The oscillation conditions such as modal shapes, natural frequencies and mass/mass inertia are set using the corresponding wind tunnel test conditions conducted by Marukawa et al. [2] The WALE subgrid scale model [3] is used to simulate fluctuating small scale turbulence, and the boundary layer turbulence generated in the simulation is acting on the building model.

The windward, transverse and rotational amplitudes of the wind-induced vibration of the building model under the free vibration condition are evaluated for several reduced wind speeds. The simulation results are compared with the corresponding experimental results [2]. The flutter for the transverse direction is simulated at the appropriate wind speed, and the amplitudes of the wind-induced vibration in the low wind speed range for three directions also show good agreement with the test results.

Key Words: *Two-phase flow, Hierarchical Cartesian Mesh, finite volume method, flooding*

Recent climate change has exacerbated flood risk, especially in urban areas. In contrast to rural areas, floods in urban areas exhibit more diverse and complex flow processes because the water flows around or within buildings and pieces of urban furniture. In the conventional numerical studies for urban flooding, one or two-dimensional models based on the shallow-water equations have been generally adopted because a three-dimensional model requires enormous computational cost. However, 1D or 2D models cannot simulate complex three-dimensional flow and unsteady fluid force acting on structures in urban areas.

Considering the background mentioned above, we propose a gas-liquid two-phase flow simulation method by the finite volume method using the building-cube method (BCM) [1-3], which is suitable for large-scale parallel computing. In BCM, the computational domain is divided into cubic regions called cubes. Each cube is divided at equal intervals, the same number of cubes is assigned to each core, and the spatial loop processing is executed for each cube for load-balancing. The cell-centered finite volume method based on the BCM has been applied to single-phase flow simulations and fluid-structure interaction simulations in conventional studies. Still, it has never been applied to gas-liquid two-phase flow simulations.

To validate the present method, we demonstrate 3D dam-break simulation and water immersion simulation inside the building during flooding and discuss complex three-dimensional flow and unsteady fluid force acting on structures.

Key Words: *LES, Urban Transformation, Ventilation, Wind Resilience*

There is an urgent need for ventilation improvement in urban areas in order to mitigate the risk of illnesses due to unexpected contagious viruses or airborne pollutants and improve the thermal environment in terms of heat stress reduction on individuals and achievement of a carbon-neutral society. These needs and the transformation of people's lifestyles will most likely bring a gradual or metabolic transformation of urban areas. Thus, it is important to investigate the performance of potential modifying strategies for existing urban space configuration. In the course of the evaluation, the safety in extreme weather events such as increasing landfalls of violent tropical cyclones needs to be carefully assessed at the same time. In this study, we evaluated near-ground ventilation performance improvement in an actual densely built-up urban area of Shibuya district in Tokyo, Japan, in various assumed changes in urban space configuration using large eddy simulation (LES) at the grid resolution of about 90 cm.

Firstly, we examined the average nature of the ventilation improvement in the traditional urban redevelopment model, comparing the current urban configuration and the future configuration where many mid and low-rise buildings are replaced with fewer high-rise buildings. The average flow rate near the ground (at approximately 10 m height) increased by about 20% as a result of the space reservation and wind induction to the streets by the high-rise buildings aligned in the wind direction. However, the maximum instantaneous wind speed also increased in those spaces, and thus, appropriate measures needs to be taken against the wind force damage. Also, the buildings located close to each other in the orthogonal to the the flow direction caused infavorable consequence in the downstream region such as significantly lowered ventilation and more intensified wind gusts.

To seek potential future urban transformation strategies, we performed an investigation on the local flow change around a triangle-shaped urban block composed of mid and low-rise buildings in the city center considering two redevelopment scenarios: the block is replaced with (i) one high-rise slender triangular prism surrounded by an open space and (ii) one mid-high wide triangular prism with a courtyard. Inflow turbulence for this simulation was generated using the meteorological model/engineering LES hybrid approach proposd by Kawaguchi and Tamura et al. (2019) [1], replicating the actual meteorological structure of Typhoon Hagibis (2018). Both cases created more organized flow patterns inside the canopy region and seemed to have better ventilation performance than the present case where the buildings with inhomogenuous heights and shapes in the block generate random small eddies. Concerning the wind resilience design, highly unsteady gusts were generated mainly around the building associated with vortex shedding in Scenario (i), while mean wind speed and gust levels increased along the leeward street in Scinario (ii). We are planning to quantitatively analyze more variations of building shapes and layouts regarding their effect on urban ventilation.

Key Words: *LES, Super High-rise Building, Peak Pressure, Typhoon*

As a concept of the city in the future, it is proposed to create a city where super high-rise buildings and low-rise buildings are combined based on an open space with abundant greenery. In this case, it is necessary to have a plan that fully considers not only comfort (heat environment, wellness) but also disaster prevention.

In particular, in the case of considering safety under strong winds, a large-scale numerical simulation of CFD [1] is required, since it is necessary to simulate a complicated flow field by reproducing detailed shapes including green areas, terrain, low-rise buildings and high-rise buildings.

In this study, we introduce the numerical simulation for the flow field of the realistic city block model planned according to the concept of the future city, in the case of an actual typhoon hits.

Key Words:*Large Eddy Simulation, Inflow Turbulence, Weather Disturbance, High-rise building*

Recently, extreme large typhoon attacks urban city and the damage of building structure occurs. For estimating damage of high rise building, the strucutural response and wind pressure on attachment of building are revealed by using wind tunnel experiment and CFD techniques. In most of cases, inflow conditions using turbulent boundary layer which develops on smooth or roughness surface are used. However, in the most of cases of strong wind events, disturbance derived from meteorological field with change of air density and temperature affects the characteristics on peak value and fluctuation of wind pressure on buildings. Now, it is possible to reproduce meteorological turbulent structure of Typhoon by meso-scale meteorological model. Large computation with spatial resolution less than 100 m makes it possible to show fine spatial structure with several hundred meters scale and velocity fluctuation with several ten seconds. In additon, techniques for generating inflow condition with high-frequency fluctuation which is impotant for estimating unsteady change of wind pressure are developed.

This study clarifies the effect of meteorological disturbance on wind pressure of high-rise building by comparing the computational cases which are different in 2 inflow conditions respectively. The one is inflow condition based on turbulent boudary layer and the other is inflow condition based on the meteorological field of Typhoon. For the inflow condition based on the meteorological field, turbulence of actual urban canopy is also included by CUBE (developed by RIKEN R-CCS) [1] computation for large urban area. Then, the generated inflow data are connected to the calculation domain of tetrahedral unstrucrture grid and wind pressure on actual high-rise buildng. Finally, the effects of large-scale flctuation derived from meteorological disturbance on wind pressure of high-rise building are revealed.

ACKNOWLEDGEMENTS

This research used computational resources of the Fugaku computer provided by the RIKEN through the HPCI System Research project (Project ID: hp210158,hp210262).

Key Words: *LES, Super High-rise Building, Peak Pressure, Conical Vortex*

In previous researches, the mechanism of the occurrence of local peak suction on single cylinder building model in turbulent flow has been investigated [1,2]. In this study, characteristics and cause of local peak pressure observed on the surface of a super high-rise building in an actual urban area are discussed through a relationship with the flow characteristics.

Large Eddy Simulation (LES) of high dense area in central Tokyo including several super high-rise buildings is carried out with the turbulent inflow boundary condition [3]. A distinctive wind pressure distribution with large negative pressure is observed at the windward corner on the sidewall of the target building. In the trace of pressure fluctuation at this point, very large suction peaks appear occasionally.

Based on computational results, the relationships between the flow characteristics and the pressure characteristics are analyzed. The wind speed at a point close to the windward corner increases before the peak suction occurs. It is found that strong flow separation generated from the windward building accelerates the conical vortex formed at the windward corner, which induces the peak suction.

Key Words: *Aerodynamic, Tapered square cylinder, eccentricity, torsional vibration, BCM*

Due to improvement of construction technology in recent years, the number of construction cases of buildings with various plane shapes is increasing. Based on this tendency, in this study, we made a square cylinder model that has the plane whose upper part is eccentric and tapered in three stages as a trial. Generally, such structure is considered to advantageous for vortex-induced vibration, but there are concerns about the effect of torsional vibration due to the eccentricity of the upper part. In this research, we check the flow field and exam the effect of torsional vibration and vortex-induced vibration of this building using CUBE (Complex Unified Building Cube Method). CUBE is a simulation framework which has orthogonal grid system consisting of cubes and elements called cells that divide them, and each cube has a mesh system consisting of the same number of cells. CUBE can generate mesh automatically and calculate with high parallelization efficiency. For more information on CUBE, please refer to the following paper ([1]). This research is expected to expand the range of plane shapes that can be constructed in the future.

Key Words: *Wind Pressure Characteristics, High-rise Building, Local Terrain, Inflow Turbulence*

The Akasaka area, which is adjacent to the green areas such as the Akasaka Imperial Property, the Hie Shrine, and the Sotobori area, is densely built with middle and high-rise buildings over the local terrain. It is important for wind resistance design to understand what kind of strong wind blows during a typhoon in such an urban area and the wind pressure acts on the buildings.

In this study, we focused on the wind of the wind direction SSE observed during Typhoon Lan (2017). We clarified the relationship between the wind flow field around buildings and the wall surface pressure by LES. The inflow turbulence obtained by the meteorological analysis and CFD for wide area was applied to the inflow boundary condition of LES.

Based on this result, we report the results of the effects of micro topography and trees on the wind flow and the wall surface pressure, and the characteristics of wind pressure acting on the uniquely shaped façade.

Key Words: *WRF-LES, Typhoon, Urban Area, Mean Wind Speed, Wind Speed Fluctuation*

In an LES (Large-Eddy Simulation) to evaluate the wind load acting on buildings, the turbulent boundary layer flow is typically set as the inflow data. However, the effect of meteorological disturbances due to large-scale flow structures cannot be considered sufficiently in this method. Attempts have recently been made to generate LES inflow data that include the effect of meteorological disturbances by using meteorological models; further advancement of wind load evaluation using LES is expected. In a previous study, we indicated that the meteorological model overestimated the mean wind speed in an urban area because of an underestimation of ground surface friction (Nakajima et al., 2021). The prediction accuracy of meteorological models in urban areas needs to be improved to generate LES inflow data that include the effect of meteorological disturbances adequately.

In this study, we investigated the influence of the ground surface boundary conditions of the meteorological model on the accuracy in predicting the mean wind speed and wind speed fluctuation in an urban area. Two types of ground surface boundary conditions (Cases 1 and 2) were created. In Case 1, the roughness length for the urban area was set to 0.5 m uniformly (default setting), whereas in Case 2, the spatial distribution of roughness length for the urban area was set based on the urban geometry (Kanda et al., 2013). In Case 2, the roughness length in the central part of Tokyo was much larger than 0.5 m and ranged from approximately 4 to 20 m.

We performed wind flow simulations in the central part of Tokyo during Typhoon Lan (2017) using WRF-LES (LES mode of Weather Research and Forecasting model) with the created ground surface boundary conditions. The simulation results were compared with observation data at multiple locations. By setting the roughness length based on the urban geometry, the accuracy in predicting the mean wind speed in the urban area was improved significantly. However, in both cases, WRF-LES underestimated the turbulence intensity, especially near the ground surface.

A Deep Convolutional Neural Network Approach as Surrogate Model for Topology Optimization

Xiangrui Kong [1*], Yu-Ching Wu [1]

[1]Tongji University, Shanghai, China
2033792@tongji.edu.cn

Key Words: *Topology optimization, finite element method, deep learning, neural network, surrogate model*

It is widely recognized that traditional topology optimization (TO) method can be time consuming, mainly due to the finite element analysis (FEA) embedded in the iteration. In the past few years, the rise of deep learning (DL) has been driving the researchers to adopt artifical neural network (ANN) as a surrogate model to accelerate TO [1-3]. However, most research focus on treating the whole TO process as a black box, taking its inputs (boundary conditions, volume fraction, etc.) and outputs (the optimized structure) to train the surrogate model. This paper propose another angle to approach the problem, which is to focus mainly on the most time-consuming FEA part in the TO process. There are a number of surrogate models existing for structural FEA [4]. In this paper, an encoder-decoder convolutional neural network (CNN) is trained using data generated from the FEA module in the 88-line matlab code implementing the classic solid isotropic material with penalization (SIMP) method [5]. The trained network takes the boundary conditions and element densities as inputs and output the compliance of each element. Then, the compliance information is fed into the traditional TO numerical optimizer to derive the final optimized structure.

The main advantages of the proposed method are listed as follows.
1) The numerical optimizer is kept in the TO process. Therefore, the structural disconnection reported in other research [1,2] is naturally avoided.
2) By performing downsampling and upsampling in the CNN, the proposed method has a certain degree of generalization ability.
3) Future research may grow on the idea of seperating the two components of TO. For example, training another surrogate model for the numerical optimizer, and combining it with the FEA surrogate model to achieve further acceleration.

Form-finding of Discrete Surfaces with Given Edge Lengths by using Force Equilibrium Method

Jingyao Zhang[1*], Makoto Ohsaki[2]

[2] Kyoto University, Kyotodaigaku-katsura, Nishikyo-ku, Kyoto, 615-8540, Japan, ohsaki@archi.kyoto-u.ac.jp

Key Words: *Discrete surface, Form-finding, Force equilibrium, Edge length*

This paper presents a practical algorithm for the form-finding problem of a discrete surface constructed by triangles with given edge lengths. This problem could have many applications, e.g., mathematical visualization, geometry processing, and architecture.

Theoretically, solutions for such form-finding problems always exist, and these solutions are not unique [1]. This characteristic enables the studies on surface deformation [2], for instance. This also gives us the chance to design a preferable shape in architecture, which is to find the shape as close as possible to the target shape designed by architects.

In many conventional methods of shape design, this geometry problem is transformed into a mechanical problem, where the edges are replaced by springs. The spring energy is then defined in terms of the difference in edge lengths, and the equilibrated shape is determined by energy minimization. However, the optimizer could get stuck in local minima, and results in an undesirable shape with local bumps and dips [3].

In this paper, we present a force equilibrium method for finding the final shape with given edge lengths. The edge lengths could be determined by using Ricci flow or other algorithms so that the surface has the specified geometric properties, such as uniform (discrete) Gaussian curvature [4]. The linear stiffness is used to predict the shape deformation in the iterative algorithm. Moreover, its pseudo-inverse is applied to compute the least-square solution for the system without boundary conditions.

Starting from the target shape, while driven by the unbalance forces due to differences in edge lengths, the proposed method enables the system to settle down quickly to the final shape having exactly the given edge lengths. More importantly, numerical examples demonstrate that the final shape is smooth and close to the initial design.

Generating Topology-Optimized Shapes with GAN: Design support framework providing diverse shapes

Tomohiro Miyake[1*] and Yohei Yokosuka [2]

[1] Kagoshima University, 1-21-40 Korimoto Kagoshima-city Kagoshima, JAPAN 890-0065, k2458811@kadai.jp

[2] Kagoshima University, 1-21-40 Korimoto Kagoshima-city Kagoshima, JAPAN 890-0065, yokosuka@aae.kagoshima-u.ac.jp

Key Words: *Topology optimization, GAN, Deep learning, CNNs, SIMP method, OC method*

We propose a new framework for more diverse design support by generating Topology-optimized shapes with GAN. In recent years, Topology-optimized shapes have been used to create attractive forms in the architectural field, as seen in the "Qatar National Convention Centre" designed by Arata Isozaki. Topology optimization has a high affinity with digital fabrication and is expected to be applied as architectural and structural design. In addition, many studies on structural design and form-finding for structural optimization by machine learning have been reported. However, a mainly progressive area of machine learning is image processing, and it is difficult to apply learning to extract features to other data structures.

Therefore, pixels in image processing and continuum elements in topology optimization can be considered as the same data structure, and thus topology optimization can be applied to deep learning using convolutional neural networks[1]. By applying GAN to learn topology-optimized shapes, it is possible to continuously generate variety of shapes with these features.

In this study, topology optimization using the SIMP method is adopted, the design domain is divided by finite elements, and the optimization process is solved using the optimality criterion method[2]. The topology optimization problem is assumed to be a compliance minimization problem. GAN is a machine learning technique that consists of two deep convolutional neural networks (CNNs), a generator and a discriminator, which are trained simultaneously while competing with each other. Here, we use Conditional GAN (CGAN), which can give directionality to the generated results by providing the class information of the dataset, labels[3].

We perform deep learning using GAN based on the data collected by the topology optimization and attempt to output the shape from the generator network after training. In this study, we execute several numerical experiments to learn topology-optimized shapes using GAN. The numerical experiments show that the GAN can reproduce the topology-optimized shape and generate various shapes by interpolating the features of the topology-optimized shape through feature learning. These results demonstrate the usefulness of GAN for generating diverse design.

Key Words: *Hanging Membrane Forms, Shell Membrane Theory, Variational Problem*

This paper presents hanging membrane forms based on formulation of differential geometry and discretized form-finding analysis. A reversed hanging membrane form in which pure compression stress state generates by acting the self-weight resist to the gravity naturally, economical construction has been implemented in consideration of construction materials. A. Gaudi was a famous architect who designed the Sagrada Familia, he applied the hanging model as an experiment to the structural form of the Sagrada Familia. H. Isler who was a structural engineer in Switzerland has constructed a lot of thin shell structures with reversed hanging membrane forms by an experimental approach in 1960's.
Recently, form-finding analysis have been developed and actively researched in architecture and computer graphics fields[1], an equilibrium form of unreinforced masonry structure can be computed using thrust network analysis[2]. An unreinforced masonry is a self-supporting structure in which only compression stress generates as with a reversed hanging membrane form. It has been confirmed that the Thrust Network Analysis (TNA) is a useful method by constructing the actual masonry structure. Airy stress function can define a horizontal stress distribution and can be applied to find equilibrium forms with in-plane stress[3]. These equilibrium forms can be described by the discretized polyhedral mesh in isotropic geometry[4].
These form-finding analysis can be formalized by various aspects such as equilibrium equations and geometric variational problems. However, consistent formulation is desirable between mechanics and mathematics, because the problem of nonlinear equations to find a structural form is important to consider the region of existence of solutions obtained form-finding analysis and certainty of the generating strass state.
In this paper, we present formulation of hanging membrane forms described by differential geometry and shell membrane theory[5]. We indicate that essential objects in hanging membrane forms are two-way nets expressed as isothermic coordinates, and show some numerical results of form-finding analysis.

Key Words: *Aluminum Alloy Beam, Beam String Structure, Cost Minimization Problem*

Industrial-use aluminum alloy materials are excellent in the lightweight and corrosion resistant, but inferior to the stiffness and material cost than steels. When the aluminum alloy is used to a girder bridge, the member cross-section must be larger than that of the steel because the same deflection limit must be applied regardless of the material types, and it results in higher material costs. Therefore, the aluminum alloy materials are often used not in the bridge girders but in the bridge components such as guardrails and lighting posts [1]. In this study, we try to apply the aluminum alloy materials to Beam String Structure (BSS) in order to improve the stiffness and reduce the material cost. In the BSS, the girder is supported by the cables through the struts to generate the negative bending moments, which can increase the stiffness of the entire girder [2]. In this paper, superiority of the BSS made of the aluminum alloy material is clarified through a combination of topology optimization and material cost minimization problem.

Fistly, configurations of the BBSs were determined by the topology optimization using grandstructure method. Then, six types of the BSSs were adopted in the material cost minimization problem, with three cable diameters and the number of struts of 1 and 2. For comparison to the BSSs, a simple supoprted steel and aluminum alloy beam were also considered. The material cost is adopted by the relative cost per unit mass multiplied by the mass of materials, referring to the literature [3]. The cross-section of the beam and strut and the height of the strut were used as design variables. The height of the beam, the width and height of the strut, the distance between the struts, the yield and buckling stress, and the deflection limit were used as constraint conditions.

The material cost of the simple supported aluminum alloy beams was approximately 42% higher than that of the simple supported steel beams. On the other hand, the material cost of the BSSs made of the aluminum alloy material was equal to or lower than that of the simple supported steel beams. Regardless of the number of struts, the material cost decreased as the cable diameter increased. Furthermore, the relationship between the span length and material cost was investigated. In contrast to the simple supported steel beam, which no longer satisfies the constraint when the span reaches a certain length, the BSS made of aluminum alloy material satisfies the constraint even when the span increased by 80% compared with that of simple supported steel beam. These results suggest that the development of lighter weight and longer span structures using aluminum alloy materials can be expected.

Key Words: *Free-form shell, Shape design, Projected stress, Pucher's formulation, Membrane theory*

Analytical shapes such as spherical shells and cylindrical shells are widely used for shell roofs covering large space of architecture. However, it is preferable that the external loads are transmitted to the supports mainly through the in-plane (membrane) stresses to fully utilize the material of thin surface. For the vertical self-weight, such shape can be obtained by hanging a membrane or cable net and inverting it to generate a convex roof surface. This process can be computationally simulated using the optimization approaches of designing free-form shells. Geometrical approaches based on graphic statistics can also be utilized for designing convex shapes of compression-only shell roofs. Miki et al. [1] proposed a design method of a parametric surface under self-weight utilizing the framework of Airy's stress function.

For a graph surface of a thin shell modelled using the membrane theory, static equilibrium of the in-plane forces is described by the stress components projected to the horizontal plane using Pucher's formulation or Monge's description. Accordingly, the formulations based on Airy's stress function, which is generally used for the plates, can be used, and the existence of stress function is to be investigated for ensuring equilibrium of the curved surface. However, the distributions of stresses projected on the plane can be directly specified allowing discontinuity without checking existence of the stress function [2].

In this study, the method proposed in Ref. [2] is extended, and the description of graph surface is converted to a parametric form to design surfaces with curved boundaries. The x- and y-coordinates on the horizontal plane are expressed by Bernstein polynomials of two parameters normalized between 0 and 1. Detailed formulations are presented for solving discretized form of vertical equilibrium equation by finite difference approximation on the parametric plane.

In the numerical examples, various shapes are found by specifying the distributions of stresses projected on the horizontal plane. Accordingly, we can specify the horizontal reaction force (thrust) that is an important design parameter for the supporting structure. It is confirmed that smoothness of the surface shape is maintained even when the normal stress is discontinuous in the direction perpendicular to its direction. A static finite element analysis is carried out to show that the stresses are sufficiently close to the specified values even considering the deformation under self-weight, if the restriction along the boundary is appropriately compensated by a forced in-plane deformation before applying the vertical loads.

Key Words: *DBSCAN, Clustering, Descent method, Optimization problem, Solution space*

This paper presents optimization problems with a density-based clustering algorithm by obtaining all extremal values of solution space. In the architecture, designing building have to take account of several field such as architectural design, environmental engineering and structural engineering. In addition, as setting numerically priorities among design, usability and safety has difficultly, providing various solutions that are well evaluated is important. Thus, proposing not only a global optimal solution but also local optimal solutions in the optimization problem is important in optimization problems of building structure with multiple extremal values. The previous study has proposed the method that obtains multiple extremal values as optimal solutions utilizing a clustering method. This optimization enables us to obtain global and local optimal solutions efficiently by introducing a clustering operation to FA[1]. However, *k*-means method of partitioning clustering algorithms requires the number of clusters as a parameter of optimization problems. If the number of predetermined clusters is less than or greater than the number of extremal values in the solution space, finding some of the extremal values is missed. This is "the lucked of diversity of solutions". In this paper, we present the method combining hill climbing method for a local search method and DBSCAN[2] for a density-based clustering algorithm, which enables us to find all extremal values of the solution space for optimization problems without predetermining the number of clusters. The method consists of a few coordinating processes. Using Latin hypercube sampling, we initiate the process by generating the random data on solution space. Hill climbing method enables us to collect the generated data around external values, which is classified into clusters with DBSCAN in the following process. The results of our numerical experiments show that proposed method could identify extremal values for several benchmark functions[3] and a structural optimization problem[4] as the number of clusters. From these results, this method would allow us to grasp extremal values in the solution space, which structural optimization problems have high-dimensional variables, as the number of clusters. Moreover, this method would be able to present various solutions for structural and architectural design.

The Reason Solving a Tension-compression Mixed Shell Form-finding is so Difficult and How to Solve it

Masaaki Miki[1]

[1] The University of Tokyo, masaakim@g.ecc.u-tokyo.ac.jp

Key Words: *Airy's stress function, shell, form-finding, nonlinear least-squares method,*

In architectural design and structural engineering, membrane-shells that stand against the gravity by in-plane membrane stresses only have been paid a consistent attention. However, the built or computed membrane shells are typically in compression-only although there is no fundamental theory contrary to a mix of tension and compression. It is expected that overhanging anticlastic surfaces can be achieved with no bending action if the forms of tension-compression mixed membrane shells can be computed numerically.
The natures of the equilibrium equations of the pure-compression and tension-compression mixed types are surprisingly different because the former is elliptic while the latter is hyperbolic. The fact that the equilibrium equation becomes hyperbolic is making the tension-compression mixed form-finding a challenge.
This paper explains why solving the tension-compression mixed form-finding problem of membrane shells is so difficult and presents a powerful strategy to solve the problem numerically. In short, there is a high possibility there being no solution. Hence, a test method to determine/evaluate if the problem solved had a solution is needed. With the concept of the Airy's stress function to compute the forms of shells, when the problem has a solution, the Airy's stress function can be recovered with no loss of information from the computed shell. If the information is lost during the recovery, the problem is judged to have no solution. This concept can be beautifully realized with the nonlinear least squares method and the problem can be solved by the variable projection method briefly overviewed by Elden and Ahmadi-Asl, 2019[1]

Key Words: *Shape Optimization, Spherical dome and Right helicoid, Gradient solvers, Optimal solution*

Each optimization program has special modules for calculation, which are based on several algorithms. Thus, the presence of a choice among the solvers contributes to the selection of the most suitable solution for any problem.

In this work two shells: spherical dome and right helicoid are calculated in the program Comsol Multiphysics in the module Shape optimization using three gradient methods: MMA (the method of Moving Asymptotes), IPOPT (Interior Point OPTimizer), which is based on the use of sequential quadratic programming (SQP) method and SNOPT (Sparse Nonlinear OPTimizer), which is based on the interior-point algorithm with a filter line search method.

The purpose of the study is to compare the three methods in detail with each other and choose the most optimal form for shape optimization. For each method, an analysis is carried out according to the following criteria: the speed of obtaining results and the greatest change in the shape geometry.

The main stages of the study are based on the following points: a study of the main functionality of solvers; modeling and further calculation of the shells with the assignment of special criteria in the programs under study; the overview of the obtained results and selection of the most optimal solver for calculation.

The solvers IPOPT and SNOPT are similar in structure, so the values obtained using these methods do not differ much, although the IPOPT method has managed to achieve the most optimal solution for shells. The smallest changes in geometry were observed using the method MMA.

Key Words: *Topology optimization, MISOCP, Global optimal solution, Interior point method, Branch-and -cut method*

It is known that the topology optimization (TopOpt) problem of frame structures can be formulated as a mixed-integer second-order cone programming problem (MISOCP), when the compliance is minimized and the cross-section of each member is selected from a set of predetermined candidates[1]. An MISOCP problem can be solved globally with a branch-and-cut method (B&C) while global optimalty is mathematically guaranteed. When the B&C makes MISOCP a continuous problem, the resulting problem is a second-order cone programming (SOCP) problem, which can be solved efficiently with a primal-dual interior-point method. Previous studies have demonstrated the effectiveness of TopOpt by MISOCP for the simple stiffness maximization problem of medium-sized structural frames[2]. However, if we consider design and construction of real-world building structures, it is insufficient to optimize only the mechanical performance. In the latest research of such optimization approach, it is confirmed that various non-mechanical constraints, such as upper bounds for the member lengths, the number of nodes, lower bounds for the joint angle of members, can be additionally taken into account[3]. On the other hand, the density of members to each joint also affects the non-mechanical performance (especially constructability), but this has not been considered in previous studies.

In this paper, TopOpt by MISOCP with new constraints that take into account the density of the members by constraining the number of members connected to each node is considered. Furthermore, TopOpt is performed for various analytical models while not only proposed constraints but also various non-mechanical constraints considered in previous studies are simultaneously taken into account.

Key Words: data augmentation, generative adversarial networks

The study of many scientific and engineering problems requires constructing predictive models of multi-scale and multiphysics systems. The recent explosion of scientific machine learning research has shown tremendous potential of enhancing new discovery in these complex systems. Yet the promise of most machine learning techniques relies on the availability of a large volume of high-quality training datasets, which are obtained through expensive experiments or simulations. Therefore, data augmentation techniques can be of great help for scientific machine learning problems. However, directly implementing data augmentation techniques originating from computer vision, can yield physically unacceptable data samples. We develop a new data augmentation technique based on generative adversarial networks (GANs). It can leverage different physics knowledge, e.g., governing equations, observable perception, and physics phenomena to improve the quality of the augmented synthetic data. We will demonstrate its efficacy by generating configuration samples of porous media with given constraints, and by augmenting spatio-temporal data using limited high-quality simulation results.

Development, Learning and Optimization of Viscoelastic Laminated Composite Beams

Hong Wang

Department of Mathematics, University of South Carolina, Columbia, South Carolina 29212, United States, hwang@math.sc.edu

Key Words: *Composite beams, Viscoelastic materials, numerical simulations*

Composite beams have found increasingly more engineering applications due to their high specific stiffness and strength. Nevertheless, these problems present challenging modelling, mathematical, and numerical issues including heterogeneous and distinct anisotropic properties, high frequencies with potential resonance issues.

We present a mathematical model for describing dynamic vibrations of viscoelastic composite beams with laminated structures. We will mathematically analyse the model, investigate performance of the model, and learning and optimization of the model.

Learning Nonlocal Operators for heterogeneous material modeling

Constitutive modeling based on the continuum mechanics theory has been a classical approach for modeling the mechanical responses of materials. However, when constitutive laws are unknown or when defects and/or high degrees of heterogeneity present, these classical models may become inaccurate. In this work, we propose to use data-driven modeling which directly utilizes high-fidelity simulation and/or experimental data on displacement fields, to predict a materials response without the necessity of using conventional constitutive models. Specifically, the material response is modeled by learning maps between loading conditions and its resultant displacement fields, so that the network is a surrogate for a solution operator. To model the material heterogeneity, integral neural operator learning methods are employed, which are resolution-independent and naturally embeds the material micromechanical properties and defects in the integrand. We demonstrate the performance of our method for a number of examples, including hyperelastic, anisotropic and brittle materials. As an application, we employ the proposed approach to learn material models directly from digital image correlation (DIC) tracking measurements, and show that the learnt solution operators substantially outperform conventional constitutive models in predicting complex material responses.

Leveraging Machine Learning for Subsurface Modeling with Fractional-Order PDEs

Mamikon Gulian

[1] Sandia National Laboratories, 7011 East Ave, Livermore, CA 94550, mgulian@sandia.gov

Key Words: Deep Learning, Fractional, Nonlocal, Subsurface, Anomalous

Data from both numerical simulations as well as physical experiments of subsurface flows reveal that contaminant tracer is often anomalous, with breakthrough curves and mean-square displacements exhibiting heavy, non-Gaussian tails characteristic of Lévy processes, the statistical properties of which are described by fractional-order models. We leverage recent machine learning approaches for inverse problems to demonstrate and compare the efficacy of fractional-order models and local models in a variety of datasets. Our results are both a novel application of machine learning approaches to model discovery for such applications and shed light on what type of models can be expected to accuractely describe subsurface flows in different materials.

Meta-Learning for Heterogeneous Materials: A Provable Nonlocal Operator Regression Approach

Yue Yu[1*], Huaiqian You[2] and Lu Zhang[3]

[1] Department of Mathematics, Lehigh University, Bethlehem, PA, USA, yuy214@lehigh.edu

[3] Department of Mathematics, Lehigh University, Bethlehem, PA, USA, luz319@lehigh.edu

Key Words: Neural Operator Learning, Representation Learning, Partial Differential Equation Learning, Meta-materials.

In this talk, we propose a meta-learnt approach for learning mappings between function spaces (operators), Meta-NOR, based on the nonlocal operator regression [1], to efficiently provide accurate model surrogates for in new and unknown governing law tasks. The proposed provably sample-efficient meta-learning algorithm uses a multi-task nonlocal operator regression model in the kernel space, which consists of two phases: (1) learning a common nonlocal kernel representation from existing tasks; and (2) transferring the learned knowledge to rapidly learn surrogate models for new tasks with different governing laws (such as with different constitutive laws or material parameters), where the governing laws could be possibly unknown and only a few test samples are provided. Under the linear kernel regression setting, a provable optimization-based approach is provided, with theoretically guaranteed transfer-learning error bounds. We apply the proposed technique in the context of meta-materials, showing that the meta-learnt kernel representation would greatly improve the sampling efficiency in new and unseen microstructures, compared to existing baselines. To handle more complex material responses, we further extend the proposed meta-learnt approach to the integral neural operator architecture [2,3], and demonstrate its performance on learning hidden governing laws of Darcy's flow.

Key Words: Nonlocal kernel, Identifiability, Inverse Problem, RKHS

Nonlocal integral operators arise in various areas such as nonlocal partial differential equations, fractional diffusions, and nonlocal networks. An important topic is to learn from data the nonlocal integral kernel, which is often radial to achieve homogeneity. We introduce a nonparametric approach to yielding a convergent estimator of the kernel as the data size increases. A key ingredient is a new spare-aware regularization method to prevent over-fitting and overcome the inverse problem's ill-posedness. The method's foundation is the function space of identifiability, a system-intrinsic data-adaptive RKHS (reproducing kernel Hilbert space). Furthermore, the identifiability theory suggests that the inverse problem is ill-posed. Thus, regularization is necessary. We systematically study the spare-aware regularization with synthetic data, showing the convergence of estimators. We also apply our method to experimental data in peridynamics, for which we learn a homogenized nonlocal model.

Bayesian Model updating of Linear dynamic systems using complex modal data

Key Words: *Bayesian Model Updating, Dynamic Condensation, TMCMC, Complex modal data.*

In the lifetime of structures, they may be exposed to damage that deviates their parameters to a new uncertain state. To predict these parameters, they must be updated using experimental data through various model updating methods. Among model updating methods, the Bayesian approach enables the exploration of all the probable models. Many approaches are available, like those that require the solution of the eigenvalue problem [1] and those that do not require the resolution of the eigenvalue problem [2, 3]. Most existing studies have assumed proportional damping, which gives real modal data, which is not the case always [4]. In this paper, a new Bayesian model updating methodology is proposed based on introducing system mode shapes, damping ratios and natural frequencies as additional uncertain parameters. A dynamic condensation technique is used to restrain the model updating problem to work on the observed degrees of freedom (DOF) field only. To decrease the number of uncertain parameters, system mode shapes are integrated out, and Transitional Monte Carlo Markov Chain (TMCMC) is used to sample from the posterior probability density function. The proposed approach has been applied to the 3-storey shear building model. Results show that the proposed methodology can predict the updated structural parameters in many cases, like the cases where the number of observed modes is greater than the number of observed DOF and if the observed modes are not the lowest-frequency modes.

Key Words: Bayesian model updating, Reliability analysis, Simulation techniques, Structural dynamics

Model updating of structural dynamical models using measured responses has an important number of applications in several areas. For a proper assessment of updated models all uncertainties involved in the problem need to be considered. In this regard, an approach for Bayesian model updating of structural dynamical systems involving multiple uncertain parameters and measured responses is presented. The proposed scheme relies on the use of structural reliability methods, where samples following the posterior distribution are obtained as failure samples corresponding to a specially devised reliability problem [1]. Subset simulation, a well known and widely applied advanced stochastic simulation technique, is adopted to generate the required failure samples [2]. The approach requires only minimal modifications of the standard formulation of subset simulation and it uses an adaptive strategy to select the threshold value that determines the last subset level. For an efficient numerical implementation, an effective parametric reduced-order model formulation based on substructure coupling for dynamic analysis is considered [3]. Due to the basis of the formulation, the approach does not make use of any problem-specific information and, therefore, any type of structural model can be considered. The performance of the proposed method is assessed numerically with an example problem involving a nonlinear three-dimensional bridge structural model with many uncertain parameters. The results suggest that the proposed approach is an effective tool to address Bayesian model updating problems involving complex structural dynamical models, measured response data and high-dimensional parameter spaces.

Key Words: *Stochastic linear system, Reliability-based optimization, Decoupling*

Reliability-based optimization (RBO) offers the means for determining optimal structural designs while explicitly taking into account the effects of uncertainty on structural performance. While the advantages of RBO over deterministic design procedures are evident, its practical implementation is usually quite challenging from a numerical viewpoint. This is a consequence of the necessity of solving simultaneously a reliability problem nested in an optimization procedure, that is, a double–loop problem.

In view of this challenge, this contribution develops a most efficient approach for RBO for a specific class of problems. The focus is on the minimization of the failure probability of linear structural systems subject to Gaussian stochastic loading under a given budget constraint. The reliability measure considered here is the first excursion probability of the structure, which is a typical means for quantifying safety in stochastic dynamics. The proposed approach is formulated within the framework of the operator norm theorem, which allows full decoupling between optimization and reliability analyses [1]. That is, the classical double–loop approach for RBO is effectively broken and reduced to the solution of a single deterministic optimization problem followed by a single reliability analysis. Such an approach allows diminishing numerical costs by orders of magnitude when compared to a traditional, double–loop implementation. The application and capabilities of the proposed approach are illustrated by means of an example.

Abstract: The probabilistic response analysis of structures subjected to combined multiplicative and additive excitations is a challenging issue. The direct probability integral method (DPIM), as a novel method, has demonstrated its high accuracy and efficiency in the random variation analysis of nonlinear multiple-degree-of-freedom (MDOF) systems under additive excitation [1, 2], i.e., Gaussian white noise excitation. In this paper, the DPIM is extended to address the probabilistic response analysis of nonlinear MDOF dynamic systems under combined multiplicative and additive excitations. The first aim of the paper is to investigate the random vibrations of the MDOF dynamic system, showing the evolutionary process of probability density functions of the response and stochastic bifurcation. To further display the global dynamics of MDOF system, the second aim of this work is to obtain the attractors, and basins of attraction. By incorporating the generalized committor functions, the basins of attraction of system are generalized via DPIM and the dynamic integrity measures are then evaluated. In the numerical examples, the effectiveness of the proposed method is verified by comparing the results of Monte Carlo simulation.

Key Words: *Robust design optimization, optimization under uncertainty, parameter uncertainty, genetic algorithm, mean–variance.*

The inherent uncertainty in the structural parameters directly affects the structural performance, and its variation may lead to improper designs and catastrophic consequences. When subjected to uncertainty, the structure design must be optimized to get an insensitive design using a Robust Design Optimization (RDO) technique. Such design aims to find a system design in which the structural performance is less sensitive (insensitive) to the uncertainty of the inherent structural parameter without eliminating them [1]. This is usually achieved by simultaneously minimizing the mean and variance of the structural performance function. Various RDO approaches, such as those based on Taylor series expansion [2] simulation-based methods [3], dimension reduction [4], and metamodel [1], can effectively take into account these uncertainties. However, the computational efficiency and accuracy in evaluating the mean and variance of the performance function remain a challenging task. To obliviate this limitation, a novel stochastic simulation-based approach is proposed in the present work. The proposed approach is built on an 'Augmented optimization problem,' in which design variables are artificially considered as an uncertain parameter. An unconstraint Genetic algorithm (GA)-based optimization approach is formulated to determine the optimal solution. As the mean and variance frequently conflict with each other, so to obtain the Pareto optimum, a linear scalarized objective function is adopted. To demonstrate the proposed approach, RDO of a four-bar and 10-bar truss structure is performed. The results obtained are compared with the conventional Monte Carlo simulation approach and confirm that the proposed approach yields accurate results. This paper allows the designers to design the insensitive structure systems by minimizing the variance of performance function. Moreover, the proposed RDO approach is not limited to the civil structures only, but it can also be enforced in the design of any realistic linear/nonlinear structures and systems such as machine components (like clutches, gears, etc.), aerospace, etc., having uncertainties in their geometry or material, such as the residual strain, modulus, thickness, density, etc.

Abstract The application of structural optimization is an effective method to create and design high-performance structures without relying on the designer's intuition, experience, or trial and error. In particular, topology optimization is used as the structural optimization method with the highest degree of design freedom. However, as the target problem becomes more complex, sensitivity analysis, which is essential for topology optimization, becomes more difficult.

In this paper, we propose valid methodologies to address that shortcoming. The density of the structure is expressed by placing equally spaced Gaussian functions in the design domain and superimposing them based on the RBF network. Furthermore, by using the height of the Gaussian function as a variable in the differential evolution calculation, the optimal structure is obtained without sensitivity analysis. Here, MLSHADE-SPA[1], which is competitive in solving large-scale global optimization problems, is employed as the differential evolution algorithm. With this method, we obtained the same optimal structure in the stiffness maximization problem as when using the conventional topology optimization method[2]. However, since the current program requires a huge computational cost, it is necessary to reduce the computational time. In future work, we hope to extend our method to some more complicated multi-physics problems such as thermal-fluid problem, electromagnetism problem, etc.

Key Words: *Generative Adversarial Networks (GANs), Genetic Algorithm (GA), Hyper-parameter*

ABSTRACT

Generative Adversarial Networks (GANs) are a kind of neural network frameworks presented by Ian Goodfellow et. Al. [1]. GANs has two neural network structure; Discriminator network and Generator network. Generator network generates prediction results and Discriminator network evaluates that the image is “real” or “fake”. GANs have been proved useful for semi-supervised learning.

In this study, GAN is applied for future image generation problem of walking pedestrians. The aim of this problem is to generate the continuous future images from their past images of walking pedestrians. The convolutional networks are adopted for both Generator and Discriminator networks in this study, instead of the fully connected network used in the previous study. Some experimental results show that the proposed algorithm is useful for future image generation of walking pedestrians.

For effectively applying the GANs-based algorithm for generating the continuous future images from their past images of walking pedestrians, however, there is one problem to be solved. The performance of the proposed algorithm depends on the hyper parameters and the number of images. For solving this problem, Genetic Algorithm is used in this study. The hyper-parameters of the Discriminator are fixed and then, the hyper-parameters and number of images for the Generator network are determined by Genetic Algorithm. The fitness function is defined by loss function of Generator network. Individual chromosome is composed of hyper-parameters of the network; number of hidden layers and activation functions at hidden layers, and numbers of input images and output images.

When the proposed algorithm is applied for future image generation of walking pedestrians, the hyper-parameters and the number of images for Generator network can be optimized automatically. Although number of hidden layers is 4 at both the original and optimized networks, the activation functions are changed. Besides, numbers of input and output images are also different at both networks. As a result, Perk Signal to Noise Ratio (PSNR) of the generated images is improved from 29.1 in the original network to 29.6 in the optimized one. Therefore, it can be concluded that the proposed algorithm can improve the hyper-parameters and number of images for the Generator network automatically.

Application of Grammatical Evolution for Design of Control Program of Robot

Firdaus Sukarman*, Ryoma Sato and Eisuke Kita

Nagoya University, Nagoya 464-8601, Japan,

Key Words: *Grammatical Evolution, Backus-Naur Form (BNF), Control Program, Mindstrom.*

Robots has become widespread in various applications. For the effective use of robots, it is necessary to design a control program that is effective for the desired movement. Since it is difficult to define the control program of a robot manually, use of evolutionary computation (EC) for designing control program is studied widely. Grammatical Evolution (GE) [1], which is one of evolutionary computations, is designed for determining the function, program or segment of program satisfying the design objective. Although aim of GE is similar to Genetic Programming (GP) [2], GE uses simpler genetic operators than GP. In this study, GE is applied for design of the control parameter of travelling robot. GE defines the candidate solutions by set of binary numbers and update them by applying the genetic operators such as selection, crossover and mutation, which are similar to them in Genetic algorithm (GA) [3]. Translation from the set of binary numbers to function or program is performed according to the translation rules defined in Backus-Naur form (BNF).

A travelling robot moves along an oval course which is drawn on the paper. GE generates the control program of LEGO Mindstorm EV3. The part of the control program which is generated by Grammatical Evolution. The function SensorValue(S3)>90 means that the robot is on the oval course. In that case, the robot goes straight. If not so, the robot turns right. The simulation and the experimental results of the robot trajectory achieved small differences. The experimental result agrees well with the simulation one.

Concurrent Multiscale Topology Optimization for Designing Displacement Inverter

Musaddiq Al Ali[1*], Masatoshi Shimoda[1]

[1] Department of Advanced Science and Technology, Toyota Technological Institute, 2-12-1 Hisakata, Tenpaku-ku, Nagoya, Aichi 468-8511, Japan

Key Words: *Topology optimization, concurrent multiscale optimization, displacement invertor, periodic microstructure. compliant mechanism.*

Structural light-weighting is vital for increasing energy efficiency and reducing CO_2 emissions. One of the mechanical structures that are used in numerous applications and can utilize lightweight is the displacement invertor. Displacement inverter is producing mechanical reaction as the reverse of the input actuating action. In this research, multiscale topology optimization of compliance mechanism is used to design lightweight displacement invertor. This is because compliant mechanisms, and in contrast to typical mechanisms that are coupled by rigid bodies, are flexible single-piece systems that achieve the desired movement through elastic deformation. Furthermore, reduced friction, wear, noise, and the ability to provide novel actuation, as well as ease of fabrication and assembly, are among the advantages of the use of compliant mechanism design concepts. Under the constraint conditions of the total area of the microstructures distributed in the macrostructure, the elastic response of the macrostructure, and the homogenization set of the periodic unit cells are used associated with the rigidity control rational problem (the ratio of the output and input displacements) of the design domain which is used as the objective function for topology optimization method. Topology optimization for material distribution is a crucial stage in the design of compliant systems. It aids designers in extending and fine-tuning a design with the optimal material distribution. It entails determining the shape and placement of a structure's cellular units, as well as the domain's connectivity. Binarization and intermediate pseudo density were investigated for the concurrent multiscale optimization of the rigidity control structures using solid isotropic material with penalization (SIMP) and evolutionary structural optimization (ESO). As a result, the effective properties obtained using the homogenization for the microstructure are evaluated with a dedicated finite element model, while the macrostructure's effective properties are calculated using a different finite element model. The adjoint approach is used to implement the sensitivity analysis efficiently for the concurrent design function in this study, which reduces the computational cost. The numerical examples showed a good design response of the microscale design with the spatial configuration and the boundary condition of the design domain on both macro and microstructure. Furthermore, this study found that addressing microscale design with the concurrent optimization process, it is possible to get a desirable spatial configuration of materials while reducing weight. the spatial arrangements for the various scenarios revealed an elaboration for distributing strain energy in the most efficient manner possible in relation to macrostructure design. As a result, the proposed design process has the potential to produce durable and new lightweight and porous displacement inverters' designs with unique and high adaptability of elastic property.

Key Words: *3D reconstruction, Clustering, DBSCAN, SfM, Point cloud, Branch-shaped complex structures*

Structure from Motion, which can reconstruct 3D point cloud, camera positions, and orientations using images of an object from different angles of view, has been widely used for visualization of structures and inspection of machined parts[1]. In this method, information other than that of the object in the image is also reconstructed. In order to remove noise, methods based on k nearest neighbors searching for reconstructed point clouds with simple shapes[2], and methods based on reconstructed object, camera positions, extracted 2D features, and so on have been proposed[3].

This research proposes an efficient noise removal method by clustering using the characteristics of object points and noise points when reconstructing an elongated object that spreads intricately in three-dimensional space, such as tree branches. The reconstruction point cloud has a partially different degree of density of points in the area. Because the noise point cloud tends to have a lower density than the object point cloud, noise is separated from the cluster. In this study, the optimum values of the parameters during clustering that enable separation were examined.

DBSCAN[4] was applied to clustering using the density of points. Since the number of points in the background is enormous and the calculation cost is high, the point cloud of the object was manually removed and clustered by dividing the point cloud into parts. Therefore, the parameters during clustering were determined by adapting to the characteristics of the tree branches. Noise could be identified by the proposed method, and the reconstruction point cloud of the object could be identified. In addition, it is considered possible to reconstruct the object surface by meshing the point cloud with noise removed.

Key Words: *Photovoltaic array*, *Placement optimization*, *Ray tracing*, *Genetic algorithm*, *Shade*

Photovoltaic arrays are installed on various shape sites to generate solar power on the ground. It is necessary to determine the arrangement of the PV array based on the influence of the solar orbit and shade to increase the amount of power generation. In order to maximize the amount of light received, the study was performed to optimize the placement of PV arrays based on the geographic data of the city[1]. Another study was conducted to determine the tilt and azimuth angles for PV arrays considering dust and maintenance space[2]. We proposed a method for finding the optimum placement of a large number of PV arrays in a site of arbitrary shape in a large-scale photovoltaic power generation facility[3].

The purpose of this study is to propose a method for analyzing shade generated in PV arrays and to clarify the effect of shade on the optimal placement results of PV arrays. An arbitrary placement in which multiple PV arrays are arranged independently on the site one by one is considered. First, the shaded area concerning the solar orbit and the array placement is formulated to estimate the decrease in the amount of light received by the shade. The area of shade on the PV array is obtained by dividing the surface of the array into triangular planes and tracing the rays obtained from the sun's orbit. An optimization problem in which the parameters are the tilted angle, azimuth angle, and placement position of the PV array is formulated. The placement is optimized to increase the amount of light received by installing multiple PV arrays at the site. A genetic algorithm is used for the optimization method.

Optimal solutions were found for some examples of optimal placement of each PV array on an arbitrary-shaped site. In the placement optimization, we compared and examined the placement results when and without considering the amount of light received due to shade and showed the effectiveness of arbitrary placement optimization considering the effects of shade.

Hierarchal Polynomial Wavelet Decomposition for Full-Field Material Calibration

Matthew W. Kury[1]

[1] Sandia National Labs, Mail Stop: 9042, 7011 East Ave, Livermore, CA 94551-0969, mwkury@sandia.gov

Key Words: Full-field, Material Calibration, Inverse Problems, Polynomial Decomposition, Digital Image Correlation, Wavelets

Physics and engineering simulation tools are becoming more prevalent in decision making processes. Core to many engineering simulation tools is a series of material models that emulate the materials' physical responses. Traditional material model calibration consists of optimizing a material model against a limited set of probe data and homogenized boundary data. These traditional methods can calibrate a wide range of material models. However, as the complexity of the models increase, the number of experimental setups required to adequately calibrate the model increases as well.

Advances in experimental techniques have enabled the use of full-field kinematic and temperature data in material model calibrations. Full-field data capture has the potential to reduce the number of experiments required by capturing more complicated material evolutions in a single experiment, than captured by traditional experimental setups [1]. Full-field data can be difficult to work with because of dimensionality of the data set. Like other scientific data, full-field data often contains significant patterns. Patterned data is an attractive application for data compression. Compressing patterned data dramatically reduces the number necessary data points, while preserving the significant information present in the data.

In this talk I will present work on a hierarchal polynomial wavelet decomposition (HPWD) method for performing calibrations to full-field data. HPWD is an unstructured data compression method based on the concepts of tree wavelets [2] and polynomial field decomposition [3]. HPWD leverages the ability of tree wavelets to efficiently capture discontinuous material behavior, while preserving polynomial field decomposition's ability to compare compressed data across different realizations of the same domain.

Numerical optimization with HPWD uses a cost function defined by the differences in the most significant compressed data components. This formulation improves the cost function topography over traditional cost function definitions and provides the means for explicit feature emphasis. We will demonstrate these capabilities though one- and two-dimensional material calibration examples.

Key Words: *Plastic injection molding, Rapid heating cycle molding, Heater system, Engineering optimization, Optimum design*

Plastic injection molding (PIM) is a typical manufacturing technology to produce plastic products, and it is important to determine process parameters for high product quality and high productivity. The process parameters are conventionally determined by trial-and-error method through experiment, but computer aided engineering (CAE) is recently used as the alternative. Since the PIM simulation is computationally expensive, response surface approach is used to determine the optimal process parameters. Weldline that is formed when two or more melt plastic flow meets is one of the major defects, and it is preferable to reduce the weldline as much as possible for the surface quality and strength of plastic products. Rapid heating cycle molding (RHCM) that the mold temperature is actively controlled has been recognized as an innovative PIM technology for weldline reduction. By heating up the mold temperature, the melt plastic is smoothly flowed into the die cavity, and consequently the weldline is well reduced. To quickly heat up the mold temperature[1], a heater system is newly introduced in the RHCM. Many papers using the RHCM discuss on the weldline reduction, but the process parameters as well as the mold temperature profile is rarely discussed. In this paper, the process parameters in the RHCM using heater system are optimized. A multi-objective optimization for minimizing both weldline and cycle time is considered, and then the process parameters as well as the mold temperature profile is determined. Sequential approximate optimization that the response surface is repeatedly constructed and optimized is adopted for the design optimization[2], and the pareto-frontier is identified. Based on the numerical result, the experiment using PIM machine (MS100, Sodick) is also conducted to examine the validity of the RHCM with heater system.

Performance Evaluation of a Plate-fin Heat Exchanger Core Designed Using Localized Topology Optimization

Mario Petrovic[1*] **and Kenichiro Fukui**[1]

[1] Sumitomo Precision Products co. ltd., Hyogo Amagasaki Fuso-cho 1-10, mario-p@spp.co.jp, https://www.spp.co.jp/

Key Words: Heat Exchange, Topology Optimization, CFD Analysis, Additive Manufacturing, Design Process

Plate-fin heat exchangers are a common type of heat exchangers often selected for their compact and lightweight designs. The flow paths of two fluids exchanging heat are separated by plates and interchangeably stacked on top of each other. Within the flow paths, the two plates are connected by fins whose design depends on the targeted performance for the heat exchanger. This design is simple and repetitive resulting in a exchanger core with a very fine internal structure that is compact and lightweight.

With the recent advances in topology optimization for fluid and thermal-fluid problems, potential improvements to heat exchanger design have been considered. However, obtaining a full heat exchanger design, by means of topology optimization, that would have the similar or better performance to conventional designs, is not feasible due to extreme computational costs associated with such an optimization analysis. Therefore, the natural approach is to constrain the optimization to a small section of the heat exchanger and extrapolate the heat exchanger design from that section.

In this study, we deploy a Level-set based topology optimization method for a thermal-fluid problem in two dimensions to obtained optimized fin cross-sections. The use of 2D optimization allows for quick generation of a relatively complex topology as opposed to 3D optimization. The resulting optimized topology shows repetitive internal sections indicating potential for more localized optimization to even higher degrees of complexity. The derived 2D cross-sections are gradually extended to small 3D sections, full flow paths, and finally the full core, with design performance evaluated at every step. To eliminate the need for costly computational fluid dynamics (CFD) analysis to obtain the performance values of the whole heat exchanger, we develop a methodology for performance evaluation of the whole design based on the performance of the single optimized section. As a result, we show that the evaluated performance is in good agreement with numerically and experimentally obtained performance values for the whole heat exchanger core.

Prediction for Behavior of Underground Structures during Construction Phase Using Data Assimilation

Key Words: *ensemble-based data assimilation, underground structures, code verification*

To ensure safety during the construction phases of underground structures, the present and future conditions of the rock and tunnel supports such as displacements and stresses, must be estimated and predicted by appropriate measurements and numerical simulations. However, many uncertainties, e.g., geological structures, mechanical properties of rocks, initial and boundary conditions, complicate numerical modelling considerably.

To solve this problem, the research developed a numerical analysis system using a data assimilation (DA) technique, that updates the numerical model based on measured data during construction. In this system, a finite volume method is applied to solve partial differential equations of rock mechanics. The Error Subspace Transform Kalman Filter is used for the DA.

To evaluate the effectiveness of the proposed system, numerical experiments were performed for a simple linear elastic problem of excavating an unsupported circular tunnel. The excavation behavior of the tunnel to be predicted was also calculated by a similar numerical analysis, instead of using the measured data of an actual tunnel. This surrogate tunnel excavation problem was adopted as subject to verification, which can be accurately predicted using this system.

The state vector included Young's modulus, E, and the displacements of the rock. The model state was sequentially updated by the system which assimilates the observed displacements using a 50-member ensemble. Observation points were established at the crown and side walls of the tunnel cross-section. The synthetic tests were performed in three ways. The first was in accordance with the general scheme of sequential DA that the latest updated ensemble was used in the next excavation stage. In the second, only the latest updated Young's modulus, E^a, was used in the next excavation stage. In the last one, E^a was introduced into initial model before excavation and then excavation analyses were performed again.

It was found that the behavior of the rock could not be predicted correctly under the conditions of this verification problem unless the latest updated E^a is introduced into initial model before excavation and the excavation analyses are redone from this stage.

Key Words: Stacking Sequence Optimization, Ply Drop-off Laminate, Empirical Constraints, Strength

This study addresses the stacking sequence optimization of the tapering laminated composite consisting of 0°, $\pm 45^\circ$ and 90° plies with ply drop-off considering the empirical constraint conditions. The stacking sequence of the thin-side laminate is determined in advance, while for the thick side, only the ply thickness ratio and the surface plies are determined in advance as the reinforcement design conditions. Then, the stacking sequence of the thick side and the order of ply drop-off are designed to maximize the strength in the ply drop-off region under following constraints. All plies of the thin-side laminate should be continued to the thick-side, the cover and the second layers should not be dropped off, and the adjacent plies should not be continuously dropped off. In addition, the allowable number of contiguous plies, the allowable orientation angle difference between neighboring plies are considered as empirical constraints. The optimization problem with these empirical constraints is solved by using genetic algorithm with our proposed genetic operators [1]. The strength criteria is evaluated at the resin pocket by using the FEM model of the tapered three-ply laminates that the middle layer is dropped off [2]. For the efficient optimization procedure, the look-up table for the strength criteria consisting of all possible combinations of the three-ply laminates is prepared in advance from the FEM analysis and just called during the optimization run [3]. Through numerical examples, the optimum designs for some kinds of tapered laminates from 48 to 24-ply tapered laminates under several conditions are evaluated. Then, validity of the proposed optimization method is discussed.

This study is supported by Council for Science Technology and Innovation (CSTI) Cross-ministerial Strategic Innovation Promotion Program (SIP), “Materials Integration” for revolutionary design system of structural materials (Funding agency: JST).

Optimization problems in thermal, structural, electrostatic and other fields governed by Laplace's and/or Poisson's equations are important in various engineering design applications. In particular, level-set based topology optimization is one of the strong approaches for solving the field shape design problems, in which the shape of the material or field is related to a distribution of a scalar function of point called level set function. From the distribution of the level set function, the boundary and the material/field domain are extracted. By updating iteratively the distribution of the level set function that satisfies a reaction-diffusion equation with a source term related to the sensitivity of the objective functional, the optimum arrangement of the material/field is obtained.

In the topology optimization problems governed by Laplace's or Poisson's equations, linear boundary conditions have usually been assumed [1]. However, there exist a class of problems in which nonlinear boundary conditions have to be considered even if the governing equation is linear, such as galvanic corrosion [2] and thermal radiation problems. In this study, we consider a topology optimization using the level-set method for a problem with arbitrary nonlinear boundary conditions. Topological derivative is derived for an objective functional under the nonlinear flux boundary condition. The finite element method software FreeFEM++ is used for calculating the topological derivative values and the numerical scheme of the topology optimization using FreeFEM++ is shown. Some numerical examples are also shown to demonstrate the present formulation.

A thermomagnetic motor[1], [2] can generate torque by changing the magnetic distribution generated by permanent magnets by heating and cooling temperature-sensitive magnetic materials[3]. Therefore, thermomagnetic motors have the potential to extract mechanical energy from hot water below 100 ° C. One of the problems with this motor is that it has not reached the stage of practical use due to its low output[1], [2].

The thermomagnetic motor proposed by the authors[2],[4] is cylindrical. Permanent magnets and yokes are located on the motor's stator, and the rotor is made of a temperature-sensitive magnetic material. Using hot and cold water to heat and cool the area between the rotor and the stator creates a temperature distribution in the temperature-sensitive magnetic material, giving it magnetic saliency. This structure does not have the flux barrier used in standard PM motors. The short circuit of the magnetic flux from the permanent magnets is large, so it is thought that sufficient rotational torque cannot be generated.

In this study, the shape of the stator region around the permanent magnet is optimized to increase the output. As a result of topology optimization, air regions that function as a flux barrier are created around the permanent magnet, and the rotational torque is improved.

Toward Concurrent Multiscale Topology Optimization for High Heat Conductive and Light Weight Structure

Musaddiq Al Ali[1*], Masatoshi Shimoda [1]

[1] Department of Advanced Science and Technology, Toyota Technological Institute, 2-12-1 Hisakata, Tenpaku-ku, Nagoya, Aichi 468-8511, Japan

Key Words: *Concurrent topology optimization, Heat conductvity, homogenization method, periodic microstructure.*

In several disciplines of engineering, high heat conductive solid structures of lightweight solid structures play a significant role. Due to advancements in computer-aided design and quick growth in additive manufacturing, topology optimization uses in designing high heat conductive structures has grown significantly in recent decades and remains a very appealing issue to be tackled. However, achieving optimal high conductive structure with utilizing topology optimization is a challenging task such that, it is quite sensitive to optimization factors such as the searching step and initial conditions. In this work, an investigation of maximizing heat conductivity with minimizing weight is conducted, with adopting heat compliance minimization as the objective function. The optimization first addressed the macro scale point of view of the structure, by investigating the optimization parameter's effect on the performance of the optimized resulted structure. Furthermore, we extended the examination toward multiscale topology optimization to achieve excessive light-weighting of heat-conductive structures. During the concurrent optimization process, the numerical homogenization approach was utilized to compute the effective heat conductivity of the microstructure and concurrently updating the macrostructure system. As a result, the periodic boundary conditions are simulated on a microscale with a dedicated finite element model, while the effective characteristics are implemented on a macroscale. the suggested design methodology of this work in several examples which showed good responses of the microscale design for the macroscale design domain boundaries conditions. This response is shown through the varied designs of multiple examples of different boundary conditions. This research showed that, utilizing weight reduction with considering the total volume reduction on macro and microscale gave better performance compared to limited the weight minimization on the macroscale alone. The volume-to-point approach was successfully expressed for the macroscale design by obtaining the micro channeling of the conductive material for the macro design domain, which is associated with better performance than single microstructure concurrent optimization, according to the studied cases of optimizing multiple micro design domains. This is because the increased freedom of attaining robust design variable distribution on both the microscale and macroscale allows for this.

Unit Cell Design of Fatigue-tolerant Lattice Structures for Bone Implants

Mengna Zheng[1*], Kazem Ghabrail[1], Wei Xu[1] and Yanan Wang[1]

[1] School of Engineering, Deakin University, Geelong, Australia

Key Words: *Lattice Structures, Design, Fatigue-tolerant, Bone implants*

The porous design of bone substitutes not only promotes bone ingrowth but also plays an essential role in facilitating vascularization as well as nutrition and waste transportation [1]. The current designs of lattice structures for bone implants mainly focus on matching the elastic modulus with the natural bone to alleviate stress shielding [2]. However, fatigue failure contributes to most of the structural breakdown even when the structure is subjected to elastic deformation under cyclic loading, which is seldom considered in lattice unit cell design. This paper presents design of fatigue tolerant lattice structures while maintaining sufficient mechanical strength using PolyStress [3]. The optimization problem model is constructed according to the work condition of hip bone implants. The fatigue strength of the design is realised by stress constraints and the elastic modulus is controlled by a stiffness constraint. The unit cell is periodically designed and several boundary conditions are considered. Compared to the traditional CAD and Triple Periodic Minimal Surface (TPMS) design of lattice structures, this newly proposed method provides unit cell topology based on its application requirements, such as the fatigue life which is beneficial to extend bone implants' service life. In addition, introducing topology optimization into the design phase creates lightweight structures and saves materials for manufacturing.

Key Words: topology optimization, level set method, adaptive remeshing

Topology optimization is devoted to the optimal design of structures. It aims at finding the best material distribution inside a working domain while fulfilling mechanical, geometrical and manufacturing specifications. The need for lighter and efficient structural solutions has made topology optimization a vigorous research field in both academic and industrial structural engineering communities. This contribution focuses on PISCO, a Research and Development software platform for shape and topology optimization where the computational process is carried out in a level set framework combined with a body-fitted approach [3]. The level set method relies on the classical sensitivity analysis from the shape optimization framework to compute a descent direction and advect the structural interface. In the present setting the level set method is coupled with a remeshing routine which enables the reconstruction of a body-fitted mesh at each step of the underlying optimization process, as proposed in [1, 2]. Since the structural interface is known explicitely at each step of the iterative procedure, the body-fitted approach simplifies the evaluation of the mechanical quantities of interest. PISCO is composed of several components including an algorithmic toolbox specialized in the treatment of level sets, a generic interface to finite element solvers, a toolbox handling mesh files in several classical formats, several algorithms for the resolution of constrained optimization problems, physical and geometrical optimization criteria and an advanced interface to the remeshing tool mmg3d. The components devoted to the physical analysis computations and the constrained optimization algorithms are implemented in a generic fashion in dedicated modules. The non-intrusiveness of the implementation is proved by the coupling with several external physical solvers. We rely on a gradient-flow numerical optimization algorithm to handle the balancing between the minimization of the objective and the non-violation of the constraints. Several industrial applications are presented to highlight the capabilities of the platform.

Accelerated Projected Gradient Method for Topology Optimization of Heat Conduction Problem

Akatsuki Nishioka* **and Yoshihiro Kanno**

The University of Tokyo

Key Words: Topology optimization, heat conduction problem, optimization algorithm, accelerated gradient method

Topology optimization problems are often large-scale. Therefore, a fast optimization algorithm that can solve a large-scale optimization problem in practical time is demanded. In our study, we extend the accelerated projected gradient method [1], which was originally developed for solving the compliance minimization problem, to the heat conduction problem.

Accelerated gradient methods have been actively studied in the machine learning community in recent years. They are first-order optimization algorithms which only use the first derivatives (gradients) of the objective function, but the convergence rate is improved compared to the conventional gradient descent method. As the iteration cost of first-order methods is very cheap compared to second-order methods (e.g. the sequential quadratic programming), first-order methods are more suited for large-scale optimization problems. Accelerated gradient methods were originally developed for convex optimization. Recently, such acceleration techniques have been extended to nonconvex optimization problems.

As many topology optimization problems are large-scale and nonconvex, accelerated gradient methods can be suitable for topology optimization. In our study, we consider the heat conduction problems with simple linear constraints so that we can use the projected gradient method. The projected gradient method is a classical way to solve a constrained optimization problem, using the projection onto the convex feasible set. We show that, in our problems, the projection onto the feasible set can be easily calculated by a bisection method both for the equality and inequality constraints on the volume. To accelerate the convergence, we use the acceleration technique by Ghadimi and Lan [2] and the heuristic stepsize policy [1] considering properties of topology optimization problems. Moreover, the proposed method is easy to implement. We conduct several numerical experiments to compare the performance of the proposed method with the existing methods (e.g. the optimality criteria method and the method of moving asymptotes). It is demonstrated that the proposed method converges faster, especially when the number of finite elements is large. We also discuss a condition under which the convergence is guaranteed.

Key Words: topology optimization, level set method, adaptive remeshing, anisotropic remeshing

Topology optimization is devoted to the optimal design of structures. It aims at finding the best material distribution inside a working domain in order to satisfy mechanical, geometrical or manufacturing specifications. The need for lighter and efficient structural solutions has made topology optimization a vigorous research field in both academic and industrial structural engineering communities. In the present setting the level set method is coupled with a remeshing routine which enables the reconstruction of a body-fitted mesh at each step of the underlying optimization process, as proposed in [1, 2]. Since the structural interface is known explicitely at each step of the iterative procedure, the body-fitted approach simplifies the evaluation of the mechanical quantities of interest. The body-fitted remeshing strategy proposed in [1, 2] is driven by global user-defined parameters such as the minimal/maximal mesh size or the gradation of the desired mesh. In this contribution we propose to couple the body-fitted approach with adaptative remeshing techniques involving an anisotropic recovery-based a posteriori error analysis. The gradient-recovery Zienkiewicz-Zhu-type error estimator developed in [4, 5] is applied to drive isotropic or anisotropic mesh adaptation at each step of the underlying optimization process. The proposed error estimator is used from one hand to control the accuracy of the discretization of the structural interface, from the other hand to control the discretization error linked to the numerical evaluation of mechanical criteria and sensitivities in order to speed up the overall optimization routine. All the proposed numerical examples are realized using PISCO, a Research and Development software platform for shape and topology optimization in active development at IRT SystemX. We rely on a gradient-flow optimization algorithm designed to decrease both the value of the objective function and the violation of the constraints. Several industrial-related applications are presented to illustrate the capabilities of the proposed method.

Key Words: Topology Optimisation, Variational Auto-Encoder, Data-driven, Model Reduction

In (PDE-constrained) structural optimisations, it is interesting and challenging to take account of "human-oriented design" because an optimisation emphasises to realise a certain functionality rather than design/outlook/form of a target object. In addition, designs made by human would be provided as sketches rather than mathematically-defined geometries, in particular, when the designs are artistic. Then, it is not easy to handle such pictures numerically. To overcome these two difficulties, Guo et al [1] proposed a framework based on Variational Auto-Encoder (VAE). The VAE enables to create an arbitrary dimension of latent variables to change the shape of a target over given designs almost continuously, although the meaning (e.g., length, angle, curvature) of the latent variables are ambiguous. Once latent variables are obtained, one can perform a structural optimisation by using latent variables as design variables in a certain optimisation method. Guo et al [1] applied their data-driven and dimension-reduced framework to a 2D heat conducting design problem with the help of the genetic algorithm.

Following Guo et al. [1], we apply their framework to a minimisation problem of the mean compliance of a 2D linear elastic body as well as a maximisation problem of the sound pressure at an observation point for 2D acoustics. To solve those problems, we first prepare several pixel data and parameterise them by some latent variables. Then, we exploit a gradient-free non-linear optimisation method (such as the COBYLA method) to minimise/maximise the objective function with respect to the latent variables. Regarding the compliance problem, we could obtain the optimised solution, which resembles to given designs. The result of the acoustic problem will be mentioned in our talk.

Key Words: Topology Optimization, Neural Network, Reparameterization, Automatic Differentiation

The rapid development of deep learning has brought new opportunities for the exploration of topology optimization methods. The combination of deep learning and topology optimization has become one of the hottest research fields at the moment. In this work, the neural network is directly used for topology optimization. The update of the design variables (pseudo-density) in the conventional topology optimization method is transformed into the update of the neural network's parameters, which is called *Neural Reparameterization*. The sensitivity analysis in the conventional topology optimization method is realized by the powerful *Automatic Differentiation* technology. We verify the effectiveness of AuTONR on various numerical examples, including the stiffness optimization problems, the stress-constrained problem, structural natural frequency optimization problems, compliant mechanism design problems, heat conduction system design problems. Compared with the existing methods that combine deep learning with topology optimization, AuTONR does not need to construct a dataset in advance and does not suffer from structural disconnection. The structures obtained by AuTONR can be comparable to the conventional methods.

Key Words: Topology optimization, Geometrical shape feature, Thickness

Thickness constraint is quite important for the structural optimization method, especially for topology optimization. Thickness control is needed for many kinds of molding processes, such as injection molding. Many studies have been conducted on the thickness constraint [1], but most of them are based on a distance function or other time-consuming methods. Since the approach using distance function is an indirect way to consider the thickness, these formulations tend to become complex.

We present an approach for the thickness constraint based on the Fictitious Physical Model (FPM). The FPM is introduced to evaluate geometric features as if they were physical phenomena expressed by the partial differential equations. The FPM is formulated as a linear partial differential equation system. The approximated local thickness is defined based on the solution of the PDE. The thickness constraint is formulated using the local thickness, and its design sensitivity can be derived based on the adjoint variable method.

The main advantages of this method are its simplicity of formulation and its computational cost when calculating the thickness. In addition, it can directly evaluate a kind of thickness, and the thickness constraint can be handled much easier than the previous methods. For example, this method may be applied to maintain the thickness constant whole design domain.

In this research, we propose a level set-based topology optimization method for thickness control. First, the definition of the local thickness is explained. Then, numerical examples are given to confirm the validity of the local thickness. Finally, the topology optimization problem with a thickness constraint is formulated and several optimized designs are provided.

Key Words: *Topology Optimization, Composite, Electric Permittivity, RVE method, Deep Learning, Collimator*

Nowadays, composite materials, which is a material that consists of various distinct constituents or phases, play an important role in aerospace and structural engineering applications. As the need for numerical implementation increases in the design of structures made of composite materials, methods for effectively deriving material properties and designing structures have been sought. With respect to these issues, we present the derivation of the effective permittivity of an anisotropic composite material based on a representative volume element method (RVE) [1,2] and machine learning (ML) [3]. After calculating the effective electrical permittivity of the anisotropic composite, ML models based on DNNs with multiple layers are used to build the continuous functions of the effective properties. With the regression function from ML, we can handle the electrical permittivity at each node point. It is noteworthy to reflect the anisotropic composite material easily in the optimization design process. Here, we conduct numerical example about a dielectric collimator design using the ML model to verify the proposed method. The finite element analysis for solving the electromagnetic wave problems in optimization procedure and conducting the RVE method were performed by using the commercial package COMSOL. The ML and the optimization process were programmed using the Matlab programming.

Key Words: *Topology optimization, turbulent flow, compressible fluid, subsonic flow.*

Topology optimization (T.O.) under compressible turbulent flow regime is still an open problem due to CFD challenges related to viscosity variation, shock waves, and compressibility factors that hinder the simulation and its adjoint model hand derivation. One work has been developed at laminar compressible regime [7] but turbulence has been treated only at incompressible flow [2][3][4][6][8]. Therefore, in this work we propose a T.O. formulation for compressible turbulent subsonic flow regime (0.3<Mach<0.7) aiming to minimize the energy dissipation. Also, turbulence is modelled by means of the Favre Averaged Navier-Stokes (FANS) equations and the Spalart-Allmaras turbulence model in a steady-state regime considering ideal-perfect gas model, and isothermal wall boundaries. The adjoint model is obtained with an automatic differentiation tool [5] that avoids hand derivation, and the internal point optimizer (IPOPT) solves the optimization problem. The primal model is solved in a finite volume method (FVM) based-software, and the adjoint model in a finite element method (FEM) based-software, which are linked in the authors' developed platform "FEniCS TopOpt Foam" [1]. Different 2D cases at compressible subsonic turbulent regime are optimized and energy dissipation is compared with baseline designs. The method is robust and flexible, establishing a first step in T.O. of the compressible turbulent regime.

Design of large displacement compliant airfoil through stress constrained topology optimization

Carlos Eduardo de Souza[1], Daniel M. De Leon[2]

[1] Federal University of Santa Maria, carlos.souza@ufsm.br
[2] Federal University of Rio Grande do Sul, daniel.leon@ufrgs.br

Key Words: *Stress-based topology optimization, morphing wings, compliant mechanisms, large displacements*

The present work investigates the design of a flexible mechanism for compliant airfoils by means of topology optimization. Compliant airfoils consists in a form of morphing concept for wings, which have been developed in recent years, aiming to reduce weight and maintenance costs, among other advantages. One way of obtaining the morphing structure is by designing a mechanism that does not have multiple separate parts connected by conventional hinges with bearings. Here, a nonlinear approach for topology optimization is considered, where the displacement of the profile trailing edge is maximized under volume and global stress constraints. The static equilibrium is obtained via a nonlinear finite element approach, with a hyperelastic material model. The method is applied to an asymmetric airfoil, where the area behind the half chord point is the design domain. A concentrated force is applied in the horizontal direction and the vertical displacement of the trailing edge is maximized, with a prescribed volume fraction of the initial design domain. The work investigates different stress limits, as well as the effect of neighbor radius and input forces. Optimized designs are obtained, resulting in efficient single compliant airfoils, respecting given constraints.

Key Words: Multi-scale Topology Optimization, Fast Fourier Transform, Homogenization Method

Thanks to the development of additive manufacturing (AM) technology, it is becoming possible to produce materials with desired mechanical properties defined by their periodic microstructures. To design optimal microstructures, multi-scale topology optimization (MTO) has been paid attention to in many engineering fields.

As an example of MTO, Kato et al. [1] proposed an analytical sensitivity analysis with an adjoint method based on a decoupling scheme [2]. This method with a simple algorithm has reduced computational cost and made MTO more feasible compared with the previous methods. However, compute time and memory requirements are still high, and these prevent practical use such as high-resolution 3D analysis for precision modeling with AM and non-linear analysis assuming actual materials.

In the above method, finite element method (FEM) is used to analyze periodic microstructures, but this research focused on an alternative approach using fast Fourier transform (FFT) by Moulinec and Suquet [3]. This FFT-based homogenization adopts simple point-wise discretization and is known as an efficient method to analyze periodic microstructures. Therefore, the application of this method to the microstructural analysis of MTO can be expected to reduce computational costs.

In this study, as a basic problem, we mainly deal with topology optimization of microstructure for maximizing linear stiffness of macrostructure. First, by comparing obtained topology and objective function values, we demonstrate that the proposed method with FFT can accurately compute and obtain almost the same result as the conventional method with FEM. Then, by measuring relations between mesh resolution and computational cost, we reveal that the proposed method can compute faster with lower memory usage, especially for 3D analysis.

Including Anisotropy of Additively Manufactured Bulk Materials in Topology-Optimized Designs

Key Words: *Topology Optimization, Additive Manufacturing, Anisotropy*

The recent rapid development of Additive Manufacturing (AM) technologies has created a need for new design methods that can leverage the new, increasingly complex fabrication possibilities. Topology optimization is frequently suggested as a powerful design-for-AM approach because it does not require a preconceived notion of the final structural layout. Therefore, the past decade has seen a significant research interest in tailoring topology-optimized design to AM. Examples include the considerations of overhang constraints, infill design and enabling design with multiple base materials. However, the anisotropic bulk material behavior associated an array of AM processes has received less attention. The anisotropy can develop (even when using isotropic base materials) as a consequence of the weak bonds along the print path and layer-by-layer fabrication process. This works seeks to address the anisotropy of bulk AM materials in topology-optimized design in two ways; both globally and locally.

Considering a globally anisotropic bulk material, this work experimentally investigates the effect of assumptions of isotropy versus anisotropy within the design framework. All test specimens are prepared using Fused Filament Fabrication (FFF). Topology-optimized designs are obtained for simply supported beams with a range of different volume fractions. A density-based approach [1] is used and the Method of Moving Asymptotes is taken as the gradient based optimizer [2]. The experimental behavior of the samples with assumptions of isotropy and anisotropy (in different directions) is evaluated and compared.

In addition, this work considers the local anisotropy induced in most material extrusion AM processes. Material extrusion here refers to technologies where a nozzle moves across a 2D slide of the design and deposits material. Based on the previous work by the authors [3], we propose a novel topology optimization algorithm which seeks to capture the local anisotropic behavior by mincing the material deposition process. This is done using modified Discrete Object Projection [4] with two distinct base materials; i) a stiff core, and ii) a more compliant bonding region. The algorithm is demonstrated on benchmark minimum compliance problems.

Key Words: Free material optimization, Heat conduction, Second-order constitutive tensor

Free Material Optimization (FMO) [1] is a structural optimization method that encompasses the design of structural materials in a broad sense, where the elements of the constitutive tensor are the design variables. When restricted to the microstructure composed of isotropic materials, the material properties can be expressed as a set of semi-positive definite symmetric constitutive tensors. This approach has been used to generate tape layup procedures for composite materials and to design local microstructures that achieve the targeted elastic tensor properties [2]. Removing the restriction of symmetry of the constitutive tensor would further extend the design space and improve the theoretical performance limit of devices, but it is not clear whether such materials exist in reality. On the other hand, it has been reported that the symmetry of this constitutive tensor can be apparently broken by combining it with other physical phenomena without closing it to a single physical phenomenon. Such a situation justifies extending the space of the constitutive tensor to an asymmetric domain, but it is necessary to deal with new constraints, such as to what extent the asymmetry should be allowed. In this study, we consider a topology optimization method with asymmetric constitutive tensors as design variables in the case of second-order constitutive tensors using the heat conduction problem as an example. Several numerical experiments will be provided in the presentation to show the validity and the utility of the design of an asymmetric constitution tensor.

Key Words: Topology optimization, Finite volume method, Parallel computing, Unsteady flow

Topology optimization methods have been adopted for not only structural problems but fluid problems in recent years. Although almost all topology optimization methods for fluid problems assume steady-state flows, Deng et al. [1] proposed a topology optimization method for unsteady flow by adding the artificial Darcy frictional force into the incompressible Navier-Stokes equations. The optimization procedure is implemented using the continuous adjoint method and the finite element method. However, the topology optimization of unsteady flows requires a high computational cost because the fine mesh is indispensable, especially for high Reynolds number flow.

Considering the background mentioned above, we propose an unsteady flow topology optimization method using the cell-centered finite volume method with the building-cube method (BCM) [2][3][4], which is suitable for massively parallel computing. In the BCM, the computational domain is divided into cubic regions called cubes. Each cube is divided at equal intervals, the same number of cubes is assigned to each core, and the spatial loop processing is executed for each cube. The sensitivity of the objective function is obtained by continuous sensitivity analysis based on the adjoint variable method for the topology optimization procedure. In the presentation, we will demonstrate several numerical examples to verify the proposed method.

Level set-based topology optimization for sound-absorbing structures including thermal and viscous boundary layer effects

Yuki Noguchi[1*] and Takayuki Yamada[2]

[1] The University of Tokyo, Yayoi 2-11-16, Bunkyo-ku, Tokyo 113-8656, Japan, noguchi@mech.t.u-tokyo.ac.jp
[2] The University of Tokyo, Yayoi 2-11-16, Bunkyo-ku, Tokyo 113-8656, Japan, t.yamada@mech.t.u-tokyo.ac.jp

Key Words: *Acoustics, Boundary layer effects, Sound absorption, Topology optimization*

In this research, we conduct topology optimization for sound-absorbing structures that efficiently absorb noises within a certain frequency range with a consideration of thermal and viscous boundary layer effects.

Acoustic devices that control the behavior of acoustic waves have been widely used in our daily life, represented by noise barriers and music instruments, etc. There have been a variety of acoustic devices over different scales proposed, and miniaturization of them is one of the hot topics in acoustics. Acoustic metamaterial [1] is a typical structure that drastically controls waves with a tiny structure much smaller than the wavelength. The functions of these acoustic devices strongly depend on their structural design, and topology optimization [2] has been introduced for them to achieve the desired performance.

In such a tiny structure, acoustic waves propagating in air-filled channels are affected by the thermal and viscous boundary layers, which are present in the vicinity of the solid surface. The behavior of waves is quite different from that in bulk due to the damping by these layers. Therefore, consideration of these boundary layer effects is essential for the design of acoustic devices that possesses tiny channels.

We propose a level set-based topology optimization method for acoustic devices with air-filled channels with the consideration of thermal and viscous boundary layers and apply the method to the design of sound-absorbing structures.A sequential linearized Navier—Stokes model [3] is introduced to model the boundary layer effects. The design sensitivity is approximately derived based on the concept of the topological derivative. Several numerical examples of sound-absorbing structures are provided using the level set-based topology optimization method and they show the validity and utility of the proposed method.

Key Words: Static Mixer, Level–set Method, Fluid Topology Optimization, Mesh Adaptation, Parallel Computing, FreeFEM-PETSc-Mmg

Static mixers are widely used in chemical industry such as gas mixing, wastewater treatment process and chemical reaction. The major concern of the static mixer from an engineering perspective is to achieve a better mixing efficient under a lower power dissipation. Therefore, we propose a topology optimization(TO) method for static mixer based on level-set method. We use reaction–diffusion equation for updating the level set function which can explicitly describe the boundaries between different material phases. We calculate the two– and three–dimensional test cases. Three remarkable key points are highlighted here: (i) we introduce a body-fitted mesh adaptation technique. The body fitted mesh relies on a third-party package Mmg; (ii) we formulate the optimum design problem for maximization of mixing and use the continuous adjoint method to derive the sensitivity. Moreover, we validate the deduced sensitivity by comparing it with a finite difference results; (iii) FreeFEM is used for finite element analysis and PETSc for parallel computing. Several benchmark numerical examples are presented to support these remarkable features.

Key Words: *Mechanism design, Transformable wheel, Topology optimization, Forward kinematics-based simulation*

A transformable wheel mechanism efficiently moves in a circular state on flat ground and adaptively overcomes obstacles by modifying the shape of the wheel when it encounters various-sized obstacles [1]. So far, the adaptive motion was mainly generated by multi degree-of-freedom (DOF) mechanisms [2]. However, the operating cost of the multi-DOF mechanism is high because of structural complexity and many actuators. To overcome this limitation, we propose designing a 1-DOF wheel mechanism generating adaptive motion. However, it is complicated to identify a climbing strategy based on 1-DOF motion, and it is further challenging to synthesize 1-DOF mechanism that satisfies the target kinematics because there are no mechanism candidates based on the adaptive climbing strategy. Here, we 1) present a forward kinematics-based simulation model to establish adaptive wheel-climbing strategies and 2) propose a topology optimization method for synthesizing mechanisms that generates the target kinematics so that the wheel structure can successfully climb indoor-sized steps. First, a kinematic analysis model was developed to identify the target movement of the end-effector of the wheel to climb obstacles of various heights. Then, we propose a topology optimization-based synthesis method for 1-DOF transformable wheel mechanism to autonomously design the wheel structure. For the synthesis, we employ the topology optimization ground structure model which consists of zero-length springs and rigid blocks, called the JBM (joint-element connection rigid block model) because the model allows us to find an appropriate mechanism without starting with any baseline candidate mechanism [3]. Besides, for reducing complexity, we design the joint composition of the planar linkage mechanism by taking advantage of springs and blocks-based ground structure model. By using the developed method, novel transformable wheel mechanisms were successfully synthesized, and the kinematic and configuration characteristics of the designed mechanisms were investigated.

Multi–material topology optimization of an eigenfrequency problem

Nari Nakayama[1*], Hao Li[1], Pierre Jolivet[2], Kozo Furuta[1], Shinji Nishiwaki[1], Kazuhiro Izui[1]

[1] Kyoto University, Kyoto 615-8540, Japan, E-mail: nakayama.nari.42z@st.kyoto-u.ac.jp
[2] Institut de Recherche en Informatique de Toulouse, Toulouse 31062, France,

Key Words: Multi–material Level–set Method, Eigenfrequency Topology Optimization, Parallel Computing, Mesh Adaptation

We propose a novel framework for the multi–material topology optimization (MMTO) of an eigenfrequency problem. From the theoretical perspective, two key ingredients are highlighted: (i) multi–material level set (MMLS) method is constructed. With this method, the interfaces between different material phases are represented by the iso-surfaces of multiple level set functions. Hence, the optimal solutions have binary structure and they are free from greyscale elements; (ii) The proposed design methodology uses a reaction-diffusion equation (RDE) for updating the level–set functions based on the topological derivative, making it possible to nucleate new holes during optimization process. From a numerical standpoint, our framework uses FreeFEM for finite element analysis (FEA) and PETSc for distributed linear algebra. Efficient preconditioner techniques enable us to solve the large-scale finite element systems. The performance of our methodology is demonstrated by showcasing two– and three–dimensional benchmark test cases.

Multiscale Topology Optimization of Buckling-resistant Structures

Federico Ferrari [1*] and Ole Sigmund [2]

feferr@mek.dtu.dk
[2] Technical University of Denmark, Nils Koppels Allé 404, 2400 Lyngby, DK

Key Words: *Multiscale design, Inverse homogenization, Buckling design, Stress analysis*

Multi-scale structures, achieving extreme and tuneable performances while being lightweight, are gaining increasingly more interest. For example, lattice materials and infilled structures have already proven to be more competitive than classical, single-scale, composites for some automotive and aerospace applications. On the other hand, the multiscale idea has recently gained popularity as a computational tool speeding up structural topology optimization. Stiffness optimized designs consisting of millions of design variables have been obtained at a remarkably low computational cost, by coupling traditional homogenization-based topology optimization with a de-homogenization step interpreting the optimized set of material properties with a single-scale structure [1].

Extending this method to the design of buckling resistant structures is the topic of this work. To do this, difficulties arising when including buckling in the analysis and design of multiscale structures must be overcome. First, analytical solutions and theoretical bounds are not known for the buckling response, and the optimized unit cells must be found numerically. Second, such unit cells show a high dependence on the stress state, making very complicate to achieve a stable design under multiple load conditions [2]. Finally, the de-homogenization is made challenging by the presence of many simultaneous, local buckling modes [3] and stress concentrations, potentially disrupting the performance of the infill.

A thorough analysis of the origins and effects of these issues is given, possible remedies are discussed, and multiscale designs optimized for extreme buckling resistance are shown.

Key Words: *Topology optimization of linkage mechanism, Knee exoskeleton, Self-alignment*

Knee joint exoskeletons play a critical role in assisting the movement of disabled and non-disabled humans. These wearable knee exoskeletons should generate sophisticated movement due to rather complicated knee joint motions and also interact safely with their wearers. Therefore, the designed knee exoskeletons should be adaptive to make them universally useful for humans of different body shapes [1]. Lightweight and cost-effectiveness are also other design considerations for the knee exoskeletons. However, because of several design requirements to consider, it is difficult or sometimes impossible to devise such knee exoskeletons even with many trials and errors. To overcome these difficulties, we present a novel design method to synthesize self-aligning and actuation-efficient knee exoskeleton mechanisms without any baseline design, a method similar to the structural topology optimization method.

The knee exoskeleton mechanism to be designed here is not just supposed to follow a specific path but to generate a desired knee instant center of rotation workspace. Furthermore, it should possess self-aligning capability by which undesirable force should not be applied to the human joint and also possibly yield the desired profile of mechanical advantage during gait motion. Here, we employ the ground model applied to the mechanism topology optimization method [2-3], which can represent any two-dimensional linkage mechanism possibly consisting of rigid links and revolute and prismatic joints. Moreover, we develop a new optimization-based formulation to achieve our design objectives. A few numerical results that validate our approach will be presented, along with a fabricated 3D-printed mock-up. Finally, the simulated actuation torque-speed curve using the designed exoskeleton confirms that the synthesized mechanism is safe and comfortable to wear and requires relatively low-powered actuation.

Key Words: *Underactuated Linkage Mechanism, Spring-linkage mechanism, Adaptive Mechanism, Path Generation Synthesis Problem, Automation Mechanism Synthesis Method.*

For a mechanism to be adaptive in a two-dimensional plane, it must have more than one-degree-of-freedom (DOF). For example, a 1-DOF fully actuated mechanism having a single actuator can only follow a specific path. On the other hand, a single actuator-driven 1-DOF underactuated spring-linkage mechanism can adaptively follow a target path blocked by an obstacle via the deformations of spring elements [1, 2]. The simultaneous use of deformable spring elements and rigid links embodies the adaptability of an underactuated mechanism operating in a two-dimensional plane. The working principle of the underactuated spring-linkage mechanism is as follows; a 1-DOF underactuated spring-linkage mechanism can generate a specific path that minimizes the entire mechanism spring energy if no obstacle is present while it can go through significant elastic deformations to overcome an obstacle if there is any. The question is how to configure spring elements for a selected baseline rigid-link mechanism and determine their specific dimensions. Because one cannot pre-determine the number of spring elements to be used, it is inefficient and cumbersome to repeat many dimensional syntheses of spring elements by trying different numbers and configurations of spring elements. To be able to perform a streamlined synthesis of spring elements without many trials and errors, we propose a new optimization-based synthesis method, similar to the mechanism topology optimization [3, 4]. While earlier studies [3, 4] considered the synthesis of a rigid-link mechanism (without spring elements) only, our approach synthesizes spring configurations in an underactuated spring-linkage mechanism. In this respect, this work has newly performed the synthesis of spring configurations in underactuated spring-linkage mechanisms. The details of the proposed method, from formulation, analysis, to optimization, will be presented here. We will also show some numerical examples, such as the design of adaptive gait mechanisms and grippers, to demonstrate the validity and effectiveness of the proposed optimization-based synthesis method.

Key Words: Maximum entropy meshless method, proportional topology optimisation, minimum compliance, stress constrained

In this paper proportional topology optimisation (PTO) with maximum entropy (maxent)-based meshless method is presented for two-dimensional linear elastic structures for both minimum compliance (PTOc) and stress constraint (PTOs) problems. The computation of maxent basis functions are efficient as compared to the standard moving least square (MLS) and possess a weak Kronecker delta properties leading to straightforward imposition of Dirichlet boundary conditions [1, 2, 3]. The PTO is a simple, non-gradient, accurate and efficient method compared to the standard topology optimisation methods [4]. A detailed and efficient implementation of the computational algorithms for both PTOc and PTOs are presented. The maxent basis functions are calculated only once at the start of simulation and used in each optimisation iteration. Young's modulus for each background cells is calculated using the modified solid isotropic material with penalisation (SIMP) method. A parametric study is also conducted on the degree of proportionality and history dependence of both PTOc and PTOs algorithms. A variety of numerical examples with simple and complex geometries, and structured and unstructured discretisations are presented to show the accuracy, efficiency and robustness of the developed computational algorithms. Both PTOc and PTOs algorithms can handle large topological changes and provide excellent optimisation convergence characteristics.

Key Words: Topology optimization, 2D swirl flow, Rotor-stator design, Discrete design variables, Integer linear programming

The fluid flow in rotating machinery is determined by the interaction between the working fluid, the rotating, and the stationary structural parts of the machines. Thus, the simultaneous design and optimization of rotating and stationary parts require modelling solid at different rotations. However, the standard fluid flow topology optimization method considers only a single stationary solid [1] or a single rotating solid [2]. Hence, this work presents a topology optimization formulation capable of optimizing structural parts at different rotations. Two mutually exclusive Darcy terms are added to the Navier-Stokes equations, with each Darcy term modelling a different rotation. The method employs two discrete design variable fields and considers three element phases: fluid, stator, and rotor. The fourth phase provided by the combination of the two discrete design variables is avoided by properly selecting the moving limits of the optimization algorithm. The optimization problem is solved by a TOBS-based approach [3]. The algorithm is applied to the design of radial and radial-axial machines. The fluid flow equations are solved by the Finite Element Method (FEM) and the sensitivity analysis follows the discrete adjoint approach.

E-mail: furuta.kozo.5n@kyoto-u.ac.jp

Key Words: *Allen-Cahn equation, Phase Field Method, Shape Optimization, Topology Optimization*

We introduce a new structural optimization method, which realize sequential topology and shape optimization, based on the Allen-Cahn equation with new expressions for double-well potential and source terms.
Takezawa et al. established a shape and topology optimization method with the phase-field method[1]. This method enables us to get an optimized shape which has clear boundary like the one obtained by the level-set method[2][3]. Also, this method doesn't require re-initialization, so the calculation is simply and easily achieved. On the other hand, it is well known that this method does not allow us to make a new hole during the optimization procedures. Here, we define two time-dependent evolutional equations; one is for the topology optimization, and the other is for the shape optimization. We firstly obtain an optimized configuration by the topology optimization, which allows us to generate holes, then we polish the first-step optimized configuration by the shape optimization. We verified the validity of our method through the several numerical examples.

Key Words: *Topology optimization, Thermal conduction, Functionally graded structure, Representative volume element, Machine learning*

This study presents a new design method for thermal conductors with functionally graded composite structures, which simultaneously optimizes the overall topological layout and the local fibrous material for high thermal conductivity. Periodic boundary conditions are imposed to unit structures configured with the design variables in the feasible set, and the corresponding anisotropic effective material properties of the composite unit microstructure can be obtained by the representative volume element (RVE) method. In addition, the machine learning method of neural network fitting is applied to discretized RVE data to build a design module to derive effective material properties according to the shape change of the unit structures [1]. In this study, with the objective function of minimizing the dissipation of heat transport potential capacity (or thermal compliance) and the multiple volume fraction constraints for each material type constituting the composite structure, thermal conduction optimization problems are formulated under various dimensions of the design domain and thermal boundary conditions. Numerical examples are introduced to verify the proposed method. Finally, the projection method is applied to the obtained topology optimization results, which converts the complex micro-scale structures to a manufacturable level [2].

Topology optimization for mass minimization design of multi-material structures using *p*-norm function

Sunghoon Lim[1*], Kozo Furuta[1], Kazuhiro Izui[1] and Shinji Nishiwaki[1]

[1] Department of Mechanical Engineering and Science, Kyoto University, Kyotodaigaku-katsura, Nishikyo-ku, Kyoto 615-8540, Japan, lim.sunghoon.7w@kyoto-u.ac.jp

Key Words: *Level Set Method, Multi-Material Topology Optimization, P-norm Function*

Since the total mass of a multi-material structure is determined by the various composition ratios of each material, the mass minimization of the structure is basically a multi-objective optimization and, hence, it is not easy to obtain a single optimized solution. In particular, when multi-material topology optimization [1] that can derive a detailed distribution of each material within the design domain is performed, a designer can drive one meaningful optimized shape of the structure, however there can always be a better optimal solution with different material volume ratios. Although the multi-objective optimization methods are a great help in examining various design candidates of multi-material structures in this situation, they are still difficult to use, requiring a lot of parameter study and computation time for non-experienced engineers.

Thus, in this study, an efficient design method based on topology optimization that can easily examine various optimized shapes of multi-material structure for mass minimization. The optimization problem is formulated using a *p*-norm type objective function [2] that can give weighting factor to each material's mass rather than the actual mass of the structure. Since the ratio of each material to the total mass of the structure can be adjusted according to the value of the penalty factor of the *p*-norm function, it is possible to easily obtain various types of mass reduction designs that satisfy the target mechanical stiffness set as the design constraint and compare them with each other. Several 3D design examples were performed to confirm the usefulness of the proposed method and the effect of the penalty factor value on the optimized results. Since the composition ratio of each material consisting the entire structure can be controlled only by the value of the penalty factor and a consistent design direction can be confirmed, this study suggests an appropriate range of *p* values that designers can use.

KEY WORDS: *Topology optimization, fracture resistance, phase filed model, reaction-diffusion equation*

Cracking is one of the most common failure modes and should be addressed since it could drastically decrease structural integrity and might lead to a serious incident. Therefore, enhancing the fracture toughness or structural persistence is of great importance in the engineering field. To maximize the fracture resistance of structures subjected to damage due to cracks, topology optimization considering crack propagation is one of the promising approaches.

Topology optimization for maximizing the fracture resistance of quasi-brittle composites is originally proposed by Xia et al [1] by combining the phase-field crack model and a gradient-based BESO optimization method and followed by Wu et al [2] who utilize a novel topological derivative in the level-set approach and adopted a reaction-diffusion equation to update the level-set function. We also explore the same objective with the latter approach but take the topological sensitivity to search for optimal topologies. Specifically, we derive the topological sensitivity to perform topology optimization for maximizing fracture resistance by combining the phase field fracture model and level-set approach with a reaction-diffusion equation. The effectiveness of the proposed updating process of the level-set function is investigated through several benchmark tests. In particular, the improvement of fracture resistance, number of design iterations, dependency of initial design are the objects of our interest.

Key Words: *Stress-based topology optimization, discrete variables, TOBS, geometry trimming*

Nowadays, stress-based topology optimization problems are well-known, but they are still a standing challenge. For continuum problems, there are three main issues to be overcome: the high nonlinearity relation between design variables and the stress values; the local nature of stress; and the singularity phenomenon. When considering discrete variables, the singularity problem is naturally avoided [1]. Thus, this work proposes a new approach to handle stress-based topology optimization problems by using the TOBS (Topology Optimization of Binary Structures) method [2] and geometry trimming (GT). The TOBS method is an optimization algorithm to update the design variables as binary values (0 or 1) by considering the linearization of the objective and constraint functions, and the subproblems created are solved using integer linear programming. GT is a technique to remove void regions of the domain so that the finite element analysis is performed only at the solid domain. Since TOBS gives clear 0-1 solution, the solid-void interfaces are easily identified. Then the jagged contours are smoothed, and a new domain is created. Because of the GT technique, re-meshing is necessary at each iteration. To avoid the discontinuity of the moving domain through the iterations, we propose to define two domains. The first one, called optimization domain, is fixed, and meshed only in the beginning of the optimization process. In the optimization domain the design variables are defined, and the mass constraint and its sensitivity are calculated. The second domain, called analysis domain, is the trimmed structure that needs to be re-meshed every iteration. It is where the finite element analysis, objective function, and its sensitivity are calculated. The TO procedure is performed in the optimization domain. Thus, the objective function sensitivity must be interpolated from the analysis domain to the optimization domain only where the design variables indicate solid regions. To avoid numerical instabilities, a spatial filtering technique is applied. The filter is also useful to extrapolate the objective sensitivities to void regions near the solid domain. This allows void elements to return to solid phase when necessary. This method is entirely implemented in Matlab and uses the LiveLink script of COMSOL only to generate the trimmed domain and mesh it. Numerical examples are presented to demonstrate the proposed method.

Key Words: *Topology Optimization, Fiber Path Design, CFRP Materials, Level Set Method*

The structural topology and fiber orientation play a very important role in the performance of carbon fiber reinforced plastic (CFRP) structures [1,2]. This study proposes a topology optimization approach for design of CFRP structures with continuously variable stiffness by using the level set method. The radial basis functions (RBFs) are employed to construct the level set function (LSF). In this way, the LSF can be formulated in a parameterized form. Fiber orientations are determined according to the LSF values at the nodes within elements [3]. The path of zero level set is extrapolated to other elements, and the fast marching method is employed as a re-initialization scheme in the optimization process to maintain the fiber paths.

In this study, two different design schemes are developed to conduct optimization of CFRP structures. One is the separate design scheme, in which conventional topology optimization with the level set method is first carried out with isotropic materials to determine clear structural boundaries. Then fiber path optimization can be performed based on the fixed topological boundaries defined by the RBF level set function. The second scheme is to carry out a parallel optimization of both structural topology and fiber paths, allowing to capture how fiber path affects structural topological boundaries.

Three illustrative examples are presented in this study to demonstrate the effectiveness of the proposed optimization method. Results indicate that optimized structures using the parallel optimization scheme offer better performances than the separate optimization scheme to a different extent, which implies that there may be considerable limits in the design space with the separate optimization scheme. The superiority of this study is that structural topology optimization and fiber path optimization are taken into account simultaneously. Besides, due to the inherent advantages of the level set method, when using advanced manufacturing techniques such as 3D printing, the fiber nozzle could move along the optimized fiber paths, and design of fiber nozzle route is no longer necessary compared with element-based fiber orientation design.

Key Words: Topology Optimization, Fluid-structure Interaction, 2D Swirl Flow, Turbulent Flow, TOBS Method, Integer Linear Programming

Design optimization of rotating structural parts, such as in turbomachinery, requires the solution of the Navier-Stokes equations that can include complex effects such as swirl flow, turbulence and fluid-solid equilibrium. While these physics have been employed successfully in the context of parametric and shape optimization, they represent considerable challenges for topology optimization. These challenges include the accurate modelling of fluid-solid walls, imposition of coupling conditions and convergence of the fluid-structure interaction (FSI) equations during optimization. This work employs a TOBS-based approach [1] that consistently produces well defined and smooth fluid-solid walls, an important step to add up extra physics or equations in the simulation during optimization. The structural compliance minimization problem subject to volume constraints is solved. The FSI problem is solved via the Finite Element Method considering axisymmetry. Rotational forces are imposed on the structural domain in the radial direction. The 2D swirl flow is governed by the Reynolds-Averaged Navier-Stokes (RANS) equations including a rotating wall in the shaft. The $k-\omega$ turbulence model is employed. Automatic differentiation is employed to compute the required sensitivities. A material model is included in the swirl flow terms to account for the sensitivities of the swirl flow loads on the structure. The optimization problem is solved by using Sequential Integer Linear Programming. Since solving a 3D-FSI topology optimization problem is computationally costly, the development of 2D swirl flow frameworks is of high interest. Results show that the proposed method can effectively achieve optimized designs of rotating structural parts under FSI loads.

Key Words: Topology optimization, BESO, Multiphysics Problems, Poroelastic materials

Multilayered structures for sound attenuation have been explored in many scenarios, ranging from civil construction to automotive and aerospace industries. However, the proper multiphysics interactions comprised by acoustic-poroelastic-elastic structures are still challenging, especially when topology optimization techniques are involved. This work entails a new topology optimization methodology based on the Bi-directional Evolutionary Structural Optimization (BESO) approach to design bidimensional multilayered structures for sound absorption enhancements. The full modeling of poroelastic bodies is done by the mixed **u**/p technique, while the elastic and acoustic (air) materials are obtained by the degeneration of the latter, leading to the well-known elasto-dynamic and Helmholtz formulations, respectively. Such procedure is done in a systematic manner by the combination of the Finite Element Method (FEM) with the Unified Multi-Phase (UMP) modeling method, which in turn contributes to the development of material interpolation schemes suited for the application. In this scenario, the topology optimization problem is established as the maximization of the sound absorption coefficient, as composed by the summation of the time-averaged power dissipated through structural damping together with its corresponding viscous and thermal dissipative components. The numerical examples show the effectiveness of the proposed methodology, since it provides well-defined topologies with generally enhanced sound attenuation performances.

Topology optimization of rotational turbulent flow utilizing TOBS with geometry trimming method

Shahin Ranjbarzadeh[1*], Anderson Soares da Costa Azevedo[1], Eduardo Moscatelli[1], Renato Picelli[1], Julio Romano Meneghini[1] and Emilio Carlos Nelli Silva[1]

*E-mail: ranjbarzadeh@usp.br

Key Words: *Topology Optimization, Swirl, Turbulent Flow, TOBS-GT*

Topology optimization (TO) of highly turbulent Flow is a challenge design problem specially when considering a rotational flow (swirl) around a shaft. This phenomenon has a wide range of applications in design of high-performance turbomachinery device such as compressors, mixers, turbines, and labyrinth seals. In the last decade, the improvement of fluidic device design has attracted significant attention and topology optimization is a feasible approach to achieve the best design for such a device. Here, we present a topology optimization method based on binary variables with geometry trimming (TOBS-GT) which considers the wall function to solve this problem. Thus, the method is implemented in COMSOL Multiphysics utilizing Reynolds Average Navier-Stokes (RANS) equation with k-ε and k-ω formulations for high Reynolds number considering a flow rotation around the shaft. The sensitivity analysis is calculated by using automatic differentiation. Topology optimization problem is solved using Integer Linear Programming (ILP). For each step, geometry trimming creates a CAD model with smooth wall for fluid region. Numerical examples from the literature are solved considering minimization of turbulent dissipation energy as objective function or in some cases maximization of turbulent dissipation energy and vorticity. Critical parameters such as Reynolds number at the inlet, shaft radius, objective function and rotation speed are investigated. The results indicate that rotation has a significant effect on the design of the fluidic device with rotational flow.

Topology Optimization of structures reinforced with fiber considering stress constraint

Andre Luis Ferreira da Silva*, Ruben Andres Salas and Emilio Carlos Nelli Silva

Department of Mechatronics an Mechanical System Enginnering, Politechnique School of University of São Paulo, Avenida Professor Mello de Morais, 2231, 05508-030, andre_fersi@usp.br

Key Words: Topology Optimization, Stress Constraint, Fiber Orientation

Several areas of Engineering, as aerospace and marine applications [1, 2], electronic industry [3], and civil engineering [4] are increasing the use of fiber-reinforced structures. In most cases, the main reason is their high strength-to-weight ratio and excellent fatigue resistance [5]. However, this is not the only reason. For the case of the concrete, the fiber-reinforced allows the creation of high-performance materials, and it is possible to project structures with non-conventional topologies using them. In the previous examples, the structures are composed of fiber and a material denominated matrix, where the reinforcement is placed. Besides, the structure's properties depend on how the fibers are oriented inside the matrix. For this reason, several works are proposed in the literature to determine the optimized fiber orientation. However, to consider the fiber orientation directly as a design variable can lead to a multiple local minima problem [6]. Particularly, there is one approach that avoids these problem considering candidate discrete angles to solve the optimization problem. This approach is implemented to solve linear and non-linear structural problems [6, 7, 8, 9, 10, 11]. Another approach is used to solve problems considering piezo composite materials, where sine and cosine function are approximated by Taylor series [12, 13]. However, a topic of research scarcely explored is the inclusion of stress constraint models in the topology optimization of composites materials [14]. In this work, the authors propose to solve the structural Topology Optimization problem considering local stress constraints for fiber-reinforced materials. The penalization for both material interpolation models is calculated automatically by including them as a design variable together with the pseudo-density. The grayscale issue is treated using the Guest projection with a proposed function to control the continuation on β variable. A benchmark example is solved to show the effectiveness of the method.

Topology optimization of subsonic compressible flow using the TOBS-GT method

Felipe Silva Maffei[1*], Luís F. N. Sá[1], Renato Picelli[1], Shahin Ranjbarzadeh[1], Julio Romano Meneghini[1] and Emílio Carlos Nelli Silva[1]

[1] Polytechnic School of the University of São Paulo, São Paulo, Brazil, maffei@usp.br

Key Words: Compressible flow, Subsonic, Topology optimization, TOBS-GT

Incompressible fluid flow includes a vast quantity of optimization engineering problems. However, depending on the flow characteristics, the compressibility of the fluid starts to be no longer negligible and the flow becomes compressible. Currently, the fields of energy generation and gas leakage control (where the flows are intrinsic compressible) have been receiving special attention in order to mitigate the greenhouse gases emissions and, consequently, climate change. To the best of the authors' knowledge, the work of [1] was the first to apply the topology optimization (TO) in laminar and compressible flows a density-based approach. Density-based models have been successfully applied to many fluid flow problems over the years. Nonetheless, the approach presents some well-known drawbacks. First, First, the optimization parameters have a high impact on the final result being often determined by a cumbersome trial and error process. Second, the presence of elements with intermediate pseudo-densities values, which may lead to artificial physics simulation. Recently, an alternative approach called Topology Optimization of Binary Structures with Geometry Trimming (TOBS-GT) was proposed by [2], aiming to reduce the influence of the optimization parameters and the appearance of gray regions. The TOBS-GT method consistently produces a clear interface between fluid and solid by trimming the solid regions from the design domain. This work expands the application of the TOBS-GT method to subsonic compressible flow problems under a low Reynolds regime. The objective function considered is the minimization of entropy generation. Three cases are evaluated, a traditional double pipe, a pipe bend, and a diffuser.

Key Words: Level–set Method, Fluid Topology Optimization, Parallel Computing, Mesh Adaptation, FreeFEM-PETSc-Mmg

We propose a novel framework for the two- and three-dimensional topology optimization (TO) of a thermal fluid–structure system. The proposed design methodology uses a reaction-diffusion equation (RDE) for updating the level-set function based on the topological sensitivity. From the numerical point of view, two key ingredients are highlighted: (i) two different types of dynamic sparse grids (adaptive mesh) are used. More accurately speaking, body-fitted mesh allows the disjoint–reunion of a global mesh whose interfaces can be described by an implicitly defined surface (zero level-set). Anisotropic mesh adaptation is highly scalable with respect to the problem size, therefore can accelerate the overall computation; (ii) our framework uses FreeFEM for finite element analysis (FEA) and PETSc for distributed linear algebra. Efficient preconditioner techniques are utilized to solve the large-scale finite element systems. From an engineering standpoint, we construct a complete product development workflow including the preprocessing, TO, B-Rep conversion, and the numerical experiment. The performance of our methodology is demonstrated by solving a variety of optimization problems: mean compliance, minimal power dissipation, dry-/wet-fluid–structure interaction (FSI), natural convection, lift–drag, and fluid-to-fluid heat exchange. For comparison and for assessing our various techniques, we benchmark our designs against state-of-the-art works.

Topology Optimization of Thin-Walled Structures with Body Conformal Adaptive Meshing

Hiroki Kobayashi[1*], Yuqing Zhou[2] and Tsuyoshi Nomura[1]

[1] Toyota Central R&D Labs., Inc., Nagakute-shi, Aichi, Japan, hiroki.kobayashi@mosk.tytlabs.co.jp

Key Words: topology optimization, adaptive mesh, level-set method, length scale constraint

Thin-walled structures are widely seen in industrial systems. A computational synthesis to design such structures are demanded. This study proposes a high-precision topology optimization method for 3D thin-walled structures. Topology optimization generally uses a fixed mesh for the structural analysis model. Therefore, the interface representation between voids and materials is less accurate than surface-represented models due to staircase approximation or grayscale band of the interface. This accuracy issue may be acceptable if the designed structure is thick, i.e., the ratio of surface to volume is small. However, this discrepancy becomes nonnegligible when designing thin-walled structures due to the increased surface area to the volume. To overcome this issue, we incorporate an adaptive meshing scheme to eliminate the staircase approximation and grayscale band by meshing conforming to the solid/void interface.

The proposed method comprises a length scale constraint for uniform thickness and an adaptive meshing scheme. The uniform thickness is achieved by the minimum and maximum feature size constraints using Helmholtz partial differential equations[1]. For the adaptive meshing, we use MMG[2] for the implicit domain meshing, which can generate a conformal mesh separated by the level-set surface. By enhancing the binarization of the design variables on the conformal mesh, the performance analysis in the optimization process can be conducted accurately.

Numerical examples are provided to demonstrate the performance of the proposed method, including the accuracy improvement for the analysis compared to the conventional fixed meshes.

Total Traction Equilibrium in Fluid-Structure Interactions with Porous Media

Mohamed Abdelhamid[1*] **and Aleksander Czekanski**[2]

[1] Department of Mechanical Engineering, York University, 4700 Keele St., Toronto M3J 1P3, Ontario, Canada, mahamid@yorku.ca

[2] Department of Mechanical Engineering, York University, 4700 Keele St., Toronto M3J 1P3, Ontario, Canada, alex.czekanski@lassonde.yorku.ca

Key Words: topology optimization, fluid-structure interactions, traction equilibrium

Fluid-structure interactions refer to problems where a deformable or a movable structure interacts with a flowing or a stationary fluid. A large body of research work has been dedicated to the numerical analysis of these interactions [1], and most multiphysics simulation packages - commercial and open source - include some degree of capability for solving these problems. However, the application of numerical design tools such as topology optimization to these problems is still lagging behind. This is mainly due to the multidisciplinary nature of the combined topology optimization of fluid-structure interactions problem and its strong nonlinear behavior resulting in numerous stability and convergence issues.

Since the first appearance of density-based topology optimization methods in the late 1980s, topology optimization has been extended to a huge range of single and multiphysics systems. In fluid flow, porous media is introduced along with some sort of penalization (typically Brinkman) to push the solution towards a 0/1 discrete state. The first appearance of high-fidelity *wet* topology optimization of fluid-structure interactions was in [2]. The fluid and solid computational domains overlapped such that the whole design domain - including the fluid-structure interface - could be optimized, hence the term *wet* topology optimization. In [2], the author extended the fluid-solid force coupling to the entire fluid domain including porous elements but only considered the hydrostatic component of the fluid stress tensor. The divergence theorem was utilized to transfer the integral from surface to volume. This step has a serious implication on the accuracy of the force coupling.

The novelty in this work can be summarized in two points: **(i)** we derived the traction equilibrium condition using the *total* stress tensor such that viscous forces are also considered, and **(ii)** we demonstrated the effect of the existence of sharp gradients in the fluid flow on the accuracy of the traction equilibrium condition.

Key Words: *Negative Poisson's ration, Metamaterial, Topology optimization, The further development of ABAQUS*

Since the concept of metamaterials was proposed in the early 21st century, after more than 20 years of development, it has gradually become an important branch of new material technology. With its excellent performance far exceeding natural materials and its designable and tunable characteristics, the arbitrary negative Poisson's ratio metamaterial has important research value and broad application prospects. In this paper, based on the topology optimization method, mechanical metamaterials of the arbitrary negative Poisson's ratio metamaterial are studied, and a novel programmable and tunable functional element design method with arbitrary negative Poisson's ratio metamaterials and structures is proposed. Its design idea combines optimization algorithms with human adjustments. When constructing a negative Poisson's ratio structural topology optimization model, directly constructing the objective function with the mathematical expression of negative Poisson's ratio will make the objective function highly nonlinear and make it difficult to analyze the sensitivity of the iterative process. Therefore, in this paper, the linear fitting method is used to construct a negative Poisson's ratio microstructure topology optimization objective function with linear characteristics. Based on the energy method and the homogenization method, a topology optimization that can quickly and accurately solve the negative Poisson's ratio is constructed. Based on the optimization model, a topological configuration and corresponding negative Poisson's ratio are obtained. Then, by introducing artificial design and using Python language, parametric modeling, GUI interface development, and calculation scripts for thermal stress homogenization methods for various element types were completed in turn on the ABAQUS platform. It not only realizes the function of quickly establishing a custom unit cell only by inputting a few parameters, but also deduces the unit cell structure under the specified Poisson's ratio, so as to realize the precise control of the Poisson's ratio of the unit cell, and truly realize the negative Programmability of Poisson's ratio metamaterial structures and tunable properties. The method in this paper not only avoids the highly nonlinear problem that occurs when the negative Poisson's ratio expression is used as the optimization function, but also reduces the complexity of the solution, providing a reference method for the design of negative Poisson's ratio microstructures.

Key Words: *Topology Optimization, Optimality Criteria Method, Density Method*

In recent years, design and production technologies have been growing rapidly in the automotive and electrical industries. Accordingly, numerical analysis has become very important. Numerical analysis requires various parameter settings. However, it should be noted that the results may vary depending on the parameter settings. The same can be said for the topology optimization, which is also attracting attention in the manufacturing industries. In this study, we focus on the update equation in the density-based topology optimization. In the topology optimizations based on the homogenization method and density method, the optimality criteria (OC) method[1] is employed as the update method. However, the conventional OC method requires the setting of several arbitrary parameters such as the move limit, which is a parameter to ensure stable updates, and weighting factor, which is a parameter for update speed. The results in Figures 1 to 3 are for the case when the move limit is not set and the penalization parameter is set to 6.0. When the modified OC method[2] is employed, the performance function does not increase as sharply as when the OC method is employed. Also, the weighting factor setting mentioned above is not necessary. In order to compare the OC method and modified OC method, the results for different parameter settings will also be presented.

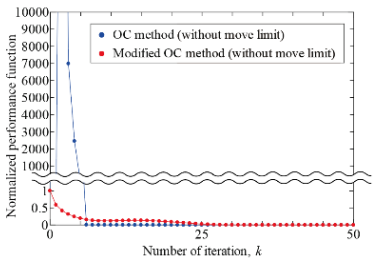

Fig. 1 History of normalized performance function.

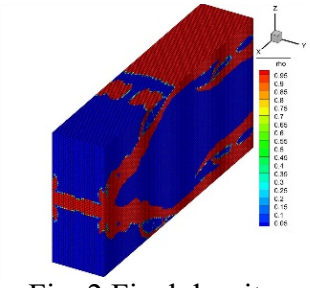

Fig. 2 Final density distribution when using the OC method.

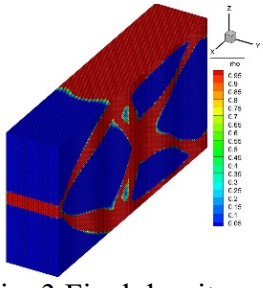

Fig. 3 Final density distribution when using the modified OC method.

Key Words: high integration; multifunction; composite materials; structural optimization

With the increasingly prominent contradiction between traditional aircraft and complex flight environment, the structure design has become more and more challenging. The integrating aircraft structure with different functional components such as flexible cables can improve the performance of the aircraft[1], which can make full use of the aircraft structure to quickly adapt to multiple missions in complex environment[2]. Integrated with different functional components, the multi-functional composite materials can have multiple functions such as support, protection, power distribution, data transmission and so on. At the same time, it can solve problems such as the difficult routing and the redundant size of cables in aircraft[3]. However, the embedded cables bring great challenges to the design and processing of composite materials. Structural design optimization of the carbon fiber composite material with embedded cables is realized in this paper by using co-simulation of ABAQUS and Python. Influence of component parameters on the mechanical properties of the composite material with embedded cables is further analyzed. According to the different load-bearing capacity in different areas of the composite material structure, topology optimization design under the constraint of embedded cables is considered, and the optimization of the layup angles of the composite material sub-area based on the multi-island genetic algorithm is further completed. The influence of the position of cables, the diameter of cables, and the distance between cables on the maximum bending stress of composite material structure is analyzed separately. Results of the research provide a certain theoretical basis for the design of composite materials with embedded cables, which can reduce the weight and cost of the aircraft structure.

Key Words: *Topology optimization, Flexoelectricity, Moving Morphable Void(MMV), Isogeometric analysis(IGA), Trimmed surface analysis(TSA)*

Flexoelectricity is the coupling between polarization and strain gradient. As the large strain gradient leads to a strong flexoelectric effect, the design of flexoelectric nano-structure via topology optimization has seen growing attentions. In the present work, an explicit topology optimization framework is proposed for flexoelectric structures design. To achieve this purpose, the Moving Morphable Void (MMV)-based approach is employed in the context of Isogeometric Analysis (IGA) combined with the Trimming Surface Analysis (TSA). Energy conversion factor and effective electric polarizability are respectively optimized to improve the flexoelectric performance of the nanostructure. Performing design under the explicit framework coupled with IGA can bring several advantages. Due to the use of NURBS basis functions of IGA, the required continuity in the approximation of the PDEs of flexoelectricity can be satisfied straightforwardly. Furthermore, with the use of the TSA technique, the occurrence of weak/grey material, which may cause numerical instability in flexoelectricity design, can be avoided. Also due to the explicit geometry description in MMV, the optimized result can be imported to the CAD system directly, which is significant for nanoscale structure from manufacturing perspective. Several representative numerical examples for topology optimization of flexoelectric structures are presented to demonstrate the effectiveness and advantages of the proposed approach.

Key Words: fiber-reinforced composites, orientation optimization, manufacturing uncertainty, robust topology optimization

In recent years, there has been increasing usage of fiber-reinforced composites in the aerospace and automobile due to their celebrated mechanical properties. So, huge research efforts are being made to develop methodologies for concurrent optimization of topology and fiber orientation of the structure. It is obvious that topology optimized continuous fiber-reinforced structures were impossible to manufacture other than additive manufacturing technology, often referred to be 3D printing. However, due to various environmental factors, there exists a gap between prescribed optimized fiber orientation and fiber orientation of manufactured composites. This presentation aims to present a robust topology optimization methodology of fiber-reinforced materials under fiber fabrication uncertainty. Our methodology is built upon SIMP type topology optimization, finite element analysis for numerical analysis and Method of Moving Asymptotes for updating design variables.

Topology optmization for transient fluid-structure interaction

Gil Ho Yoon[1*]

[1] Department of mechanical engineering, Seoul, Korea, ghy@hanyang.ac.kr

Key Words: Topology optimization, Multiphysics Problems, transient system, fluid-structure interaction

This study proposes a topology optimization method for transient coupled fluid-structure interaction problems [1]. The transient FSI problem is formulated with the monolithic design approach combining the design variables and the governing equations. This developed approach allows a possibility to consider the effect of transient fluid-structure interaction on the topologically optimized layouts. Throughout the work, the analysis domain for fluid and structure is modelled with the unified monolithic approach at which the structure equation and the Navier-Stokes equation are coupled. With a fixed mesh and the design variables assigned to each finite element, the governing equations as well as the material properties are interpolated. This innovative modeling and analysis approaches provide accurate solutions to the strongly coupled governing equations. The adjoint approach for calculating the sensitivity information and a gradient-based optimizer are employed. Several numerical examples are solved to reveal the importance of the consideration of the transient fluid-structure interaction in structural optimization. In addition, these examples show that the present approach can control control of a transient FSI phenomena.

Key Words: *Topology optimization; Degradation modelling; Biodegradable metal matrix composite structures; time-changeable stiffness*

Recent advances in biomedical engineering have promoted the development of innovative metal implants that have integrated mechanical and biodegradable properties. Most of the existing implant designs were created by using a trial-and-error approach, which depends on the designer's experience. Alternatively, inverse design approaches, such as topology optimization, have evolved into an efficient design solution to optimize the structural and material layout within a given design domain. Here we introduce a novel multiscale topology optimization scheme to support the design of biodegradable metal matrix composite structures (BM-MCS) with tunable time-changeable stiffness. The effect of material degradation on the mechanical performance of the structure is considered by integrating a degradation simulation algorithm into the structural finite element (FE) analysis. The objective function is to minimize the structural compliance at macroscale in a certain number of time steps to realize sufficient structural integrity in the initial bone healing stage, and the different stiffness degeneration properties can be adjusted by changing the volume ratio of the two base constitutive biomaterials. The sensitivity of the above objective function concerning design variables was derived with considering the time-dependent degradation of the biomaterial. Several numerical design examples were presented and benchmarked with classical designs. Finally, several prototypes were fabricated by integrating additive manufacturing with casting technology. Collectively, this demonstrates the feasibility and effectiveness of the proposed inverse design method for additive manufacturing.

Key Words: *Topology Optimization, Thermoelectric devices*

Thermoelectric devices have a wide range of application as energy converters due to their simplicity and reliability. Typical examples are energy recovery through heat-loss, solar energy, electronics cooling or temperature sensors [3]. The physics governing these devices is non-linear [2], making computational optimization demanding because of the many linear solves of large linear systems. However, during the last decade there have been several attempts to improve the performance of thermoelectric devices by changing their shape [1]. Furthermore, thermoelectric devices are subjected to thermal and installation related stresses that can reduce their efficiency [4].

The focus of this presentation is on the use of topology optimization and finite element methods to improve the performance of non-linear thermoelectrical devices and surrounding structures. By including the mechanical response of the device to external loads we can improve the thermoelectric device reliability with respect to installation loads and thermal cycling. It is also worth noting that these devices have an optimum operational point that will change with their geometry. For this reason, the operational point must also be optimized along with the topology of the device.

The procedure to follow for the optimization thermoelectric devices with 3D elements will be detailed together with different methods to improve computational performance and convergence. Finally, the results from the optimization for a single thermoelectric unit is showcased with the increased performance for different operational conditions.

Key Words: *Inverse Design, 4D printing, Multimaterial, Shape Shifting, Machine Learning, Image Segmentation, Finite element analysis (FEA)*

Conventional methods for fabricating three-dimensional (3D) shell-like plastic objects include injection molding and direct 3D printing. However, injection molding requires expensive molds and machines, which is not suitable for high-mix, low-volume production. Direct 3D printing, on the other hand, is slow and consumes much sacrificial supporting material. In this paper, we develop an approach to overcoming those limitations by using multi-material four-dimensional (4D) printing. 4D printing integrates 3D printing and active material technologies to realize printed components transformed between different configurations upon heating [1-3]. Specifically, we aim to fabricate complicated 3D gridshells by transforming simple 2D grids by 4D printing. This is an inverse design problem in which one needs to determine the geometry and material configuration of a 2D grid given a target 3D gridshell. We print 2D grids consisting of rectangular arranged double-layered segments. Each layer is made of shape memory polymer (SMP55) or PLA, resulting in four combinations for each segment. The size and material combination of each 2D grid is specified to control both global and local curvatures of the deformed gridshell. As exemplars, we design three traditional Japanese “Noh masks” as the targets because Noh masks are an ideal model system as each mask has unique aesthetic features. Therefore, we conduct FEA for simulating the heating process and improving the design efficiency. Although FEA accelerates manual design, we build a machine learning model using image segmentation to predict 2D material patterns of corresponding 3D geometries. We show that the FEA simulations are consistent with the experimental results and successfully demonstrate the feasibility of our approach to producing complex 3D curved surfaces. Our method is eco-friendly, economical, and suitable for high-mix, low-volume production, and has considerable potential for further applications.

Key Words: *Coupled solvers, fusion reactors, digital twin*

Fusion energy systems require highly complex multi-physics models for understanding and optimizing performance. This is especially true for the blanket, the device where heat is extracted for power generation as well as tritium created from transmuted lithium, necessary for fuel production. In their most typical form, a fusion blanket requires coupling physical processes including radiation transport with isotope transmutation and depletion, thermo-hydraulics, quasi-static electromagnetics, solid mechanics, and heat transfer. More radical designs may include high-temperature gas flows and/or liquid metal free-surface flows facilitated by surface tension. Coupling between different physical processes may occur through the volume (radiation-induced heating and damage, Lorentz forces, Joule heating) and through coupling via surfaces (fluid-structure interaction, conjugate heat transfer). The Fusion Energy Reactor Models Integrator (FERMI) code suite is envisioned as a tool to enable these complex analyses, both to de-risk designs as well as provide a means towards optimization thereof. A range of solvers will be coupled in a single multiphysics simulation environment using the open-source coupling library preCICE. A selection of different electro-thermal-hydraulics and neutronics solvers will be coupled together along with the structural mechanics package Diablo for simulation of a blanket design. We analyze the performance and suitability of various coupling strategies in the context of the analysis of a conceptual blanket design.

3D Topology Optimization of an Axisymmetric Wheel and Axle Structure with Orthotropic Constitutive Properties

Lee Alacoque[1*] and Kai A. James[2]

Key Words: *Topology Optimization, Design Automation, Machine Synthesis, Variable Loading*

In this work, we present a topology optimization methodology for automatically designing axisymmetric structures with arbitrary boundary conditions, arbitrarily shaped finite element meshes and design domains, and variable loads. We use the design problem of a wheelset: a rolling structure where wheels are fixed to the ends of an axle. Believed to be the first invention of the wheel used for transporting cargo out of early mines in the Carpathian Mountains [1], these wheelsets could conceivably have been crafted from wooden logs available near the mine entrances. To reduce the amount of work required to push heavy mine cars, the axles would have been made as thin as possible to minimize rolling resistance caused by friction at the surface of the axle. We replicate this historical design process using our modern and automated topology optimization algorithm.

To achieve an axisymmetric geometry while retaining the ability to apply arbitrary load and support boundary conditions, we use a manufacturing constraint in the form of a milling filter [2] that we have modified and extended as a 3D turning filter. The filter enforces axisymmetry of the density design variables about the symmetry axis, and in our implementation, we discretize rectangular shaped design domains using structured grids of finite elements. This produces geometries that can be manufactured by cutting a block of material using a turning machine tool such as a lathe. For modelling the axisymmetric material properties of a wooden log, we use orthotropic constitutive properties in a cylindrical coordinate system of longitudinal, radial, and tangential directions. Each element in the mesh is assigned stiffness properties corresponding to the constitutive matrix rotated according to the local orientation of the element. The stiffness of intermediate density material is then interpolated and penalized using the SIMP (Solid Isotropic Material with Penalization) method applied to the orthotropic constitutive matrix, or SOMP (Solid Orthotropic Material with Penalization).

The optimization problem is set up such that a wheelset structure is automatically generated given the simple objective of minimizing the radius of the axle and the mass of the structure, subject to a structural compliance constraint. The load is applied to the surface of the axle, whose geometry changes during the optimization process. This makes the wheelset structure a design-dependent loading problem; however, we do not apply any restrictions on the location of the load. Instead, we allow the numerical optimization process to find the optimal location along the axle's surface by treating the load coordinates as design variables [3]. We ensure that the load remains applied to the solid-void interface by projecting a moveable void space radially outward from the load application area. Ultimately, our proposed methodology successfully synthesizes a primitive wheelset geometry depicting circular discs connected to the ends of a narrow cylindrical axle.

A Geometric Feature-Mapping Approach to Buckling and Fail-Safety Criteria in Topology Optimization

Hollis Smith,[1*] Julián Norato,[2] Joshua Deaton,[3] and Raymond Kolonay[4]

[1,2]UConn, Storrs, CT 06269, USA. [1]hollis.smith@uconn.edu, [2]julian.norato@uconn.edu

Key Words: Topology Optimization, Geometry Projection, Stability, Redundancy

Stability and redundancy requirements can be critical to structures in many applications. In civil and aerospace contexts, unstable or damage-intolerant designs can render catastrophic consequences. Despite the clear importance of stability and redundancy, the thin and fully-stressed members typical of stiffness or strength optimized designs are diametrically opposed to these requirements.

Stability and buckling have endowed considerable attention since the onset of structural optimization. In truss optimization, local stability has been imposed via stress or displacement constraints on individual members. However, only a small number of works consider buckling in topology optimization of continua. In this setting, nearly all works consider a linearized bifurcation-buckling analysis. However, a geometric feature-mapping topology optimization approach provides direct representation and control of distinct structural members in a continuum setting. This enables certain local buckling modes to be intuitively and efficiently stabilized via geometric criteria in a continuum topology optimization.

Redundancy is essential to the safety of structures in the case of damage. If all structural members are indispensable, then only a small amount of damage can result in complete structural failure. In truss topology optimization, damage to the structure is modeled by eliminating or eroding a truss element. However, in continuum topology optimization, it is not straightforward to remove a distinct structural member. Damage scenarios in a continuum setting are often considered by removing patches of a fixed size, shape and location, or by degrading the entire structure by offsetting the boundary. A feature-mapping approach can enable modeling damage to the structure consistently with established fail-safe design principles by removing distinct geometric members from the design.

In this work, we exploit the underlying geometric design representation of the geometry projection method to formulate optimization constraints that heuristically increase buckling load factor and promote structural redundancy. This approach addresses buckling and fail-safety design requirements at a substantially lower computational cost than a purely physics-based approach. We demonstrate the efficacy and efficiency of our method via numerical examples.

A Practicable Two-material Interpolation Method for Isotropic Brittle-ductile Topology Optimization

Hiroya Hoshiba[1*], Mutsuki Fujiwara[1] and Junji Kato[1]

[1] Nagoya University, Furo-cho, Chikusa-ku, Nagoya-shi, Aichi-ken 464-8603, Japan
hiroyahoshiba@nagoya-u.jp

Key Words: *Topology Optimization, Nonlinear Composite Structures*

The purpose of this study is to develop an optimal design method for improving both strength and toughness for composite structures that combine brittle and ductile materials. Based on the basic topology optimization method using SIMP, we propose one idea about the material representation method in a simple and easy-to-control scheme: interpolation of nonlinear material constitutive law.

The well-known composite structure of reinforced concrete has both high strength and toughness in the entire structure by supplementing concrete with high compressive strength but is fragile to tensile strength with reinforcing bars that can be tenaciously deformed. In this way, by combining two types of materials with different properties, it is possible to realize ideal mechanical behavior as a structure that is "brittle-ductile" There is still room for further investigation in the geometric design of such composite structures, and there seems to be an opportunity to improve performance by optimization simulation.

In the topology optimization method based on SIMP, a few material parameters such as Young's modulus are interpolated in order to express the mechanical behavior of a phase in which a solid material and a void or two different materials are mixed. However, when the concept is applied to a complex nonlinear material that switches discontinuously at a threshold with a stress-strain relationship or exhibits softening behavior, the evaluation function and the optimization problem become non-convex or discontinuous. When such an irrational problem occurs, the design variables vibrate and stay in grayscale, making it extremely difficult to reach the optimum solution by the optimization algorithm. Therefore, usually, the instability is mitigated to a level where the calculation can be executed by finely tuning the interior parameters and filtering settings, but in that case, the calculation result strongly depends on these settings, and the degree of freedom in design is not a little lost.

In this study, we assume a two-phase material consisting of a unilateral damage material and a von Mises elastoplastic material, and interpolate the material parameters between these materials. Therefore, we limit the target of interpolation to material parameters such as Young's modulus, initial yield stress, and initial damage strain, and try to formulate as simple as possible. This maximizes the effort and impact of tuning to mitigate optimization instability and improves the ease of handling the simulation. In this presentation, we will show some optimization results assuming a steel-concrete composite and discuss the mechanical rationality, numerical stability, and dependence of the optimal solution on interior parameters.

An Evolutionary Approach to Stress-constrained Topology Optimization

Liang Xia*

Huazhong University of Science and Technology, Wuhan, 430074, China
xialiang@hust.edu.cn
https://scholar.google.com/citations?user=8X8N_tQAAAAJ

Key Words: *Topology Optimization, BESO, Strength Design, Industrial Application*

We proposed recently an evolutionary approach to stress-constrained topology optimization using Bi-directional Evolutionary Structural Optimization (BESO) method. The discrete nature of the BESO avoids naturally the well-known "singularity" problem in density-based methods due to the degenerated materials. The p-norm stress aggregation scheme is adopted for the measure of global stress level. The compliance objective is augmented with the aggregated stress constraints by introducing one or multiple Lagrange multipliers. The Lagrange multipliers are employed to yield compromised designs between compliance and stresses. A computationally efficient sensitivity number formulation is derived from the adjoint sensitivity of the global stress measure. With regard to the highly nonlinear stress behaviour, both sensitivity numbers and topology variables are filtered to stabilize the optimization procedure; meanwhile, the filtered sensitivity numbers are further stabilized with their historical information. The method has been shown efficient, practical and easy-to-implement through a series of benchmark designs including the L-bracket benchmark. A series of comparison study has been conducted to test the feasibility of the method on the L-bracket benchmark design problem. The method has also been applied for the design of a typical aircraft engine bracket considering multiple practical load conditions. The resulting bracket topology from stress-constrained design is further smoothed and detailed using basic CAD (Computer-Aided Design) primitives. Numerical results show that the reconstructed bracket design evidently outperforms than the original bracket design in terms of weight, stiffness and strength.

Key Words: *Topology optimization, Thermoelastic compliance, Structural nonlinearity*

In the topology optimization of a structure experiencing both thermal and mechanical loads (i.e., thermoelastic loads), consideration of the structural nonlinearity is crucial because the optimality of the resulting design is highly deteriorated otherwise. However, the choice of the objective function of thermoelastic compliances, which is widely used to maximize the stiffness of the structure, is limited in the finite strain setting because the thermoelastic load cannot be linearly decomposed into the mechanical and thermal ones. For example, the mean compliance function that is an inner product of total displacement and the sum of the thermal and mechanical load is not available yet the function is one of the most widely used objective function due to its resemblance to the strain energy. In this respect, the end compliance and strain energy functions are used as the alternative to the mean compliance. However, their respective results, including the optimized layouts, have not been discussed. Therefore, this study examines the differences between two notable thermoelastic compliances in topology optimization considering structural nonlinearity: end compliance and strain energy.
This talk addresses two main findings in the study. First, we carefully examine the optimized layouts that depend on the objective functions and thermoelastic loading conditions. Through the examination, we revealed the optimality of the layout through the re-analysis, and at the same time, the changes of design capability leveraging the fact that the one can have negative value while the other is not. Lastly, the same objective functions are optimized in the structurally linear case and compared with the nonlinear ones, again emphasizing the importance of finite strain formulation in thermoelastic topology optimization.

Concurrent Topology Optimization of Parts and Supports for Additive Manufacturing Considering Thermal Deformation

Yichang Liu[1], Mingdong Zhou[1*]

[1] Shanghai Jiao Tong University, Shanghai, China,
[*] mdzhou@sjtu.edu.cn

Key Words: *Topology optimization, Additive Manufacturing, AM-process simulation, thermal deformation, inherent strain method.*

In metal additive manufacturing (AM) e.g. selective laser melting, thermal deformation is an important factor affecting the manufacturing quality, improper control of which will jeopardize the size accuracy of the final prototype and even lead to manufacturing failure caused by the crash between the printed part and the powder re-coater. This work presents a density based topology optimization approach to concurrently design parts and supports for a perfect match between mechanical properties and manufacturing qualities. A layer-by-layer AM process simulation model based on an inherent strain method is developed to capture the thermal deformation during the AM process, which is further developed into a novel thermal deformation constraint and incorporated into the topology optimization model. Besides, an overhang constraint and a two-field based length scale control formulation are also considered, ensuring the overall manufacturability. With the proposed approach, lightweight structures with optimized mechanical properties and controlled thermal deformation can be obtained. Numerical examples are given to demonstrate the applicability of the proposed approach.

Concurrent Topology Optimization of Two-Scale Transient Heat Analysis Considering Size Effect

Key Words: *Concurrent topology optimization, Multi-scale, Transient heat, Size effect*

Nowadays, topology optimization and additive manufacturing are widely used to design and fabricate heat dissipation structures [1], and many innovative designs are proposed due to their superb capabilities, e.g., free-form design, printing custom shapes, and rapid fabrication. For heat dissipation problems, lattice and porous structures with a high surface area frequently appear as the optimal layout. To design this kind of structure, multi-scale topology optimization which includes characteristics of heat dissipation of lattice and porous structures is required to be adopted. However, only a few studies have investigated topology optimization by not only taking into account the multi-scale heat behaviour but also transient heat analysis.

In the present study, a concurrent two-scale topology optimization framework for transient heat analysis is proposed. The homogenization method which is capable of considering the size effect of microscopic heat transfer is adopted [2] to deal with the multi-scale analysis of lattice and porous structures. Heat compliance is chosen to be an objective function, and then analytical sensitivity formulations are derived for each scale by using the adjoint variable method. Selected numerical examples are used to demonstrate the robust performance of the proposed framework. The analysis shows that the framework captures not only the transient heat but also the size effect of the microstructure in a transient heat analysis.

Key Words: *Deformation Behavior, Topology Optimization, Crash Load, Clustering, Time Series data, Dynamic Time Warping*

Multi-objective topology optimization has been receiving more and more attention in structural design recently. It attempts to maximize several performance objectives by redistributing the material in a design space for a given set of boundary conditions and constraints, yielding many Pareto-optimal solutions. However, the high number of solutions makes it difficult to identify preferred designs. Therefore, an automated way of summarizing solutions is needed for selecting interesting designs according to certain criteria, such as crashworthiness, deformation, and stress state. One approach for summarization is to cluster similar designs and obtain design representatives based on a suitable metric [1]. For example, with Euclidean distance of the objective vectors as the metric, design groups with similar performance can be identified and only the representative designs from different clusters may be analyzed. However, previous research has not dealt with deformation-related time-series data and structures with different topology. Since the non-linear dynamic behavior of designs is important in various fields such as vehicular crashworthiness, clustering methods based on the time-dependent behavior of structures is proposed here using metrics of time-series, such as DTW (Dynamic Time Warping) [2], for the comparison of displacement data of selected points on the structure. This is combined with clustering techniques such as *k*-Medoids [3] and OPTICS (Ordering Points To Identify the Clustering Structure) [4], and we investigate the use of unsupervised learning methods to identify and group similar designs using the time series of nodal displacement data. In the first part, we create artificial time-series datasets using mass-spring systems and a beam structure to validate the proposed methods. Each dataset has clusters of data with distinct behavior such as different periods or modes. Then, we find that the combination of DTW and OPTICS can identify the clusters of similar behavior accurately. In the second part, we apply these methods to a more realistic, engineering dataset which contains the crash behavior of topologically-optimized designs. We identify similar structures and obtain representative designs from each cluster, demonstrating the capability of our method for analyzing dynamic behavior, which supports the designers in selecting representative structures based on deformation data at the early stages of design process.

Key Words: *Topology optimization, Multi-material, Interface representation, Stress constraint*

In recent years, the use of multi-material has been paid attention in the field of structural design to reduce weight and increase stiffness and strength. In order to make the most of the advantages of this multi-material technology, design techniques that effectively utilize materials with different properties in the right places are required. Therefore, a series of studies on the multi-material topology optimization has been actively pursued.

However, studies on multi-material topology optimization have been limited to extending single-material models, such as the SIMP method and level-set method, to multiphase materials. On the other hand, few studies take into account the strength of each material. Furthermore, the interfacial strengths of different materials are rarely considered, which often causes damage in structure.

One of the reasons for this is the difficulty in representing the bonding behavior. In density-based methods, such as the SIMP method, it is difficult to explicitly reproduce the interface and its bonding effect although it is easy to handle. On the contrary, the level-set method could represent the interface explicitly, the optimization results may be highly dependent on the initial configuration of the interface. In a recent paper, a level set method that takes into account the strength of the material interface was proposed by Liu et al[1].

In this study, we will develop a topology optimization method considering strength of each solid material and the interface simultaneously. We extend the graded interface proposed by Clausen et al[2] and Chu et al[3] to represent the interfacial strength. By comparing the optimal layout obtained by the proposed method with the ones obtained by the conventional mean compliance minimization problem, it is shown that the proposed method is more suitable for the actual design.

Length Scale Control Schemes for Bi-directional Evolutionary Structural Optimization Method and its Application to Shell-infill Structures

Wenke Qiu* **and Liang Xia**

Huazhong University of Science and Technology, Wuhan 430074, China
wenke_q@hust.edu.cn & xialiang@hust.edu.cn

Key Words: *Topology optimization, BESO, P-norm, Skeleton, Length scale control, Infill architecture*

This research develops length scale control schemes for Bi-directional Evolutionary Structural Optimization (BESO) method, enabling an enhanced and flexible control of the method on structural member sizes. Specifically, the maximum length scale control is achieved by constraining local material volumes below a threshold value, which is determined upon the allowed maximum length. The massive per-element volume constraints are aggregated by the p-norm global measure. The aggregated volume constraint is augmented to the conventional compliance design objective through a Lagrange multiplier. On the other hand, the minimum length scale control is achieved by a post-processing modification of local feature according to the skeleton detected from a preliminarily optimized topology. The sensitivity numbers of the local structural features that violate the minimum length scale constraint are compensated during the post-processing modification. The effective and efficient of the proposed schemes in controlling both the maximum and minimum structural length scales are demonstrated by 2D and 3D benchmark design. Meanwhile, the proposed method accounting for length scale control can efficiently generate porous lattice structures, making it a powerful means for the infill architecture design. And it is successfully applied to the infill architecture design of shell-infill structures. Both numerical and experimental results show that the achieved shell-infill MBB beams outperform than the reference design with uniform lattice infill of the same weight in terms of stiffness and fracture resistance.

Microstructure Control through Topology Optimization for Additive Manufacturing

Vibhas Mishra*, Can Ayas, Matthijs Langelaar and Fred van Keulen

Delft University of Technology, Mekelweg 2,
2628 CD Delft, The Netherlands, v.mishra@tudelft.nl

Key Words: Thermal history, Microstructure, Wire and Arc Additive Manufacturing (WAAM), Topology Optimization

In Wire and Arc Additive Manufacturing (WAAM), a metal wire is melted and deposited simultaneously along a predefined deposition path using a robotic arm. WAAM is used to manufacture large-scale structures such as ship propellers and airplane components. Mechanical behaviour of a WAAM part depends, among others, on microstructure development during the manufacturing process. Evolution of microstructure is dictated by the thermal history experienced by the part. For high strength low alloy steels, time spent by a material point between a critical temperature range $800°C - 500°C$ ($t_{8/5}$) affects the local microstructure development and, consequently, yield strength [1, 2]. As the thermal history of a material point during WAAM is influenced by the part geometry, this offers an opportunity to tailor mechanical properties through design.

In this study, we present a new method to control $t_{8/5}$ of critical structural regions through topology optimization. Firstly, the thermal history experienced by critical structural regions is evaluated through a simplified process modelling. In the process model, to simulate material deposition in WAAM, finite element activation approach is used. The finite elements are activated in layer-by-layer manner. For a particular layer, elements associated to it and previous layers are activated. A heat flux is subjected to the top surface of the finite elements associated to the latest activated layer for a particular period of time to simulate the heat input in WAAM. Secondly, it is essential to evaluate design sensitivities of $t_{8/5}$ for topology optimization, therefore, a continuous and differentiable approach is proposed to evaluate $t_{8/5}$ of critical structural regions. Thereafter, a study will be shown in which the effect of design changes on $t_{8/5}$ is investigated. The results show that overhanging features orthogonal to the deposition directions of layers have high $t_{8/5}$. High $t_{8/5}$ can lead to low yield strength due to development of microstructure with high volume fractions of solid phases with low hardness [1]. Thus, in this work we present a novel integrated approach to generate optimized structural design considering the stress generated in the critical regions and yield strength which is result of the microstructure development during the manufacturing process.

Microstructure Optimization for One-Dimensional Nonlinear Constitutive Laws Under Tensile Loading

Brianna MacNider[1]*, H Alicia Kim[1] and Nicholas Boechler[1]

[1] University of California San Diego, 9500 Gilman Drive, La Jolla, 92093, *bmacnide@ucsd.edu, hak113@ucsd.edu, nboechler@ucsd.edu

Key Words: Topology Optimization, Microstructure Tailoring, Nonlinear Optimization, Finite Strain Optimization, Constitutive Laws

Topology optimization has previously been used to tailor microstructural motifs towards the realization of specific desired bulk material properties. However, optimizing a nonlinear microstructure geometry has received limited attention. Most efforts toward matching a nonlinear constitutive law have either focused on one-dimensional bar and beam problems [1], or, within continuum designs, on the simpler problem of minimizing or maximizing mechanical response at single loading conditions of interest, rather than matching responses of a single designed structure throughout a range of loading conditions.

We explore microstructure optimization to induce softening and stiffening in nonlinear stress-strain behavior in a two-dimensional (2D) continuum setting. We employ a geometrically nonlinear, finite strain, displacement control level set topology optimization scheme. The use of the level set method allows us to avoid the intermediate density elements typically encountered in density-based optimization. Within the context of a 2D continuum, we demonstrate nonlinear constitutive law matching across a range of displacements, within the vicinity of a local optimum. We further explore the use of various guiding metrics, including strain energy measures and polynomial fitting, in order to expand the capabilities of this method to target desired stress-strain curves across a broader range of the highly nonlinear design space, so that a wide range of desired constitutive laws can be achieved.

The ongoing maturation of this method aims to physically realize systems that have previously only been theorized and simulated, which require the expression of specific nonlinear stress-strain curves not easily found in existing materials or designs [2]. The ability to optimize for any desired general constitutive law shape will enable exciting research opportunities in metamaterials, nonlinear dynamics, waves, and impact absorption applications.

Multi-material Topology Optimization Model using the Multi-phase-field Method

Satoshi Sugimoto[1*], Shinji Sakane[1] and Tomohiro Takaki[1]

[1] Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606-8585, Japan;
b8123038@edu.kit.ac.jp, sakane@kit.ac.jp, takaki@kit.ac.jp

Key Words: *Topology Optimization, Multi-material, Multi-phase-field Method*

Topology optimization is the most flexible method in structural design, and its practicality is increasing because the development of additive manufacturing (AM) has facilitated the creation of products with complex shapes. In addition, AM has recently enabled the fabrication of products using multiple materials. Therefore, an optimization technique that includes the degree of freedom of both shapes and materials should be established.

The solid isotropic material with penalization method, which is widely used for the topology optimization of a single material, is difficult to be feasibly extended to multiple materials. The phase-field method is a stable interface tracking method, which has been applied for topology optimization of multiple materials [1, 2]; however, a definitive method has not yet been developed. In this study, we apply the multi-phase-field model—which has been used for multiphase and polycrystalline problems in materials science—for the topology optimization of multiple materials.

On geometrically Nonlinear Stability Constraints in Topology Optimization

Peter D. Dunning[1*]

[1] University of Aberdeen, School of Engineering, King's College, Aberdeen, AB24 3UE, UK, peter.dunning@abdn.ac.uk

Key Words: *Topology optimization, nonlinear geometry, stability constraints.*

Stability constraints play an important role in structural optimization problems to ensure that optimized designs can safely support the intended loads without undergoing large displacements, or even collapse, due to instabilities such as buckling. Topology optimization problems that minimize linear compliance (maximize linear stiffness) often result in structures with thin members under compression that are susceptible to failure by buckling instability. This is a well-known issue and has led to research on including stability constraints in topology optimization problems. This is usually achieved by estimating the critical load factor by a linear buckling analysis [1,2]. However, buckling is inherently a geometrically nonlinear problem and the linear approximation may over or underestimate the true load capacity of the structure.

Therefore, a geometrically nonlinear analysis can be used to compute the critical load factor more accurately [3]. However, this approach has received less attention, possibly because of the high computational cost of the nonlinear analysis. Another issue is that accurately identifying the limit point for the critical load level is difficult because the tangent stiffness matrix becomes singular at a limit point. Thus, in practice, we can only obtain a solution near a limit point [3]. This leads to inaccuracies in the computed gradients, which can cause convergence issues when using gradient-based optimizers, especially if the geometrically nonlinear stability constraint is difficult to satisfy (i.e. the optimal design with a stability constraint is significantly different to one without).

Two strategies are proposed to overcome this issue, which are tested using benchmark problems. The first strategy is simply to "go slow" by using small updates of the design variables each iteration, which reduces the influence of inaccurate gradients on convergence. This strategy leads to more stable convergence, but extra computational cost, as more design iterations are required. However, computational cost may be reduced by reusing information from the previous iteration to speed up convergence of the geometrically nonlinear analysis. The second strategy is to achieve the desired stability constraint using an implicit formulation based on nonlinear stiffness measures. This strategy reduces computational cost and avoids issues of inaccurate gradients, as the limit point is not explicitly computed. However, because stability is only implicitly enforced, this strategy may result in an overdesigned structure.

Optimal Design for Continuous Fiber Layout of 3D-printing FRP

Takahito Moribe[1*], Hiroya Hoshiba[1] and Junji Kato[1]

[1] Nagoya University
Furo-cho, Chikusa-ku, Nagoya-shi, Aichi 464-8603, JAPAN
moribe.takahito@k.mbox.nagoya-u.ac.jp

Key Words: *Additive Manufacturing, 3D-printer, Fiber Reinforced Polymer, Optimization*

In the last few decades, additive manufacturing technology has been actively developed and various materials such as metal, resin, ceramic, cement and eventually continuous fiber reinforced polymer (FRP) can be printed by 3D-printer. The emergence of 3D-printing technology for continuous FRP is expected to open up a new era of manufacturing in various engineering fields. The most important feature of this new technology is the ability to freely change the arrangement and orientation of continuous fibers in the laminate plane, which have superior strength and stiffness to short fibers. However, the design method of continuous reinforced fiber orientation of FRP which is premised to be produced by 3D-printer, has yet to be deeply investigated. Under this circumstance, this study aims to establish an optimal design method for 3DP-FRP.

A conventional design method for 3DP-FRP is a density-based approach based on the SIMP [1] in consideration with anisotropy. In this method, each discretized element based on the finite element method has two design variables, material density (fiber arrangement) and angle (fiber orientation), and then the objective function is minimized/maximized by updating these variables [2]. Since the fibers are discretized, the continuity of fibers, which is the main feature of 3DP-FRP, cannot be expressed in this framework. As a result, it is necessary to introduce a filter to ensure the continuity of the fibers, or a post-process procedure to joint them together: this kind of post process may lose the mechanical reliability to the optimal layout.

To avoid such a problem, we propose a method in which the design variables are defined at the nodes of finite elements. The isosurfaces created by these values are regarded as fiber paths, and the arrangement and orientation of the continuous fibers are optimized by varying the nodal values instead of the density and angle.

liu.guangwei@k.mbox.nagoya-u.ac.jp

Key Words: *Topology Optimization, Dynamic Structural Problem, Viscoelasticity, Generalized Maxwell Model*

In dynamic structural systems, the capability to restore or dissipate energy is one of the priorities when concerning the optimal dynamic performance design [1]. To achieve this purpose, viscoelastic material such as rubber-like material is often applied. However, the concern of how to represent the characteristics of real dynamic response has yet to be clarified [2], [3]. To fulfil this design, development of multi-material topology optimization considering dynamic loading with a realistic viscoelastic material model is required.
In the present study, we addresses a design scheme for maximization of storage and/or loss energy under dynamic loading assuming viscoelastic bi-material. The generalized Maxwell model, which shows good consistency with viscoelastic performance, is used with the SIMP-like interpolation scheme. For the sensitivity analysis, an analytical adjoint variables method is used.
Finally, the proposed method is verified by a series of numerical examples.

Key Words: *Structure topology optimization, Granular material model, Tension-compression asymmetry material, Eigenfrequency optimization, Interval frequency topology optimization*

Granular material is an aggregate formed by numerous discrete solid particles through particle-to-particle interactions. It is ubiquitous in nature, daily life and engineering applications. Due to the tension-compression asymmetry of granular materials under external loadings, this fields becomes a hot field in bionics techniques and simulating the mechanic behaviours of bio-structure. This paper uses the method of micro mechanics, which bridges the micro-scale structure and the macro-scale mechanical phenomena. The macroscopic constitutive equation of granular material is established by the stiffness coefficient between particles. Topological optimization of structures composed of granular materials can create unique structures. When the external exciting frequency is approximating to some order of eigenfrequency in structure, the system will resonate. To avoid resonance of structure resulted from external exciting source, this work proposed the mathematical formulation to adjust eigenfrequency band between two consecutive eigenfrequencies of the granular material structure. The mathematical formulation of topology optimization can be stated as follows, in which difference of successive two frequencies for the structure was taken as objective and constitutive equation of cementitious was applied.

Benchmark problems are optimized to verify the correctness and effectiveness of the proposed mathematical formulation. The effect of granular material structure on the structural topology was investigated. Resultant topologies show that the dynamic topology optimized design obtained from the newly proposed material model is different from the traditional material design due to the tension-compression asymmetry at the microscopic scale. Additionally, the damage to the structure caused by resonance is effectively avoided through topology optimization.

Thermostructural Topology Optimization of a Heat Exchanger with Stress Constraints

Waheed B. Bello[1*], Kai A. James[2]

[1] University of Illinois at Urbana-Champaign, Urbana, IL, wbello2@illinois.edu,
[2] University of Illinois at Urbana-Champaign, Urbana, IL, kaijames@illinois.edu,
https://publish.illinois.edu/designlab/

Key Words: *Topology Optimization, Heat Exchanger Design, Geometric Projection, Design-Dependent Convection Loads, Coupled Thermoelastic Analysis, Adjoint Sensitivity Analysis*

The application of topology optimization to the design of heat exchangers has not been explored in detail. Therefore, we present a method for designing heat exchangers with geometric projection and density-based topology optimization. The goal of the optimization process is to minimize the maximum von Mises stress caused by thermal expansion within the heat exchanger, subject to a constraint on thermal efficiency. The locations and sizes of the air channels are the design variables used to parameterize the Heat Exchanger geometry, and those air channels are projected onto the design domain via geometric projection [1]. Iga's method for formulating design-dependent heat convection loads [2] is modified to model heat transfer along the projected air channel boundaries. A smooth Hat function is used to identify the elements along the material interface which forms the boundaries of the air channels through which heat convection occurs. A coupled thermoelastic model is developed using finite element analysis, and the design sensitivities are derived and evaluated using an adjoint analytical method. The interpolation of both the thermal and elastic material properties is based on the standard Solid Isotropic Material with Penalization (SIMP) method. Results are presented for a varying range of temperature difference between the inner and outer fluid streams. Results show that the maximum local stress within the optimized heat exchanger can be decreased significantly to avoid exceeding the yield strength of the material. Future work will include extending this framework to three dimensions where the number of plate layers and faces can also be modified during the optimization process. In addition, the optimization process will be developed further to maximize the transfer of heat from the hot fluid within the air channels to the surrounding cooler fluid.

Key Words: *Topology optimization, thermal design, Multi-physics*

Topology optimization is attracting attention as a powerful design tool that can determine the optimum structural layout and material arrangement, and has been introduced in various engineering fields. In addition, topology optimization technology will be required more and more in the future because it has a high affinity with a next-generation manufacturing, namely additive manufacturing.

Thermal design, which is particularly important for electronic devices, is one of the representative engineering problems in which many beneficial results have reported with topology optimization [1], [2]. However, only a few studies have taken unsteady state thermal-fluid problem into consideration. In actual design problems, there are lots of cases in which temporal changes in temperature distribution are important rather than steady state.

In this study, the framework of a density-based topology optimization method for unsteady thermal-fluid problem is proposed. The governing equations are unsteady-state imcompressible Naiver-Stokes equation and thermal convection-diffusion equation, discretized with stabilized finite element method. The design sensitivity is computed accurately based on the adjoint variable method. The numerical analysis shows that the proposed framework captures the transient effect correctly and the results of optimization are physically reliable.

Key Words: Topology optimization, Lattice Boltzmann method, Natural convection, Unsteady problem, Parallel computing

Natural convection is a thermal-fluid phenomenon driven by buoyancy force and widely investigated from numerical and experimental aspects. Among the previous works, mathematical optimization concerning natural convection is recognized as an important research topic for designing high-performance cooling systems such as heat sinks, energy storage devices, etc.

Topology optimization for natural convection is a relatively new and undeveloped research topic since Alexandersen et al. [1] have pioneered it in 2014. One of the difficulties of natural convection is treating the two-way coupling; fluid and temperature fields interfere. Hence, numerical simulation of natural convection is typically more challenging and needs higher computational cost under the same degree of freedom as forced convection. Consequently, research on topology optimization for natural convection is still limited; especially, large-scale unsteady natural convection is an open research problem.

To tackle unsteady natural convection problems, we propose a topology optimization method based on the previous work [2], in which the lattice Boltzmann method (LBM) is employed for solving forward and adjoint problems based on the so-called adjoint LBM. The LBM is suitable for solving fluid flows with parallel computing; additionally, many researchers have demonstrated the LBM can be applied for large-scale natural convection. So far, since any LBM-based topology optimization has not been proposed, even the steady-state, we first validate the proposed method via topology optimization for a steady natural convection problem as with the previous work [1]. We then demonstrate the efficacy of the proposed method through numerical examples of 2D and 3D unsteady natural convection problems.

Topology Optimization of 3D-Welded Frame Structures with regards to Manufacturing Cost

Hongye Gu[1*] **and Julián A. Norato**[2]

[1] University of Connecticut, 191 Auditorium Road, U-3139, Storrs, CT, 06269, USA

[2] University of Connecticut, 191 Auditorium Road, U-3139, Storrs, CT, 06269, USA
julian.norato@uconn.edu

Key Words: Manufacturing cost, Topology optimization, Welded frame structure

Manufacturing cost is seldom considered in the topology optimization of structures, which is often based solely on structural criteria and weight. Consequently, the optimal design may exhibit superior mechanical performance but be costly to manufacture. While the amount of material in a structure may contribute significantly to its cost, there are also other costs associated with the fabrication process. In the case of the welded frames considered in this work, for example, the manufacturing cost is influenced by the cost of cutting, welding and painting frame members.

Ground structure methods have been used to minimize the manufacturing cost of truss structures. In these methods, which use 1D-elements to represent the structure and for analysis, it is easy to compute costs associated with, for example, the length of the truss elements and the number of struts. However, other cost components, such as the cost of welding, cannot be readily computed because they require a calculation of the welding length, which is difficult to compute from the 1D-representation. Moreover, the structure must be a topological subset of the initial design (the ground structure), thus they cannot model arbitrary topologies. Some density-based topology optimization techniques for continua consider the manufacturing cost of additive manufactured components. For these manufacturing processes, it is possible to express the manufacturing cost in terms of quantities that can be computed from the field representation, such as surface area and the volume of the support material.

We propose a method for the topology optimization of welded frame structures with regards to manufacturing cost. The frame is modeled as the union of 3D-primitives. The analysis is performed on a fixed finite element mesh as in density-based methods. To represent the frame using primitives but still perform the analysis on a fixed mesh as in density-based methods, we employ the geometry projection method. In this technique, the geometric parameters of the primitives are mapped onto a density field that is subsequently used to interpolate material properties, just as in density-based methods. The proposed approach has several advantages. Each term of the manufacturing cost function of 3D-primitives can be computed directly in terms of the geometric parameters of the primitive or through the projected density. The geometry projection mapping is differentiable, hence we can use efficient gradient-based methods for the optimization. Re-meshing is circumvented. We present examples of 3D-truss and plate frame designs with minimized manufacturing cost subject to a maximum displacement constraint.

Key Words: *Multi-material, Topology optimization, Interface property, Interface thickness, Finite strain*

Multi-material design is known as one of effective ways to achieve a lightweight and high strength structure. Recently, computer-oriented design approaches have been applied to multi-material structure design [1, 2]. In a multi-material structure, the stress and strain are localized along the interface between different materials. However, the interface is generally assumed as perfect bonded in these design approaches.

In this study, a computational design method of duplex structure considering interface strength was proposed based on topology optimization method using level-set function [3]. A simple interface debonding model based on maximum principal stress was integrated into an implicit nonlinear finite element method at finite strain. Here, the interface was described as finite volume region centred on the boundaries between the two materials using a distance function. In topology optimization, a standard topological derivative based on adjoint variable method was employed for the update of the structure in consideration of the debonding state at previous iteration. Numerical demonstrations were performed to present the applicability.

Topology Optimization of Finite Strain Dynamic Structural Problem

Takumi Sugiura[1], **Hiroya Hoshiba**[1] **and Junji Kato**[1*]

[1] Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464-8603, Japan
junjikato@nagoya-u.jp

Key Words: *Topology optimization, Dynamic structural behavior, Finite strain, Stabilization*

The present study addresses topology optimization of finite strain dynamic structural problem with a volume constraint. The difficulty in topology optimization considering both dynamic structural behavior and finite deformation may be how to define/formulate the physically understandable and appropriate objective function and how to deal with severe mesh distortion of low density elements. Furthermore, convergence to the optimal solution deteriorates, remaining the grayscale in the final layout.

In this study, we assume a problem setting that the structure is subjected to a temporal dynamic load and then put the structure in a state of free vibration after the load released. To stabilize the structural analysis, the interpolation scheme for fictitious domain techniques by Wang et al. [1] is applied.

Firstly, the time integral of the squared nodal displacement at the target point is chosen as the objective function. Secondary, mean compliance is chosen as the objective function and the optimization results are compared with those of the first objective function. Finally, the characteristic problems in topology optimization of finite strain dynamic structural problem are discussed through a series of numerical examples.

Topology Optimization of Piezoelectric Energy Harvesters for Output Power under Harmonic Loads

Meng He* **and Liang Xia**

Huazhong University of Science and Technology, Wuhan 430074, China,
hemeng@hust.edu.cn & xialiang@hust.edu.cn

Key Words: *Topology optimization, Piezoelectric energy harvester, Output power, Polarization directions, Harmonic loads*

Output power and operational bandwidth are the two most important metrics for piezoelectric energy harvesters (PEHs) in practice. Upon literature, previous researches on topology optimization for PEHs are mainly limited to energy conversion efficiency enhancement, while much less attention has been given to the output power. This work proposes to enhance the output power by simultaneously optimizing the topological distribution of piezoelectric materials and their polarization directions. A finite element model subject to harmonic loads is particularly established, which is capable of accounting for both PEH design and external electrical resistance. To facilitate the use of gradient-based mathematical programming algorithms, the adjoint method is adopted for sensitivity analysis. Numerical examples show that the proposed method can effectively enhance the output power by simultaneous designing the piezoelectric materials and polarization directions. The effectiveness of the design results has also been further calibrated by their CAD (computer-aided design) reconstructed designs with smooth and clear boundaries.

Key Words: *Topology optimization, length scale, density filter*

Topology optimization (TO) is a widely used computational design method for achieving an optimal structure for a given design statement. The problem includes an objective that needs to be minimized, such as weight or cost, considering a few constraints, such as allowable stress and deformation. The method updates the design iteratively using the design sensitivities of the objective and constraints. For some optimization problems, the optimized structure may include thin members that might not be manufacturable. The most common tool for constraining the length scale of structural features is by using a filter, much like in image processing, which enforces a minimum length scale on the structure. In density based TO, the filter essentially averages material densities in the vicinity of each design point and its size is considered an input parameter.

The main purpose of the proposed research is to extend the basic formulation of TO such that the minimum length scale is a design variable, alongside the pointwise density. This extension can provide many advantages compared to traditional formulations, for example: avoiding stress concentrations by local increase in length scale; and reducing manufacturing costs by forming a structure with constant length scale, that can be milled with a minimal number of tools.

Controlling the length scale of the optimized structure will be achieved by applying a PDE filter. This filter utilizes the FEM solution of a Helmholtz-type PDE to generate the filtered densities from the underlying mathematical densities that are the design variables in density based TO. The PDE filter approach is computationally more economical than the more common discrete filter. At first, the length scale parameter of the PDE filter is introduced as a single design variable, allowing the optimizer to find the best minimum length scale that is constant in space. Later, we treat the minimum length scale as a continuous field that is represented by distributing design variables throughout the design space. This enables us to tackle several problems that consist of opposing functionals, such as: maximum stiffness versus minimal stress concentrations; and maximum stiffness versus minimum size variability.

[3] Dongguk University-Seoul, 04620, Seoul, Korea, heungsoo@dgu.edu

Key Words: *Variable Stiffness Composite, Multi-Fidelity Surrogate Model, Optimal Design*

Because of their superior mechanical properties, variable stiffness composite laminates with spatially varied orientation angles have gained widespread attentions from academic and engineering communities. To accurately model the spatial variation characteristic, a finite element model with refined meshes is required, resulting in high computation consumptions and making the design optimization quite changeling. Thus, optimization techniques based on surrogate models have been developed to relieve the high computation burden; however, as they rely on high-fidelity models with refined meshes, high computational resources are still involved and the information in low-fidelity models with coarse meshes are neglected. For this reason, studies with multi-fidelity surrogate models have been conducted to further reduce the computational costs, but neglecting fiber steering constraints and making the result not manufacturable. The present work is dedicated to presenting an efficient methodology based on adaptive multi-fidelity surrogate models for variable stiffness composite optimization with manufacturing constraints.

In this study, datasets consisting of many cheap low-fidelity analysis models and a few expensive high-fidelity models are sequentially sampled in the feasible design space with the use of a distance-based criterion. Multi-fidelity surrogate models are subsequently constructed assisted by Gaussian process regression; the optimization problem is solved employing the genetic algorithm, where the initial population is randomly produced in the feasible region and the fitness function is built with a penalized term of fiber steering constraints. The solution from the genetic algorithm is selected based on the distance infill criterion to adaptively update the multi-fidelity surrogate model. The above processes are sequentially executed until the convergence criteria are satisfied. When establishing the multi-fidelity surrogate model, three types of surrogate models are newly proposed, i.e. an exponential correction function, a hierarchical Gaussian process regression with shared datasets, and a hierarchical Gaussian process regression with non-shared datasets, and compared with two classical types of surrogate model, i.e. an additive correction function and a multiplicative correction function. The proposed optimization strategy is applied in cases studies of a composite plate and a composite cylinder, and optimization results demonstrate that the developed framework calls for significantly less computational consumption. Accordingly, a novel framework for variable stiffness composite optimization with fiber steering constraints based on an adaptive multi-fidelity surrogate model is proposed and its efficacy is demonstrated.

Key Words: Topology, Anisotropy, Composites, Optimization, Strength

The aim of topology optimization is to define an optimal material distribution for a prescribed load case. Nonetheless, this material distribution is influenced by the considered material properties. It was demonstrated that for compliance minimisation, the simultaneous optimization of material distribution and material orthotropy results in improved yet less bulky solutions [2]. However, the optimization algorithm used by Ranaivomiarana *et al.* [2] is limited to only compliance minimization. Furthermore, strength considerations should be included for a more relevant industrial application, and require the use of a gradient-based algorithm, such as done in [1]. Therefore, whilst taking advantage of the simultaneous anisotropy optimization with the inclusion of strength constraints, a novel topology optimization approach is first proposed. This entails a gradient based topology optimization, with the concurrent consideration of anisotropy and compared to the results of Ranaivomiarana *et al.* [2] for validation. The suggested method is constructed on the adequate combination of approximation in the Methods of Moving Asymptotes algorithm class [3] based on the nature of the variable. The polar formalism is used to characterize the anisotropy, which is limited to the space of composite laminates by means of the geometric bounds [4]. With similar results for compliance minimization, strength considerations are being included in the optimization structure. Failure will be considered by means of an anisotropic failure envelope, and aggregated into a single value in order to improve computational cost. This method was shown to be effective by Mirzendehdel *et al.* [1]. This framework will also be used for the further incorporation of buckling constraints. This research project is funded by STELIA Aerospace.

[3] The University of Tokyo, Yayoi 2-11-16, Bunkyo-ku, Tokyo 113-8656, Japan, t.yamada@mech.t.u-tokyo.ac.jp

Key Words: *Extended Level Set Method, Topology Optimization, Multi-material*

Topology optimization is one of the most flexible design methods among structural optimization methods, and it is capable of drastic improvement without depending on the initial structure, so it is expected to be very useful in engineering applications. On the other hand, in order to satisfy the required functions and cost constraints of a mechanical system, it is necessary to select materials with appropriate properties according to the application and to arrange them appropriately. Therefore, research on multi-material topology optimization methods that extend the framework of topology optimization has been actively conducted.

In this study, we propose a new multi-material representation method, the extended level set method. In this method, the level set method in two materials, is generally extended. Proposing method uses the same number of level set functions, as the number of possible phase changes in multi-material topology optimization, i.e., the number of combinations to choose two materials from among those used. The existing methods use only a smaller number of level set functions, which leads to complicated design sensitivity and high initial structure dependence.

First, we explain the formulation of the proposed method. Then construct a multi-material topology optimization method based on the new material representation method. After that, the numerical implementation method is described. Finally, numerical examples of the method applied to elastic and thermal problems are given to demonstrate the usefulness of the method. In the numerical examples, reasonable results were obtained not only for the usual stiffness maximization but also for the compliant mechanism design problem. It was also applied to the problem of maximizing thermal diffusion in a system with internal heat generation, which has few examples in multiple materials, and reasonable results were obtained. In addition, it was shown that the geometric complexity can be controlled for each combination of two materials.

We believe that this method will become one of the key concepts in multi-material topology optimization. Based on this method, the multi-material topology optimization method will be applied to a variety of mechanical problems. In addition, this method may also be applied not only to topology optimization, but also to various other fields of numerical computation that deal with multiple spatial domains.

Key Words: Digital Image Correlation, Inverse Problems, Composite materials, Finite Elements Method

We present a novel application of integrated digital image correlation to the identification of spatially variable elastic fields, applied to Discontinuous Long-Fiber (DLF) composites.

DLF composites such as carbon fiber sheet-molding compounds (CF-SMC) show good potential as a substitute to metal parts in the automotive industry due to their high specific stiffness and low-cost manufactiring process. However, the use of long fiber bundles leads to a microstructure with no scale separation, resulting in variable mechanical properties at the scale of a part. Common approaches to characterize DLF compostes rely on micromechanics simulations based on synthetic microstructures, generated from various chips packing algorithms that, in some cases, model the fibers flow and reorientation during the molding process [1]. These methods, although useful for estimating the macroscopic properties of DLF parts, show no application for identification of mechanical properties of specific parts.

Digital Image Correlation (DIC) is a common technique to measure the strain field of a material sample under loading. Digital twinning tensile tests have lead to the so called Integrated DIC (I-DIC) method, and was successfuly employed to identify parameters of non-linear constitutive laws, by minimizing the simulation to experiment gap [2]. In this work, we extend the I-DIC method to the identification of spatially varying elastic fields. Our main contribution is the identification of fields in a high dimensional space. As opposed to common application, approximating the parameter of interest sensitivity fields with finite differences is intractable, and we resort to an adjoint-based inverse problem formulation with proper regularization. Our method also recovers the experiment uncertainty parameters, such as non-uniform boundary conditions and rigid body motions. The identified elastic field of interest allows further mechanical simulation to identify local weak spots under a given loading. To the knowledge of the authors, this is the first time that non-constant elastic fields are recovered from real data.

[5]tortorelli2@llnl.gov, [6]watts24@llnl.gov

Key Words: *Reduced Order Model, Finite Element Analysis, Shape Optimization, Lattice Structures*

Micro-architected cellular structures are defined as large macroscale structures composed of unit cells. One variety of such structures are truss lattices, which are comprised of, e.g., octet truss unit cells. The fabrication of micro-architected cellular structures at fine scales over large volumes has been enabled by recent advances in additive manufacturing. Consequently, the need for accurate and efficient analysis and design optimization of these structures has increased considerably. Homogenization methods, which replace a detailed model of a unit cell with bulk properties at the macroscale, are quite popular for the simulation of cellular structures [1]. However, in practice, these approximations are often employed beyond their range of validity. On the other hand, it is costly to simulate large cellular structures using a fully resolved finite element analysis; particularly in an iterative design optimization context that requires many such simulations.

To balance accuracy and cost, we utilize a Reduced Order Model (ROM) that models the deformation of a complex unit cell structure as a type of super element [2]. Specifically, a fine-scale conformal FEM mesh of the unit cell is mapped to a single, high-order element, and the stiffness matrix of this element is computed using ideas akin to influence coefficients. The influence coefficient displacement fields serve as the element interpolation functions, rather than the usual shape functions. This technique also guarantees displacement continuity throughout the macroscopic structure, even when neighboring unit cells have dissimilar structures. Furthermore, increasing the order of the super element will yield greater accuracy. To demonstrate the performance of the proposed ROM method, we compare it against fully resolved FEM simulations of large cellular structures. Our numerical experiments show that the ROM solution converges to the fine-scale solution as the ROM order is increased.

Finally, we explore the suitability of this method for parameter-based shape optimization. In our approach, the internal characteristics of the unit cells, e.g., the thickness of the rods in truss lattices, serve as design variables. We interpolate the ROM stiffness matrix at any point in the design space using geometric mappings and machine learning. A small set of matrices for different unit cells are computed *a priori* to feed into our ML interpolation algorithms. In the optimization, we minimize the macroscopic structure's compliance subject to a constraint on its mass. We compare our results against traditional density-based methods with homogenization.

Key Words: Topology Optimization, Fiber Orientation Optimization, Composite Plates, Lamination Parameters, Variable Stiffness

In the last decades, composite materials have gained increasing interest in many industrial applications due to their advantageous mechanical properties. In addition, thanks to the recent improvements in manufacturing technologies, the fibers within the laminate can be curved to further improve performance by achieving variable-stiffness characteristics. However, in the design of variable-stiffness composites, complicated procedures are required to maximally utilize the tailoring potential while ensuring the manufacturability. The structural performance of laminates can also be enhanced through topology optimization techniques, which are mainly implemented for isotropic materials and are more recently extended for constant-stiffness composites [1]. This study addresses the optimization of both laminate topology and fiber orientation by combining moving morphable components [2] and the lamination parameter interpolation method [3] for efficient parametrization of the material layout and stiffness directionality, respectively. The topology of the structure is first optimized by assuming isotropic material properties. Then, to curb the problem dimensionality and to ensure a smooth distribution of fibers on the laminate, master nodes are placed on the key points within the optimal topology. Finally, the optimal lamination distribution in the part of the domain occupied by material is determined through distance-based interpolation. Multiple static test cases have been considered to demonstrate the applicability of the proposed approach. Since the optimization is carried out by using black-box optimization techniques, this study represents a good basis for crashworthiness applications, where the objective functions are highly multimodal and gradients are not available.

Key Words: Multiscale, Multiphysics Problems, Uncertainty propagation

Topological optimization is an example of a design that is based on the use of numerical simulation to predict the performance of a structure that does not yet exist, but whose sizing is to be guided. These approaches belong to the so called inverse many-query problems (such as uncertainty propagation) which make many calls to the direct problem of predicting the performance of a given structure. This direct problem must therefore be able to be solved at low computation cost.

In the case where micro-architectural materials are used (for example heterogeneous materials whose microstructure is made up of several phases), and with additive manufacturing techniques such as 3D printing, the microstructure (geometry and / or phases) can also be optimized on a small scale. Effective techniques must then be put in place to avoid the explosion of computational costs. Another objective is also to ensure manufacturability, with constraints on the feasibility of the microstructure. In addition, manufacturing technology needs to consider the variability in production.

We are here concerned by thermo-mechanical problems (we restrict ourselves to simplify cases of coupled linear behavior), A pseudo-periodic homogenization technique is used to understand the multiscale aspect (an additional constraint will therefore be to verify the conditions of pseudo-periodicity of the microstructure). Topological optimization is used at the macroscopic scale only, the microstructure being parameterized so as to be able to restrict the allowable (manufacturable) range of the optimization parameters of the microstructure. A previous approach was to build an abacus of macroscopic characteristics in the offline phase [2], which may turn out to be a phase expensive.

The target optimization problem is of the multiscale, multiphysical and potentially robust type. The computational cost is controlled by the use of polynomial chaos methods for the propagation of uncertainties and micro-macro substitution models [1].

Identification of a Phase Field Model for Brittle Fracture in Random Heterogeneous Elastic Media

I. Satgun[1,*], F. Pled[1] and C. Desceliers[1]

[1] Univ Gustave Eiffel, MSME UMR 8208 CNRS, F-77454 Marne-la-Vallée, France, {idiris.satgun, florent.pled, christophe.desceliers}@univ-eiffel.fr and http://msme.u-pem.fr

Key Words: Phase field model, Brittle fracture, Statistical inverse problems, Random heterogeneous elastic media

Within the framework of linear elasticity theory and fracture mechanics, this work deals with the statistical identification of a phase field model [1] for brittle fracture in random heterogeneous elastic media. Such a phase field model is typically parameterized by the critical energy release rate (or fracture toughness) and the regularization length (describing the actual width of the smeared crack representation) which are considered as deterministic and homogeneous parameters to be identified. We consider a random heterogeneous material for which the apparent elasticity properties at a given mesoscale are modeled as a non-Gaussian tensor-valued random field [2].

The identification of the fracture properties of a cracking heterogeneous elastic material requires solving a challenging statistical inverse problem. An identification method with an *ad hoc* cost function is specifically developed for solving this statistical inverse problem. The performances of the proposed identification method are illustrated on a classical benchmark problem for brittle fracture.

On the Design of Artificial Neural Networks for solving Statistical Inverse Problems in Computational Biomechanics

F. Pled[1,*] **and C. Desceliers**[1]

[1] Univ Gustave Eiffel, MSME UMR 8208 CNRS, F-77454 Marne-la-Vallée, France, {florent.pled, christophe.desceliers}@univ-eiffel.fr and http://msme.u-pem.fr

Key Words: Identification, Statistical inverse problems, Artificial neural networks, Biomechanics

This work deals with the statistical inverse identification of geometrical and mechanical properties of a biological tissue (cortical bone) using artificial neural networks (ANNs). The stochastic computational model (SCM) corresponds to a random elasto-acoustic multilayer model [1] for the ultrasonic characterization of cortical bone properties with the axial transmission technique. It allows for simulating the propagation of ultrasonic waves through a three-layer biological system made up of two deterministic homogeneous acoustic fluid layers (soft tissues and marrow bone) surrounding a random heterogeneous elastic solid layer (weaken cortical bone). A probabilistic model of the random elasticity field is introduced to take into account the uncertainties induced by the experimental configuration. The input hyperparameters of the SCM are the thicknesses of healthy and weaken parts of cortical bone, a dispersion parameter controlling the statistical fluctuations of the random elasticity field, and a spatial correlation length along the thickness direction characterizing the spatial correlation structure of the random elasticity field. The output quantities of interest of the SCM are the scattered acoustic energies stored at 14 receivers located inside the soft tissues layer. The statistical inverse problem related to the identification of these hyperparameters from given quantities of interest may be solved using classical stochastic optimization algorithms that usually require many calls to the SCM, thus resulting in a high computational cost. Alternatively, an ANN-based identification method [2] is proposed here and applied to the identification of the hyperparameters from the quantities of interest of the SCM. An initial database is first generated by using forward simulations of the SCM and allows a dataset of hyperparameters and quantities of interest to be collected. A processed database is then constructed by conditioning the hyperparameters with respect to the quantities of interest using classical kernel density estimation methods for improving the ANN performance. A multilayer ANN is finally designed and trained from the processed database to learn the nonlinear mapping between the quantities of interest (ANN inputs) and the corresponding expected mean value of the hyperparameters (ANN outputs). Lastly, the trained ANN can be used to directly perform the identification of the hyperparameters from given quantities of interest.

Semi-supervised deep learning of constitutive relations

Marius Duvillard, Loïc Giraldi* and Thomas Helfer

CEA, DES, IRESNE, DEC, Cadarache F-13108 Saint-Paul-Lez-Durance, France,
{Marius.DUVILLARD, Loic.GIRALDI, Thomas.HELFER}@cea.fr

Key Words: Constitutive relations, semi-supervised learning, deep learning, neural networks

Nuclear fuel performance codes, developed in the framework of the PLEIADES platform, require the description of complex nonlinear mechanical behaviors able to represent the microstructural evolutions of the materials under irradiation [3]. Therefore, modeling the constitutive relations is a major hurdle in order to perform mechanical computations. In this work, the constitutive relation is replaced by a neural network model, as proposed in [1]. The method has three advantages: explicit formulation of the constitutive equation is *not required*, the approach is *non-intrusive*, and the *tangent operator is directly available* thanks to automatic differentiation mechanisms implemented in modern deep learning libraries.

Different neural network models trained on synthetic datasets are presented. First, we approximate a parametric nonlinear elastic material with a deep feedforward neural network, then a history dependent material with a recurrent architecture.

Data augmentation strategies are discussed in order to tackle small labeled datasets. Moreover, the numerical stability of the computations is improved by considering constraints during the learning phase. These constraints are taken into account using two different methodologies, via the neural network architecture [4] or using a semi-supervised learning approach. The latter consists in combining a *small* labeled dataset of *strain-stress* samples with a *large* unlabeled dataset of *strain only* samples to train the model.

Finally, the methodology is applied to toy examples using the PyTorch deep learning library, the MFront material knowledge tool [2], and the FEniCS finite element platform.

Key Words: *Additive manufacturing; Bistable; Compression-torsion; Mechanical metamaterial*

Bistable structures have two stable equilibrium states in the absence of external loadings. They have been widely used in the applications of actuators, energy absorbing, precise motion control and reconfigurable structures[1]. To date, most designed bistable structures can achieve either uniaxial deformations under axial loads or torsions under torsional loads[2]. The remained open questions are that how to design the structures to achieve an extended type of deformation modes[3].

Here, we create a novel structure configuration, which realizes torsional bistability subjected to uniaxial compressive loads. The geometry of the structure is combined by two twisting chiral frame structures, which have opposite twisting modes under the same compressive loadings. In order to achieve bistability, some struts are composed of two materials which have different stiffness. By carrying out a parameter study, various compression-torsion bistable structures have been made. Furthermore, the designed compression-torsion bistable structures can be made as lattice structures and acquire multi-stability. Last, the bi-material structures are manufactured in an integrated manner by using the Stratasys® J750 3D printer. Our study provides new deformation modes and deformation mechanisms of bistable structures, and it's the first time to realize torsional bistable deformations under compression load.

Key Words: Energy Harvesting, Isogeometric Analysis, Mechanical Metamaterials, Piezoelectric, Shape Optimization, Vibrations

With the rapid development of Internet of Things (IoT) technology, worldwide efforts to seek continuous energy sources for various information sensing devices remains critical. A meritable pathway to mitigating environmental degradation is to investigate and innovate more effective renewable energy solutions that capitalise on the natural phenomena around us. Energy from mechanical vibrations provides a sustainable source that accelerates the renewable energy movement. Vibrational Energy Harvesting involves converting mechanical energy available in the environment into electrical power. Piezoelectric Energy Harvesters (PEHs) stand out over other methods due to their higher efficiency per area unit. However, scalability is their main challenge due to low energy generation and poor sensitivity to aperiodic and broadband vibrations. This study investigated the Shape Optimization of metamaterial-inspired structures to improve voltage generation. The device design consists of a periodic cells array which induces local resonance inside the structure. Here, PEHs are modelled according to the Kirchhoff-Love Plate theory and solved numerically with Isogeometric Analysis. Nitsche's Method has been used to couple multiple unit cell patches, creating a PEH plate. Comparing experimental results and the IGA solution verifies PEH dynamic behaviour from model predictions. By investigating the frequency response functions of PEH plates composed of different cell geometries, variations in metastructure designs to improve voltage output when exposed to low-frequency vibrations are studied. Developing high-performing PEHs will provide a promising pathway for manufacturing versatile piezoelectric harvesters and sustainable monitoring devices for IoT technology.

Key Words: *Cellular Materials, Effective Properties, TPMS, Finite Element Analysis*

The study of cellular materials, especially triply periodic minimal surfaces (TPMS) and their properties has gained considerable significance in the recent years due to the advancement in additive manufacturing technologies. In this study, 21 TPMS architectures are studied by comparing their effective stiffness, strength, buckling and anisotropic properties. The TPMS lattices are generated using level set equations where the relative density of each lattice is varied to study the effective properties as a function of relative density. Finite element models of these lattices are built to study the deformation behaviour under uniaxial, shear, hydrostatic and buckling loading conditions. Effective properties such as Young's modulus, shear modulus, bulk modulus, Poisson's ratio and strengths under uniaxial, shear, hydrostatic and buckling loading are computed and compared against each other and other common lattice structures[1]. In addition, anisotropic behaviour as well as the orientation dependence of the properties of each lattice are also studied. The geometric efficiency criterion is predominantly used to evaluate the different structures and the results obtained are consolidated in both quantitative and qualitative manner. Gyroid, Y and C(Y) lattice structures have the least geometric efficiency at both low and high relative densities, even though Y lattice shows higher than normal shear stiffness. The FRD, OCTO, Batwing and IWP lattices show good overall promising geometric efficiencies for most of the properties. In fact, most of the existing literature on investigating the mechanical properties of TPMS lattices and employing theme for enhancing structural efficiency has been focused on the Gyroid lattice. It is shown in this study that other lattices (e.g., FRD and IWP) are much more promising to be further investigated and employed for various structural applications. Also, Primitive lattice is highly recommended for structural applications where shear stresses and deformations are dominant such as sandwich panels. LACE (Lattice Architectures for Cellular Engineering), an open-source software which runs on MATLAB runtime library was developed to design complex TPMS architectures. LACE gives the end user the flexibility to generate intricate geometries that meets the strength and stiffness requirements for any application. The effective properties database together with LACE provides a robust framework for solving a wide range of engineering design and optimization problems.

Key Words: *frequency-adaptable, metasurface, phase shift, FEMs*

A metasurface is a two-dimensional metamaterial that possesses remarkable wave manipulation properties by controlling the wavefront arbitrarily. Based on the concept of generalized Snell's law, a metasurface could achieve any desired phase profile that covers the full 2π phase span. Nevertheless, most conventional metasurfaces are limited to permanent functionalities or working frequencies once manufactured. This hinders their applications in intelligent systems, as well as in application scenarios embedded in sharply changeable environment, which may cause their working frequency shift or even make them fail. To overcome this disadvantage, we propose an adaptive elastic metasurface composed of piezoelectric stacks to manipulate elastic longitudinal waves with high transmission performance at different frequencies. In this study, piezoelectric stacks are connected to shunted negative capacitance circuits to realize multiple functionalities without changing the structure of the metasurface. Through proper tuning of the negative capacitance in the shunting circuit, the effective modulus of the metasurface units could be tuned continuously, which enables the metasurface to produce local phase shift cover 0 to 2π range. Both analytical model and numerical simulations are developed to obtain the corresponding negative capacitances. Furthermore, computational method is used to study the effect of negative capacitances on transmission and phase shift of the waves in broadband frequencies. The proposed metasurfaces are simulated based on FEM to illustrate the functionalities, such as anomalous refraction, wave focusing and nonparaxial propagation at different frequencies, which can be easily performed by tuning the negative capacitance.

Hierarchical Isotropic Microstructures

Xue Yu[1], Yiqiang Wang[2,*]

[1] State Key Laboratory of Structural Analysis for Industrial Equipment, Dalian University of Technology, Dalian, 116024, People's Republic of China
[2] State Key Laboratory of Structural Analysis for Industrial Equipment, Dalian University of Technology, Dalian, 116024, People's Republic of China, wangyq@dlut.edu.cn

Key Words: *Microstructure, Isotropy, Hierarchical microstructures, 3D-printing*

Isotropic microstructures have identical stiffness along all directions, and they are widely used in engineering applications. Up to date, a various number of isotropic microstructures have been designed. For instance, 2D hexagonal and triangle microstructures are isotropic in plane. In 3D, a family of combined isotropic microstructures has been designed[1,2], which combines two or three elementary microstructures (i.e. simple cubics, body-centred cubics and face-centred cubics) in a right proportion. Besides, another family of quasiperiodic *n*-fold microstructures is identified to achieve isotropic stiffness[3]. Both theoretical proofs and numerical results have proved that the above two families of microstructures are able to attain the stiffness upper bounds in theory in the case of low density limit. More isotropic microstructures can also be designed by using the topology optimization technology[4].

Here, we present a novel category of isotropic hierarchical microstructures (Iso-HMs). These Iso-HMs are built by incorporating second-order microstructures into the solid regions of the first-order orthotropic microstructures. The underlying concept to achieve isotropy is to identify the right second-order microstructures that have complementary directional stiffness with respect to the first-order ones. That is, in the direction of the highest stiffness for the first-order microstructure, the second-order microstructures have the weakest stiffness, and vice versa. Several examples are presented based on the square unit cell with rectangular central holes in the first-order, wherein the crossing type microstructures are employed in the second order. By using such a design methodology, various isotropic hierarchical microstructures are obtained. It is observed that the isotropic stiffness is between the highest and lowest directional stiffness of the first-order microstructure. Also, the hierarchical microstructures have higher buckling strength than the original first-order microstructure. We will also show that by using a high-resolution PuSL 3DP technology, these Iso-HMs can be fabricated. The samples have minimal 50um features and the ratio between the maximal and minimal feature sizes reaches over 1000:1. Such a design framework could help identify a wider range of microstructures that have superior stiffness and strength, and also multi-functionals.

Intracranial Acoustic Field Optimization of a Point-Like-Scatterers-Arrayed Transcranial Lens

Tsuyoshi Ueta[1*]

[1] The Jikei University School of Medicine, 8-3-1 Kokuryo-cho, Chofu, Tokyo 182-8570, Japan,
tsuyoshi_ueta@jikei.ac.jp

Key Words: Fresnel Lens, Point-like Scatterers, Optimization, Integral Equation, Transcranial Focusing

In order to promote the effect of a thrombolytic agent as a non-invasive cure for the cerebral infarction of an acute stage, a real-time adaptive ultrasonic lens constructed by arranging point-like scatterers on a lattice has been proposed according to the concept of Fresnel lens. The structure was optimized from the initial arrangement of the scatterers.

The dependence of convergence of optimization on the initial state and on the thickness of lattice has already been investigated. Four kinds of the initial states was considered, that is, the holographically generated configuration, the configuration without the scatterers on all of lattice points, the configuration with the scatterers on all of lattice points and the configuration with the randomly distributed scatterers. It has been found that the initial configuration without the scatterers shows the fastest convergence and increase of the number of layers improves the ratio of the power of the ultrasound wave at a focal point to that of the background. The convergence of optimization for three kinds of thickness, that is, the number of layers has also systematically investigated.

The proposed lens constructed by optimally arranged point-like scatterers on a lattice has showed superior performance focusing the incident plane wave on a focal point and suppressing the sound field except the vicinity of the focal point. In the present study, we have investigated the transcranial focusing performance of the point-like-scatterers-arrayed lens. The purpose function is defined as the sound field vanishes within the skull except the focus(es) and becomes higher at the focus(es) than around. The placement of the point-like scatterers is optimized in terms of the purpose function. It has confirmed that the lens focused the incident plane wave with enough intensity even transcranially.

Key Words: *Multiscale Optimization, Resonant Frequencies, Additive Manufacturing, Lattice*

In this work a novel method of resonant frequency optimization is demonstrated using a multiscale, functionally-graded metamaterial optimization approach to predict and alter the structural and dynamic properties of an additively manufactured lattice structure. The ability to tailor resonant frequencies of structural components offers much greater design freedom for engineers and offers savings in weight and cost alongside the improved resonant properties. The metamaterial used is a 7 member, open-truss lattice with spatially varying truss radii capable of producing a functionally graded lattice structure [1].

The work employs multiscale methods using homogenization of structural properties of the unit cell dependent on the radii of its 7 members. This is achieved by determining homogenized material properties using finite element analysis (FEA) of the microscale structures subject to periodic boundary conditions. This approach is implemented in the open source, python based FEA solver, FEniCS. These simulations are used to determine the homogenized stiffness of the unit cells in the 3 principal directions and 3 shear terms as well as the lattice volume fractions. This database is then used to fit a series of 7th-order polynomials which predict the homogenized material properties based on the lattice parameters of each unit cell. During macroscale optimization the member radii are used to evaluate the material properties of the macroscale finite elements and hence evaluate the global resonant frequencies and volume fractions.

For the macroscale optimization an interior point algorithm is employed using the open source optimization software IPOPT. In this approach the truss radii represent the design variables of the optimization and the objective is the tailoring of resonant frequencies subject to volume constraints. The inclusion of a modal tracking algorithm allows for the optimizer to track resonant modes based on their mode shapes rather than frequencies. This method allows for the order of resonant modes to be changed during optimization as well as preventing localized mode shapes from interfering with the optimization process.

The work has been demonstrated through optimization of a Payload Attach Fitting (PAF) used to attach payloads to a spacecraft. The interface can be used to drastically alter and optimize the resonant frequencies of the combined PAF and payload structure. Using this multiscale optimization approach allows increased versatility, lower mass and improved resonant properties without increasing design cost. The final oral presentation will demonstrate the metamaterial's ability to achieve a large range of resonant frequencies as well as demonstrate excitation avoidance.

Key Words: *electromagnetic metamaterial, multiscale optimization, homogenization method, topology optimization*

Electromagnetic metamaterials are artificially designed materials that have special electromagnetic properties induced by a local resonance in a periodic array of unit cells, such as negative permeability. Metamaterials are expected to be applied to innovative devices, for example, superlens, filtering devices, and cloaking devices.

Designing metamaterials by trial and error is difficult because the local resonance depends on the structure of the unit cell and small differences in the design affect their overall performance. One way to solve this problem is to use topology optimization for the design. During the optimization, it needs to evaluate the performance of a metamaterial, however, it takes a huge computational cost to solve the Helmholtz equation directly to obtain the wave propagation in the metamaterial. Therefore, a more efficient method is required to optimize the metamaterial's structure. To reduce the computation cost, we introduce a high-contrast homogenization method, that was proposed in the previous work [1]. This method is suitable for the optimization of metamaterials compared to the classical homogenization methods; it can be used in a wide frequency range even if the local resonance is induced in the unit cell.

In this research, we propose a multiscale topology optimization method for the design of metamaterials that incorporates the high-contrast homogenization method with a level set-based topology optimization method [2]. First, the high-contrast homogenization method is introduced for the Transverse magnetic wave (TM wave), governed by the Helmholtz equation. Next, the multiscale topology optimization problem is formulated, in which the objective function is defined with the macro scale solution of the homogenized equation whereas the microscale structures are set as design variables. We derive the design sensitivity based on the concept of topological derivative. As numerical examples, we present waveguide problems in the T-junction structure and the demultiplexer to demonstrate the effectiveness of our method.

Key Words: *Topology optimization, Multifunctional metamaterial, Bionic design, Negative thermal expansion*

As the design of single-function metamaterials becomes more and more abundant, the importance of multi-function metamaterials design is gradually increasing. Among them, chiral metamaterials with compression-torsion coupling function have been widely studied because of their geometric characteristics and good energy absorption function. In this paper, we design a chiral metamaterial with negative thermal expansion and energy absorption buffering based on topology optimization. We find that topological results are nested by two chiral structures with fractal characteristics similar to biological structures. Inspired by this, and combined with bionic and typing design concepts, we further designed the chiral structure and added more layers. Numerical simulation shows that the enhanced fractal structure can effectively maintain the negative thermal expansion of the material. In addition, the experiments show that the multi-level metamaterial can restrain the large damage caused by structural fracture more effectively than the traditional single-layered chiral structure, and the property is universal to brittle and ductile materials.

Title

Optimization of Structures with Self-supporting Enclosed Voids and Build Orientation for Selective Laser Melting

Authors: Yu Wang, Enli Lyu, Jiaming Guo, Zhixiong Zeng, Yanhua Liu

Address: College of Engineering, South China Agricultural University, Guangzhou 510642, China

Abstract

To compromise the manufacturability and performance for additive manufactured products, this paper proposes an alternative optimization approach to achieve rational topological designs by constraining the overhang feature only in the enclosed voids and determining the build orientation in the framework of selective laser melting technique. An identification scheme based on the algorithms in image processing is proposed to detect surfaces on the closed voids. Meanwhile, a filtering technique is employed to constrain both overhang angle and overhang height of enclosed voids. Then, the identification scheme of enclosed voids and overhang feature control are integrated in integral element-wise framework to the optimize the part topology and build orientation simultaneously. In order to demonstrate the effectiveness of the proposed approach, the popular compliance minimization problems are applied in both 2D and 3D numerical cases.

[2] A.vanKeulen@tudelft.nl, [3] J.F.L.Goosen@tudelft.nl, [4] A.M.Aragon@tudelft.nl, am-aragon.science

Key Words: Ultrasonic flowmeter, 3D phononic crystals, wave rejection, multi-objective optimization, model reduction, additive manufacturing, ultrasonic transient experiments, Industrial Applications.

Ultrasonic flowmeters that use transit-time ultrasonic transducers face measurement errors due to "crosstalk," whereby the working signal travels through the solid region faster than the measuring fluid. Various solutions to this issue include isolating the sensor portion of the flowmeter from the surrounding, using damping systems inside the flowmeter, and attaching various resonators to the flowmeter. However, the resonators and damping systems are limited to relatively low frequencies (a few hundred kHz), and acoustic insulation becomes an issue in high-pressure environments. We propose a mounting mechanism based on a single-phase 3D phononic crystal (PnC), which can mitigate crosstalk at high frequencies (in MHz range) and thus improves the measurement accuracy. PnCs are artificial materials that possess bandgaps (BGs)—ranges of frequencies where elastic/acoustic waves are attenuated—that are generated due to Bragg scattering. We designed a PnC wave filter by engineering the BG frequency range to the working signal, and we fabricated it using additive manufacturing. Furthermore, we connected this wave filter to a transducer by using adequate mounting structures. We then verified the PnC wave filter's performance through transient ultrasonic experiments. Since the transducer is subjected to high pressures, we introduced additional objectives during the design procedure. A multi-objective constrained optimization problem to maximize both attenuation performance and mechanical strength was formulated, which was carried out via parametric optimization and sensitivity analysis. Since the finite element analysis of the entire structure is computationally intensive, we performed a model reduction at different stages of the optimization. Finally, we obtained a closed 3D PnC waveguide design satisfying both objectives.

Robust topology optimization for thermoelastic structures with random and interval hybrid uncertainties

Jing Zheng [1*], Hong Chen [1] and Chao Jiang [1]

[1] School of Mechanical and Vehicle Engineering, Hunan University, Changsha, Hunan Province,

jingzheng@hnu.edu.cn

Key Words: *Topology optimization; thermoelastic; robust design; hybrid uncertainties*

Considering the complex multi-physics service conditions for advanced equipment, many developments have been achieved for thermo-mechanical topology optimizations [1]. Most of these research works are focus on deterministic assumptions. However, the random and interval hybrid uncertainties related to material properties, loadings, etc. unavoidably exist in structures and may have notable influence on structural optimization [2]. A new robust topology optimization method is developed for structures under thermo-mechanical loadings considering hybrid uncertainties. Firstly, the robust objective function is defined by the lower order moments and the topology optimization model is provided under the worst case. Secondly, an efficient dimension reduction method based orthogonal polynomial expansion method is developed to calculate the statistical moments of the structural compliance, in which the multi-dimensional integrations to calculate the expansion coefficients is approximated by a series of univariate integrations. Finally, several numerical examples are provided to verify the effectiveness of the proposed method. It is proved that the robust designs have better robustness than the deterministic designs considering hybrid uncertainties.

Topology Optimization for Pentamode Lattice Metamaterials

Zuyu Li[1*], and Zhen Luo[2]

[1] University of Technology Sydney, Ultimo, NSW 2007, Australia, zuyu.Li@student.uts.edu.au
[2] University of Technology Sydney, Ultimo, NSW 2007, Australia, zhen.luo@uts.edu.au

Key Words: *Pentamode, Mechanical Metamaterials, Lattice, Topology Optimization*

Pentamode metamaterials are a new class of artificially engineered lattice metamaterials with vanishing shear modulus and able to support single mode of stress. In this research, a topological optimization method is first developed to generate pentamode lattices which will exibit effective material properties over a range of relative densities. The design of the pentamode microstructure is defined as a three-dimensional ground structure with at least orthotropic symmetry. Then, the necessary and sufficient condition for the elasticity matrices of pentamode metamaterials with at least orthotropic symmetry is proposed. This research shows that a large ratio between the bulk modulus and the shear modulus is not a sufficient condition for pentamode metamaterials that are not isotropic. After that, a range of new pentamode microstructures are created to demonstrate the effectiveness of the proposed design method. This study will supply a very solid foundation in princicple for application of pentamode applications, including cloaking devices.

Two-scale Concurrent Structural Topology Optimization Considering the Microstructural Connectivity

Pai Liu*, Zhan Kang and Yangjun Luo

Dalian University of Technology, China. No.2 Linggong Road, Ganjingzi District, Dalian City, Liaoning Province, P.R.C., 116024. pailiu@dlut.edu.cn

Key Words: *Topology Optimization, Homogenization, Microstructure Connectivity*

The simultaneous optimization of the spatial distribution of multiple kinds of microstructures within a structure and their geometry configurations can effectively tailor the structural mechanical performance and enhance the multi-physics functionalities. The topology optimization technique in combination with the homogenization method have been widely adopted in such two-scale design problems. However, the homogenization-based design methods do not necessarily ensure the connectivity between different kinds of the optimized microstructures. Several methods [1-2] have been proposed to enhance the microstructural connectivity by setting up non-design domains in the microstructure based on the design experience or applying multiple optimization constraints on the microstructural boundaries.

To handle the microstructural connectivity issue, this paper proposes a microstructural connectable region method in the context of two-scale concurrent multi-material structural topology optimization. On the microscale, we parameterize the microstructural topology with the elemental relative densities, and compute their effective properties using the homogenization method. On the macroscale, we employ the discrete material optimization (DMO) method to describe the distributions of the multiple kinds of cellular materials within the design domain.

By predefining a connectable region within each kind of the designable microstructure and linking the microscale design variables therein, the connectivity between any two kinds of the microstructures is ensured naturally without applying any optimization constraints. The two-scale concurrent topology optimization problem is solved with the method of asymptotic method. This method is verified by the two-scale concurrent structural topology optimization 2D and 3D problems.

Construction of the Education Tools for the Computer Programming - by the use of Problem Solving Environment –

Shinji Hioki

Tezukayama University, 7-1-1 Tezukayama , Nara 631-8501, JAPAN,
hioki@tezukayama-u.ac.jp

Key Words: *Programming, Education, Data Science, Society5.0, PSE,(Problem Solving Environment)*

In Japan, programming has become a important subject in elementary, junior high, and high schools in order to develop human resources who can cope with the Society 5.0 society. Data science education is also highly expected in universities.

There are many books, Internet sites, and paid workshops for learning programming in the world. When beginners learn programming, what can they expect to have learned?

There are various certifications available for this purpose. However, most of the certifications are knowledge-based, and it is a fact that they are not always practical in the real world.

Therefore, I propose a problem-solving type learning tool as an internet site.[1]
Here, if you can solve a problem, you can be considered to have learned programming.

We will prepare various problems with many examples in several languages to help the students learning.

For languages, we have so far prepared scratch, Python, and C++ [2], and we will add HTML, CSS, and PHP to them.

As for the problems, we have added access counters, bulletin boards, and the use of arrays and random numbers.

I hope that this site will help people (especially beginners) to learn programming.

Key Words: *Underwater Mapping Data, AUV, ASV, Deep Learning, CNN, PointNet*

The recent development of underwater robots and measurement equipment, it has become possible to achieve high-quality underwater mapping using acoustic survey equipment with high resolution. The underwater mapping data obtained by these methods are expressed by the intensity of sound reflection and do not have color information. As a result, object identification from the acquired data depends on discrimination by professional engineer, and it is not only difficult to identify objects automatically and quickly, but also involves human error due to differences in the experience of the engineer and routine tasks.

In this presentation, a fast and accurate classification method for underwater objects using underwater mapping data obtained by a small Autonomous Underwater Vehicle (AUV) and autonomous surface vehicle (ASV) is presented. For the mapping data, in addition to underwater acoustic reflection intensity images, water depth data, point cloud data and backscattering reflection intensity data are employed. We propose the automatic classification and semantic segmentation method on deep learning using a convolutional neural network (CNN) and PointNet. In order to verify the effectiveness of the present method, we applied it to the measured several underwater mapping data.

Tsunami Evacuation Simulation Considering Building Collapse and Fire Spread

kaz@civil.chuo-u.ac.jp

Key Words: *Multi Agent Model, Evacuation Simulation, Building Collapse, Fire*

Japan is one of the world's leading disaster-prone countries, and has an extremely high frequency of natural disasters such as earthquakes, tsunami and typhoons. Regarding the Great East Japan Earthquake in 2011, it had been found that there is a limit to disaster prevention measures on the hardware aspects such as construction of breakwaters. And the importance of the software measures was confirmed. As one of the software measures, each municipality has been preparing hazard maps. However, hazard maps make it difficult to understand when and how to evacuate. Thus, research on evacuation simulation, which can show the above at a glance, has been widely conducted in recent years.

The present authors have also developed a tsunami evacuation system using multi-agent models. However, not only tsunami but also building collapse and fire spread have a significant impact on evacuation behaviours and survival rates of refugees as secondary damages of earthquakes.

Therefore, the purpose of this study is to develop a tsunami evacuation simulation system that considers building collapse and fire spread. The road blockage is determined by calculating the probability of road blockage due to building collapse, taking into account the scale of the assumed earthquake, the location of buildings, and the type of building [1]. For fire spread simulation, an existing simulator [2] based on the fire spread rate equation is used. Under the condition of average wind direction and wind speed in the target area, the fire spread is represented by setting any fire point and using the fire time of each building obtained by the simulation. The present system is applied to several examples to demonstrate the validity and effectiveness of the system.

Key Words: *Augmented Reality, GNSS, marker tracking,*

The visualization method for flow simulation based on Augmented Reality (AR) and Virtual Reality (VR) are becoming more powerful and popular tool for planning and design of various construction projects in accordance with the development of AR and VR technology. Focusing on AR, the AR visualization method using smartphone is attracting attention from the viewpoint of usability. The present authors have been presented a AR visualization system based on markerless augmented reality for water environmental flow problems [1]. In this system, a landscape image is used as a marker. However, this method has a problem in the stability of superimposition of CG image.

Recently, the AR using the data obtained Global Navigation Satellite System (GNSS) has been attraction attention due to the improvement of accuracy of GPS. In addition, the use of GNSS data in AR visualization has the advantage that it is not affected by the presence or absence of feature points acquired from cameras or the setting of marker locations used in marker superimposition.

This paper presents an AR visualization system for flow simulation based on AR using GNSS data. The target of visualization deals with the flow of river and sea. The present system is applied to several visualization examples to demonstrate the validity and effectiveness of the system.

Key Words: *VR, Full Sky Images, Elementary School, Field Trip, Covid-19,*

The spread of Covid-19, which began at the end of 2019, has led to significant changes in school education. In particular, the simultaneous closure of schools in March 2020 is still fresh in our minds, but even after that, the field of education has been subjected to various restrictions (e.g., wearing masks, dispersed school attendance, silent meals during school lunch hours, etc.).

One of the most serious cases is the cancellation of social studies field trips. The Ministry of Education, Culture, Sports, Science and Technology's Guidelines for the Course of Study (Social Studies)[1] mentions that "it is important to allow students to conduct specific research by incorporating field trips and using materials prepared by relevant organizations, according to the actual conditions of the region. This is important in terms of learning through actual experience. However, under the Covid-19 epidemic, social studies tours have been cancelled, and students have lost the opportunity to study in the field.

Therefore, with the planning and cooperation of the Ministry of Land, Infrastructure, Transport and Tourism, we created a VR tour of the Gojiri Dam and the Kawaji Dam in Tochigi Prefecture. The tour was held in November 2021 for a total of 32 fourth and fifth graders of Kinugawa Elementary School.

The purpose of this presentation is to report the outline of the VR tour and to contribute to the consideration of the use of VR in school education.

Key Words: contact mechanics, AMT, load balancing

Robust contact search and enforcement is one of the more computationally intensive aspects of solid mechanics simulations. Distributed contact problems often engender a divergence between the cost of executing non-contact work versus contact work during the simulation. Implementations typically decompose mesh elements statically according to the expected load during the non-contact steps. However, the unpredictability of workloads during the contact search and enforcement step can lead to suboptimal performance with these decompositions due to imbalances that cause some processors to idle. These imbalances can be remedied by remapping contact work to other processors dynamically over the course of the simulation's timesteps.

We propose a contact algorithm that uses the dynamic load capabilities of the DARMA/vt asynchronous distributed tasking library to automatically rebalance computational loads. By exploiting the principle of persistence, we utilize instrumentation from previous time steps to load balance the current time step. This approach also accounts for migration and ghosting of elements onto processors for evaluating the contact kernels in an efficient manner. We examine several problems with a varying degree of load imbalance issues and show how our load balancing approach can improve performance significantly.

Discretizations of high-frequency wave propagation problems on next-generation computing architectures

Julia Plews[1], **Gregory Bunting, Jerry Rouse, and Clark Dohrmann**

Sandia National Laboratories, Albuquerque, NM, USA
email: japlews@sandia.gov

Key Words: High-order, discontinuous Petrov-Galerkin, p-FEM, wave propagation

Solutions to high-frequency wave-propagation problems using traditional, low-order finite element discretizations suffer from the well-known pollution effect. Several strategies are readily available to circumvent pollution error, including high-polynomial-order finite element formulations and adapted meshes (*hp*-FEM), as well as advanced alternative discretization approaches. We concentrate on high-order continuous Galerkin FEM, as well as the discontinuous Petrov-Galerkin (DPG) method, which reduces or eliminates pollution error in numerical simulations of wave propagation problems [1]. Unfortunately, high mesh refinement and p-order required to resolve very high-frequency waves at acceptable fidelity and with minimal pollution present a challenge for ordinary computational resources. Innovations in simulation software design and increased computing power are needed to address high computational complexity and memory use.

In this talk, we look to on-node accelerators to enable high-order simulations. Graphics processing units (GPUs), with their high throughput on intensive mathematical operations, lend themselves naturally to this application. We will discuss the performance-portable discretization software tools developed as part of this work, leveraging GPU-enabled packages for high-order discretizations, linear solvers, and linear algebra operations in the Trilinos library [2]. Accuracy and performance of high-order FEM and DPG applied to the wave propagation problems of interest will also be demonstrated, investigating in detail the behavior of these methods on both conventional CPU and GPU-accelerated computers.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Ensemble Computations on Heterogeneous Supercomputers

Gianluca Iaccarino[1]

[1] Mechanical Engineering Department,
Stanford University, Stanford 94035 CA (USA)
jops@stanford.edu

Key Words: *Uncertainty Quantification, Multiphysics Problems, Multifidelity Ensemble, Task-based programming, Heterogeneous Computations*

Computer simulations are pervasive in science and engineering. Computations, together with theoretical analysis and experiments, constitute the foundation for building knowledge, whether it be to investigate a new physical phenomenon or to assess the performance of an innovative device. However, a single computation, despite its sophistication and complexity, can rarely provide sufficient and credible evidence to support a decision. To build confidence in computed outcomes, one typically conducts sensitivity analyses, investigates uncertainty, and explores design variations. All these approaches require an ensemble of computations whose results are combined rigorously via statistical analysis or optimization. In this talk we discuss the use of ensemble of simulations for multidisciplinary design under uncertainty; we have developed a novel algorithm to handle ensemble with different fidelity implemented in a new programming environment that enables the efficient use of next generation supercomputers, i.e. a hybrid CPU/GPU multimode machine. The approach is based on the Legion programming system, a data-centric task-based approach that has been shown to achieve portability and performance on a variety of modern systems (including Summit) and different complex multiphysics applications. We will present uncertainty quantification studies carried out for a solar received device and for a laser-based ignition systems using high-fidelity simulation codes written entirely in Legion. Furthermore, a theoretical framework for optimal multi-fidelity scheduling on heterogeneous computer architectures will be discussed.

Solving real-world industry problems in the field of simulation and digital twins can be really challenging in terms of computational resources. This stems, not only from the complexity and sheer magnitude of the computational models of such problems but also from the fact that the evaluation of the model response model involves the repeated solution of near-by problems, either from the evaluation of non-linear transient response and/or from the evaluation of the uncertainty response of the model [2].

Computational challenges are also present when considering multiscale analysis since the evaluation of the constitutive behavior of a material involves the solution of another detailed model. The combination of both, especially for the case where the aforementioned computational models have uncertain properties, can result in enormous computational demands that can be met only with the use of HPC platforms and algorithms.

In an effort to provide pay-as-you-go computational mechanics services where such challenges need to be addressed, NComp has utilized MSolve [1] and developed specialized HPC modules that utilize distributed parallel algorithms that harness the power of both CPUs and GPUs [3] in order to solve such demanding problems in reasonable wall clock times, relying on public cloud resources. In this work, we will describe the computational paradigms, APIs and algorithms that were used for this endeavor.

Optimizing Open-Source CFD Software on a GPU Supercomputer

Yosuke Oyama[1*] **and Koichi Shirahata**[1]

[1] Fujitsu Limited, Kamikodanaka 4-1-1, Nakahara-ku, Kawasaki 211-8588, Japan,
{oyama.yosuke, k.shirahata}@fujitsu.com

Key Words: OpenFOAM, RapidCFD, conjugate gradient method, DIC, DILU

OpenFOAM [1, 2] is GPL licensed open-source CFD software. OpenFOAM runs as a single CPU process, but also as multiple MPI processes by applying spatial decomposition to the target domain. Studies have been reported that the software scales to thousands of CPU cores [3]. However, it does not support any accelerators such as HPC-oriented GPUs, which usually have higher memory bandwidth than high-performance CPUs.

In this presentation, we propose various techniques to accelerate RapidCFD [4], a GPU version of OpenFOAM mainly developed by SIMFLOW Technologies: 1) We propose a GPU-accelerated version of the Diagonal-based Incomplete Cholesky (DIC) and the Diagonal-based Incomplete LU (DILU) preconditioners. Our DIC/DILU implementation applies a graph-coloring algorithm to coefficient matrices to detect available parallelism on its forward and backward substitution steps. 2) We identify and resolve RapidCFD's potential performance issues that become bottlenecks on large-scale runs, including redundant memory allocation/deallocation and fragmented GPU kernels. 3) We propose an adaptive method to adjust collective communication frequency among processes during CG iterations.

We evaluate the performance of our proposed methods on the ABCI supercomputer; we achieve a 2.6x speedup than OpenFOAM on ABCI's 64 NVIDIA A100 GPUs to compute a 68 M-cells unstructured mesh. We also evaluate the effectivity of 3) under a strong-scaling configuration, resulting in a 1.6x speedup than the original code on 32 A100 GPUs. In addition, we discuss performance advantages of the two different architectures (CPUs and GPUs) for such CFD software and its future prospect.

Understanding the current computer systems limitations and their abilities to run application programs at peak performance is an important requirement for designing the next generation of parallel architectures. A software approach relies on profiling the performance bottlenecks to uncover parts of the architecture which should be enhanced. We focus our analysis on a real application that we received from industrial users: a large-scale simulation of Kumamoto earthquake used in design innovation. This application is governed by a time marching loop (Newmark-beta) and a nonlinear loop (Newton-Raphson) nested inside. Iteratively, a discretization (FEM) builds the input matrix and a solver computes the linear solution.

Structural Analysis simulations are often memory-bound due to large matrix processing. To alleviate this problem, domain decomposition is applied on the input mesh so that multiprocessing can accelerate the computation on distributed memory. However, our analysis shows that several aspects limit the performances on both Fugaku and ABCI supercomputers. Locally, the matrix generation hotspot loops are slow down by the CPU cache hit latency and inefficient memory access. At large scale, the strong scalability is limited by the preconditioner power, a high load-imbalance affects the parallel efficiency of matrix generation and a 30% communication overhead degrades the solver computation.

In this work, we propose a series of performance tuning for the *FrontISTR* nonlinear dynamic solver based on a systematic approach which is driven by the roofline model for assessing hardware limitations of computer systems. We identified the main performance bottlenecks with profilers then we generated and located the positions of each hotspot loop kernels on the roofline model. From such insights, we applied appropriate optimizations (vector alignment, loop unrolling, arithmetic tuning, dimension exchange) and analysed the effect of various parameters (stride memory accesses, store, fma and simd instructions) to minimize the gap between kernel points and the compute/memory performance ceilings.

Our performance tuning achieved a 3x acceleration of the two main hotspot loops among others, resulting in a 1.83x speed-up of the overall stiffness matrix generation computation.

Key Words: Multiscale Problems, Matrix-free solvers, software design, high performance computing

Ratel is a new, open-source package built on libCEED [1] and PETSc [2] capable of solving complex solid/fluid mechanics problems without sacrificing computational performance. This package provides a flexible yet intuitive user interface that reduces the prerequisite effort required for use, encouraging community involvement and development. Similar to libCEED and PETSc, Ratel is both performance portable and scalable allowing for effective material simulations on a variety of computing systems. Notably, Ratel uses single-source physics implementations with Just-In-Time compilations (rather than with domain specific languages or templates) and supports matrix-free high order elements. Additionally, we discuss high-performance automatic differentiation using Enzyme [3] to simplify the development of new material models with consistent Jacobians. We discuss Ratel's solver functionality including quasi-static and dynamic solvers and composite material support. In this presentation we also investigate Ratel's performance on CPUs and GPUs, number of nodes, and solver degree for various physical simulations taken from Ratel's example suite. Finally, Ratel is structured to support uncertainty quantification and optimization studies.

Design of Filters Consist of Resolvents with Real Shifts for Solving Eigenpairs with Lowest Eigenvalues

Hiroshi Murakami[1*]

[1] Tokyo Metropolitan University, 1-1 Minami-Osawa, Hachi-Oji, Tokyo, Japan,
<mrkmhrsh@tmu.ac.jp>

Key Words: Eigenproblem, Filter, Resolvents, Real Shifts

By using a filter, we solve a small number of eigenpairs of a real symmetric-definite generalized eigenproblem whose eigenvalues are lowest. The filter we use is a Chebyshev polynomial composed of a linear combination of a small number of resolvents and an identity. In present study, all shifts of the resolvents used are restricted to real numbers less than the lowest eigenvalue. Then the filter's transmission function is a Chebyshev polynomial composed of a rational function of the eigenvalue. And the rational function is a sum of a small number of the inverses of the shifted eigenvalues and a constant.

For each case of the number of resolvents is from one to three, for the specified three important parameters on the shape of the filter's transmission function, we try to find the combination of the degree of the Chebyshev polynomial and the rational function. If it exists, correspondingly the filter can be constructed as the Chebyshev polynomial of the linear combination of resolvents and an identity. To find the combination, first the degree of the Chebyshev polynomial is assumed, and then the shifts and the constant which determine the rational function are searched, so that the ranges of the value of the rational function satisfy conditions in three regions of eigenvalue of the filter namely the pass-band, the transition-band and the stop-band. When complex shifts were allowed, for any number of resolvents the rational function was given from the best approximation theory. But the theory does not apply when shifts are restricted to be real, and the filter's transmission properties become not very good.

By restricting shifts to real, we have an advantage especially when the system of linear equations is solved by some matrix factorization method. The computational requirement of an application of a resolvent by solving a system of linear equations is reduced when the shift is real than it is imaginary. For example, the amount of storage required with real shift is about a half of that with imaginary shift. The count of arithmetic operation is also reduced. But, the poor properties of filter's transmission when all shifts are reals may require the repeated applications of the filter or increased number of vectors to be filtered than when shifts are complex numbers especially when higher accuracies of eigenpairs are desired.

First order least-squares formulations for eigenvalue problems

Fleurianne Bertrand*

University of Twente, f.bertrand@utwente.nl

Key Words: *First order least-squares, eigenvalue problems*

In this talk we discuss spectral properties of operators associated with the least-squares finite element approximation of elliptic partial differential equations. The convergence of the discrete eigenvalues and eigenfunctions towards the corresponding continuous eigenmodes is studied and analyzed. a priori and a posteriori estimates are proved in the Poisson and linear elastic case.

Applications to vibration analysis in elastic structures and in problems concerning the fluid–structure interactions are presented. In fact, the common way to determine vibration modes, the primal approach based on the minimization of an energy depending on the displacement variable does not lead to uniform accuracy for nearly incompressible materials such as common blood vessel walls or the heart muscle, except if the degree of the polynomial approximation is kept very high, leading to a high computational effort.

Stresses can be computed from the primal approach in post-processing, but this approach leads to stresses where divergence is not squarely integrable. They are not H(div)-conforming and surface or interface traction forces cannot be evaluated. Moreover, momentum cannot be conserved exactly. As these quantities are driving quantities, the standard methods are not accurate enough in many challenging applications and stress-based methods are known to be a game changer. However, the symmetric gradient arising in the corresponding PDE is a difficult condition to impose at the discrete level. The conforming discretization of those stresses (so-called Arnold-Winther approach [1]) is sophisticated and increases the computational cost enormously. To develop a new class of extremely efficient numerical methods that compute vibrations with high guaranteed accuracy,

One of the major advantages of the Least-Squares method, is the symmetry and positive definiteness of the formulation. At first glance, the consideration for eigenvalue problems seems to conserve neither the minimization property nor the symmetry and complex approximations were obtained in [2]. However, [3] shows that the symmetry of the methods can be recovered, as well as the inherent error estimator. The approach leads to optimal convergence of the eigenvalues.

Sequences of structured matrices of increasing size arise in many scientific applications and especially in the numerical discretization of linear differential problems. We assume as a working hypothesis that the eigenvalues of a matrix X_n belonging to a sequence of this kind are given by a regular expansion. Based on this working hypothesis, which is illustrated to be plausible through numerical experiments, we propose an eigensolver [1] for the computation of the eigenvalues of X_n for large n. The eigensolver is called matrix-less because it does not operate on the matrix X_n but on a few similar matrices of smaller size combined with an interpolation-extrapolation strategy. Its performance is benchmarked on several numerical examples, with a special focus on matrices arising from the discretization of differential problems, and turns out to be quite satisfactory in all cases.

{manni,speleers}@mat.uniroma2.it

Key Words: Fractional Operators, B-spline Collocation, Toeplitz Matrices, Spectral Analysis

Fractional operators, see e.g. [3], are a mathematical tool that received much attention in the last decades because of their non-local behavior which has been demonstrated to be useful when modeling anomalous diffusion phenomena appearing, e.g., in imaging or electrophysiology. The improved physical description of the considered phenomenon obtained by replacing a standard derivative with a fractional one, however, translates in a more challenging numerical treatment of the corresponding discretized problems. Indeed, even when standard local discretization methods are adopted, the non-locality of the fractional operators causes absence of sparsity in the discretization matrices. This makes fractional problems computationally more demanding than standard partial differential problems and stresses the need of a proper numerical linear algebra analysis.

In this work, we focus on a fractional differential equation of order α in Riesz form discretized by a polynomial B-spline collocation method [2]. For an arbitrary polynomial degree p, we show that the resulting coefficient matrices possess a Toeplitz-like structure [1]. As such, we investigate their spectral properties via their symbol, a function which describes the asymptotic spectral distribution of a sequence of matrices, as the size tends to infinity. We prove that, like for second order differential problems, also in this case the given matrices are ill-conditioned both in the low and high frequencies for large p, with a mitigated conditioning in the low frequencies and a deterioration in the high ones. Moreover, as a side result of the symbol computation, we are able to express the central entries of the coefficient matrix as inner products of two fractional derivatives of cardinal B-splines. Finally, we perform a numerical study of the approximation behavior of polynomial B-spline collocation which suggests that the approximation order for smooth solutions is $p+2-\alpha$ for even p, and $p+1-\alpha$ for odd p.

[2] Inst. of App. and Comp. Math. (IACM), FORTH, Heraklion 71110, Greece
[3] King Abdullah University of Science and Technology, Thuwal 23955-6900, Saudi Arabia

Key Words: Elastodynamics, Optimization, Galerkin methods

In [1] the system of elastodynamics in 1D was discretised in time and the resulting semidiscrete scheme is shown to admit a variational formulation. The solutions of this variational problem are shown to converge as the discretization parameter vanishes, in some sense, to the solution of the original continuous problem. This approach can be extended also to higher dimensions and produces solutions which are admissible in the sense that satisfy entropy inequalities. In this work we consider this approach from the point of view of constructing a new class of numerical schemes for approximating solutions to the system of elastodynamics. The approximation is associated to viewing the equations of elasticity as a Hamiltonian system, and considering the time-discretization of the dynamics.

The basic idea of the time discrete scheme is that given the solution at the first $j-1$ time steps, j-th time step is approximated by solving a constrained minimization problem. We propose a fully discrete scheme where we minimize the associated functional using optimization techniques. The fully discrete scheme is based on the continuous or discontinuous Galerkin finite element method, [2, 3]. The Gradient Descent method is utillized for approximating solutions to the optimization problem and it's enhanced with various accelerating techniques for overcoming well known pitfalls of the algorithm.

We investigate the computational efficiency and stability of the new class of schemes and we compare them with the standard finite volume and discontinuous Galerkin schemes for conservation laws. We consider test cases with smooth and non-smooth solutions and the preliminary results are very encouraging.

[3] University of the Basque Country UPV/EHU, Leioa, Spain
[4] Ikerbasque – Basque Foundation for Sciences, Bilbao, Spain
[5] Faculty of Science and Engineering, Curtin University, Perth, Australia

Key Words: Quadratic eigenproblems, Refined isogeometric analysis, Krylov eigensolvers.

We propose to use refined isogeometric analysis (rIGA) [1] to solve quadratic eigenproblems. rIGA, while conserving desirable properties of maximum-continuity isogeometric analysis (IGA), reduces the interconnection between degrees of freedom by adding low-continuity basis functions. Herein, we consider rIGA and IGA discretizations when employing Krylov eigensolvers to solve quadratic eigensystems arising in 2D vector-valued multifield problems. We use C^0 and C^1 separators at certain element interfaces for our rIGA generalizations of the curl-conforming Nédélec and divergence-conforming Raviart–Thomas finite elements [2]. For large problem sizes, the eigencomputation cost is governed by the cost of LU factorization [3], followed by costs of matrix–vector and vector–vector multiplications in the sense of Krylov projection. Let p be the polynomial degree of basis functions, the LU factorization is up to $\mathcal{O}\big((p-1)^2\big)$ times faster when using rIGA compared to IGA in the asymptotic regime. Thus, rIGA theoretically improves the total eigencomputation cost by $\mathcal{O}\big((p-1)^2\big)$ for sufficiently large problem sizes. In practical moderate-size problems, the improvement rate deteriorates when increasing the number of requested eigenvalues because of multiple matrix–vector and vector–vector operations. Our numerical tests show rIGA improves the total eigencomputation cost of quadratic eigensystems by $\mathcal{O}(p-1)$ for moderately sized problems when we seek to compute a reasonable number of eigenvalues.

[2] CERMICS, ENPC & INRIA Paris, France, alexandre.ern@enpc.fr
[3] EECMS, Curtin University, victor.calo@curtin.edu.au

Key Words: eigenvalue, elliptic operator, finite element method, isogeometric analysis

I this talk, the speaker will present the recently developed methods, namely, the soft finite element method (softFEM) and the soft isogeometric analysis (softIGA), for solving the elliptic eigenvalue problem. The prefix "soft" refers to the main idea that the stiffness of the discretized system is softened. We remove the non-physical energy associated with the high-frequencies in the spectrum via penalty terms with negative coefficients . At the matrix level, this means that condition number is reduced. The stiffness (or condition number) reduction ratio scales linearly with the oder of the underlying element and is $1 + \frac{p}{2}$ for softFEM (FEM to softFEM raito). The two key advantages are to improve the approximation of the eigenvalues in the upper part of the discrete spectrum and to reduce the condition number of the stiffness matrix. In the end, the speaker will discuss how these methods can be applied to time-dependent problems with larger time steps for explicit time-marching schemes while ensuring the stability.

Key Words: Partial differential equation, eigenvalue problem, virtual element method, parameter dependent matrices

In this talk we consider the virtual element approximation of the solution of eigenvalue problems associated with partial differential equations. Due to the need of stabilizing the bilinear forms involved in the discrete formulation of the problem, the matrices appearing in the associated generalized eigenvalue system might depend on parameters (see [1]). We discuss how the presence of such parameters can produce unexpected results even in the approximation of the Laplace eigenvalue problem and try to address the question of finding the best choice in order to achieve spectral correctness together with optimal approximation properties. The virtual element approximation of eigenvalue problems for several applications has been investigated in recent years, however the question of the choice of the optimal parameters is only occasionally addressed (see [2] for a survey). We investigate further the VEM discretization of the acoustic vibration problem, and show that in this case there is no need of using any stabilization for the stiffness and mass matrix.

Key Words: approximate inverse preconditioning, Krylov subspace method, graphics processing unit

In recent years, graphics processing units (GPUs) have been used to efficiently solve a linear system by means of a preconditioned Krylov subspace iterative method. To fully exploit the potential of GPUs for massive data processing, the preconditioner is required to have a high degree of parallelism. Whereas most ILU–type preconditioners, based on the ILU (or IC) factorization, require forward/backward substitution in their preconditioning operations, the approximate inverse (AINV) preconditioner [1], which is one of the sparse approximate inverse preconditioners, is implemented by sparse matrix-vector multiplication (SpMV). SpMV has a higher degree of parallelism than the forward/backward substitution because SpMV does not involve data dependencies, unlike the forward/backward substitution. From this perspective, the AINV preconditioner is more suitable for execution on GPUs than the ILU–type preconditioners. However, the incomplete conjugate algorithm (AINV algorithm), which constructs the AINV preconditioner, tends to take a long time compared to the ILU factorization [2]. Therefore, it is important to improve the AINV algorithm to make AINV preconditioning more attractive.

Considering this background, we propose a new version of the AINV algorithm: position-based simplified AINV (PS-AINV) algorithm. The basic idea of the PS-AINV algorithm is to simplify the standard AINV algorithm based on the positions of the nonzero elements of a coefficient matrix. Thanks to the simplification, the PS-AINV algorithm not only runs faster but also has coarse-grained parallelism; that is, speed-ups by both simplification itself and multi-thread parallelization are expected. Numerical results showed that the PS-AINV algorithm constructs the preconditioner faster than the standard AINV algorithm without significant performance degradation in the iterative part. As a result, the performance of the whole solver (the sum of preconditioner construction and PCG iteration) was also improved.

Key Words: *Mixed Precision, Energy Optimization, Auto-tuning, ppOpen-AT*

To have a technological breakthrough in Post Moore's era, several challenges have been studied. One of promising approaches is utilizing mixed precision computations to obtain speedup and low power computations. However, it is not easy way to adapt mixed precision computations to arbitrary codes, since the speedup factors depends on hardware. In addition, down of computation accuracy also depends on nature of treated numerical problems.

To shove the above problem, we propose an auto-tuning (AT) function for dedicated AT language, named ppOpen-AT [1]. The ppOpen-AT is a directive-based computer language to adapt AT function into arbitrary parts of programs. The proposed function can specify lower types of accuracies into the following two parts: (1) Specified variables or arrays (SVA) in definition parts in program; (2) Specified blocks in the program (SBP).

To autotune its computational accuracy, software developers need to specify acceptable down of accuracies in advance for software developers. After specified targets of changing accuracies, code generator of ppOpen-AT generates all combinations of candidate codes. There is an additional process is automatically generated in the target parts, such as copies and stores from arrays with higher precision to arrays with lower precision. This causes overhead of execution time, and additional power consumptions for the generated code.

Effectiveness of the proposed functions are evaluated with NICAM [2], which is a practical numerical simulation code with global cloud resolving model. In this evaluation, we use a part of tiny cloud physical computations. The part consist of a subroutine of **physicskernel_microphysics** in **mod_mp_nsw6.f90** in NICAM benchmark, **nicam_dckernel_2016**. Target part is a three-folded loop with heavy loop body for computations. In this evaluation, length of loop is fixed. There are several output values after exiting the target loop. Hence computations with lower accuracies directly affect computational accuracies.

Result of the above evaluation indicates that: (1) speedup factor of 1.04x and 1.06x reduction of energy consumption by keeping accuracy of 1.E-13 for the SVA; (2) speedup factor of 1.12x and 1.06x reduction of energy consumption, if we accept down of accuracy for 3.E-4 for the SBP.

Key Words: *Heterogeneous system, Coupled simulation, Atmospheric model, Machine learning*

In this presentation, we discuss coupled computation of multiple models in a heterogeneous system consisting of a group of nodes with different architectures. This computation is referred to as heterogeneous coupling, and we introduce our studies on heterogeneous coupling.
The system utilized herein is the Wisteria/BDEC-01 of the University of Tokyo. Wisteria/BDEC-01 is a hybrid system with two groups of compute nodes: simulation nodes (Odyssey), which equips A64FX, and data/learning nodes (Aquarius) with Intel Xeon processors and NVIDIA A100 Tensor Core GPUs. Additionally, the target programs are the atmospheric model, NICAM [1], and the data analysis software, ADA. Herein, ADA is applied to the machine learning library PyTorch. This study aims to couple NICAM on Odyssey and ADA on Aquarius, as well as perform real-time machine learning on the computed values of NICAM.
To achieve this goal, we developed two software packages; WaitIO-Socket, which is a low-level data communication software, and h3-Open-UTIL/MP [2], which is a general-purpose coupling software. In general, MPI is used for data communication between programs in MPMD calculation. However, MPI library cannot be applied between Odyssey and Aquarius. Therefore, we developed the WaitIO-Socket to realize the communication between the two systems.
It uses TCP/IP for communication and implements an MPI-compliant interface. h3-Open-UTIL/MP is a coupling software that performs grid remapping and data exchange among multiple models. For NICAM-ADA coupling, h3-Open-UTIL/MP is utilized to convert NICAM data of high-resolution grid to low-resolution grid for machine learning. Originally, only MPI communication was implemented in the h3-Open-UTIL/MP, and heterogeneous coupling between Odyssey and Aquarius becomes possible by adding WaitIO-Socket.
The problem with heterogeneous coupling is the computation speed when using processors of different architectures and the communication speed between different machines. NICAM has been tuned to provide sufficient calculation performance on the Odyssey's A64FX. Conversely, PyTorch, as it is called by ADA, supports GPUs and can perform fast operations on Aquarius' Tensor Core. Therefore, both models are well suited for their respective machine architectures based on computational speed. For the communication speed, a test program with the same number of grid points as that of the NICAM-ADA coupling confirmed that practical performance could be obtained.

Key Words: *Computing by Adaptive Precision, Machine Learning, Data Analytics*

We are developing an innovative method for computational science for sustainable promotion of scientific discovery by supercomputers in the Exascale Era by combining (Simulation + Data + Learning (S+D+L)). The Wisteria/BDEC-01 system (Big Data & Extreme Computing), which started its operation in May 2021 at the Information Technology Center, the Tokyo University, is a Hierarchical, Hybrid, Heterogeneous (h3) system, which consists of computing nodes for computational science and engineering with A64FX (simulation nodes) and those for data analytics/AI with NVIDIA A100 GPU's (data/learning nodes).

In this study, we consider the Wisteria/BDEC-01 as the platform for integration of (S+D+L), develop an innovative software infrastructure "h3-Open-BDEC" for integration of (S+D+L), and evaluate the effects of integration of (S+D+L) on the Wisteria/BDEC-01 system. The h3-Open-BDEC is designed for extracting the maximum performance of the supercomputers with minimum energy consumption focusing on (1) innovative method for numerical analysis with high-performance/high-reliability/power-saving based on the new principle of computing by adaptive precision, accuracy verification and automatic tuning, and (2) Hierarchical Data Driven Approach (hDDA) based on machine learning.

The h3-Open-BDEC is the first innovative software platform to realize integration of (S+D+L) on supercomputers in the Exascale Era, where computational scientists can achieve such integration without supports by other experts. Source codes and documents are open to public for various kinds of computational environments. This integration by h3-Open-BDEC enables significant reduction of computations and power consumptions, compared to those by conventional simulations.

This talk overviews the h3-Open-BDEC project, summarizes the various achievements and results, and provides future perspective. of the recent progress

Improved Initial Approximations for Pressure Correction Schemes

Alexander Magro[1*], Kengo Nakajima[1]

[1] University of Tokyo

Key Words: *Multigrid, Incompressible Flow, Computational Fluid Dynamics, Pressure Correction, Conjugate Gradient Method, Parallel Computing, Large Scale Systems, Navier Stokes*

Numerical simulations for the incompressible Navier-Stokes equations are most often solved using a pressure correction scheme, such as Marker-and-Cell type methods, or the SIMPLE method. These methods bind the continuity equation to the pressure in order to solve the non-linear momentum and velocity terms implicitly. These semi-implicit methods lead to a pressure correction scheme in the form of a discretized Poisson equation. Despite pressure being generally undesired in applications, solving the system equations derived from the Poisson equation takes the majority of computational cost in these types of methods.

These large scale systems are generally solved using a preconditioned iterative method, such as the conjugate gradient method. While traditionally, the CG method begins with a 0 vector initial estimate, we use information from previous time steps, previous pressure correction equations, information about the system, and information about the preconditioned iterative method itself to predict an initial approximation vector that can be used to improve convergence of the iterative method, thus decreasing overall computation time.

In particular, we use a machine learning scheme to predict the right hand side of the system of equations, allowing us to solve an approximate problem in parallel, in advance. The solution to this approximate problem is used as an initial estimate for the true problem when it is derived by one of the semi-implicit methods above. This leads to a faster algorithm overall.

Key Words: Immersed boundary method, Lattice Boltzmann method, High performance computing, GPU acceleration

Computational fluid dynamics (CFD) are recently used in a broad field, such as industrial, medical and video. In CFD, the simulation of flow around objects moving freely is called as moving boundary flow, and it is one of important themes of CFD. In order to solve moving boundary flow quickly, we use immersed boundary-lattice Boltzmann method (IB-LBM), which is easy to parallel computing using GPU. The parallel computing shortens the computing time of IB-LBM, and using multiple GPUs does more. However, in multi-GPU computing, it is necessary to communicate data between GPUs. It results in decrease of parallel efficiency.

We implement IB-LBM in three ways in order to increase parallel efficiency. One implementation is naive. In another implementation, we reduce amount of communication data, for example, considering the velocity direction of particles. In the other implementation, calculation time hides communication time. CPU communicates data while GPU computes domain that is not related to communication. As a result, second implementation improve performance of IB-LBM, and third more.

In addition, we evaluate performance of IB-LBM, changing the way to assign GPUs to subdomains when two dimension split. Split direction and whether GPUs are in same compute node affect communication time between the GPUs. In order to hide communication time to the fullest extent, we have to assign GPUs to subdomains properly. By doing this, we improve performance of IB-LBM.

In this talk, we present the implementation of IB-LBM and assigning GPUs to subdomains properly, and show the performance improvement by the implementation and the way to assign GPUs.

Key Words: A64FX, Lattice Boltzmann method, optimization

A64FX is processor made by Fujitsu. It is famous for Fugaku which is the fastest supercomputer in the world at TOP500 which is performance ranking of the Linpack benchmark. The feature of A64FX is 64-bit ARM architecture and Scalable Vector Extension SIMD instruction. Moreover, one A64FX chip is consist of 4 Core Memory Group (CMG) that has 13 cores (12 calculation core and 1 assistant core), 2nd cache, and memory controller. As a result of it, we have to consider it when you do optimization of software. The performance of system which installs A64FX in TOP500 is very good, although we have to think about general purpose of using A64FX. And to do it, we must know the characteristics of processor and compiler. The object of this talk is it.

In HPC field, computational fluid dynamics (CFD) is one of the popular research subjects because of its amount of calculation. Lattice Boltzmann methods (LBM) is popular and often used because we can provide better performance easily with parallel computing. It is consist of streaming process and collision process. Streaming process is memory copy part. Collision process is calculation part. Therefore, performance of LBM is an important optimization problem and a good benchmark of supercomputer.

As a part of this study, we first optimize LBM with 1 CMG on A64FX at Wisteria-Odyssey that is operated at Information Technology Center, The University of Tokyo. We use (x, y, z) = (256, 256, 256) grid point simulation and D3Q27 model. The baseline optimization is very important. For example, blocking algorithm and code style for compiler SIMD optimization are effective. Secondly, we work on the optimization of 1 core (4 CMGs). We have to consider the communication between CMGs. Lastly, we optimize LBM with many cores.

In this talk, we provide the optimization method of LBM on A64FX, and difficulty information. We also show the result of optimization of LBM. For example, blocking and compiler SIMD optimization are very important.

A Novel Method to Impose Velocity Boundary Conditions for Eulerian Fluid-structure Interaction Scheme Using Lagrangian Marker Particles

Key Words: *Fluid-Structure Interaction, Eulerian Formulation, Immersed Boundary Method, Particle Method*

A full Eulerian fluid-structure interaction (FSI) formulation is an attractive method for high-performance computing and treating large deformation of solid. In this method, motions of solid and fluid are numerically solved with a spatially fixed mesh. In short, material interfaces cannot be captured by computational meshes and need to be represented by a color function in this method. Conventional full Eulerian methods cannot avoid the numerical dissipation of interfaces due to solving their advection equations. And also, imposing velocity boundary conditions to arbitrary positions and shapes in a computational domain.

In order to overcome the numerical dissipation of interfaces, we have proposed the full Eulerian FSI formulation with Lagrangian marker particles[1]. However, it is still difficult to impose velocity boundary conditions for arbitrary positions and shapes in a computational domain. For non-conforming mesh methods, immersed boundary methods have been proposed to impose velocity boundary conditions to arbitrary positions and shapes. Thus, in this research, we introduce the immersed boundary method[2] to our method[1] to impose velocity boundary conditions for arbitrary positions and shapes in a computational domain.

ABSTRACT

A multi-phase multi-component thermal-hydraulic simulation code JUPITER[1] has been developed to analyze the molten material behaviour under severe accident conditions in nuclear reactors. In JUPITER, the THINC/WLIC method[2] was implemented as an interface tracking method, which enabled us to accurately calculate the dynamics of the multiphase interface of the molten material at relatively low flow velocity. However, when JUPITER is applied to air-water two phase flows in fuel bundles, there is a problem that the Volume of Fluid (VOF) value is stripped from the interface and small VOF values drift in turbulent flows where coalescence and separation of the interface are active. To improve the interface tracking method of the JUPITER code, the applicability of the phase-field method[3] has been investigated. In this study, the phase-field method is applied to the JUPITER code and the droplet oscillation phenomena are analyzed. The numerical results are compared with the theoretical solution to clarify the sensitivity of the phase-field method to its hyperparameters such as the mobility and the interface width.

Key Words: *Liquid film, Surfactant, Langmuir model, Tree-based AMR method, GPU computing*

Direct numerical simulation of the formation and rupture of thin liquid film is performed by using weakly compressible scheme with interface-adapted adaptive mesh refinement (AMR) method. In conventional semi-implicit method that solves the pressure Poisson equation to solve the incompressible two-phase flows, the computational cost increases drastically as the size of problem becomes larger, which cause a severe scalability problem and is not suitable for parallel computing. Based on low-Mach-number assumption and isothermal Navier-Stokes equation, an independent hyperbolic pressure evolution equation is derived and a fully explicit time integration that has good scalability and efficiency is developed.

To capture the moving gas-liquid interface, a coupled phase-field and level-set method is developed. Finite Volume Method (FVM) is used to solve the conservative Allen-Cahn equation and conserve the total mass of each phase. The normal vector of interface used in Allen-Cahn is derived by level-set function, which can provide better accuracy. The time evolution of level-set function is based on advection. Level-set function is re-initialized by phase-field function every several dozen steps during the simulation to keep the unique property that the absolute value of the gradient of level-set function is one.

GPU code for parallel computing based on CUDA is developed for a tree-based AMR that is able to reduce the computational cost by assigning a high-resolution mesh around the moving interface region automatically. A two-dimensional soap bubble growing simulation is performed with and without considering the Marangoni effect caused by the transportation of surfactant. Langmuir model is adopted to numerically describe the adsorption and desorption of surfactant on the liquid-gas interface. The finest cell size is 0.0195mm, which is equivalent to 8,192×8,192 uniform cells. This computation indicates that the behavior of the thin liquid film is reproduced by the explicit scheme and AMR method.

Acceleration of Phase-field Data Assimilation using Multiple-GPU Parallel Computing to Infer Interfacial Properties of Zinc Alloys

Koki Nagao[1*], Shinji Sakane[1] and Tomohiro Takaki[1]

[1] Kyoto Institute of Technology, Matsugasaki, Sakyo–ku, Kyoto 606–8585, Japan;
b8123507@edu.kit.ac.jp, sakane@kit.ac.jp, takaki@kit.ac.jp

Key Words: *Hot-dip Galvanizing, Dendrite, Solidification, Phase-field Method, Data Assimilation, High-performance Computing*

Hot-dip galvanizing (HDG) is a surface coating technology used for corrosion protection of steel; it is widely used for commercial purposes because by employing this method, steel can be mass-produced using continuous HDG lines. Surfaces of HDG films have a shiny and beautiful texture, termed as “spangle,” which greatly influences corrosion resistance and appearance. Therefore, it is essential to reveal the formation mechanism of the spangle texture during galvanization.

Recently, Takaki et al. [1] and Kim et al. [2] conducted phase-field simulations to reveal the formation mechanism of the spangle texture, and both the studies revealed that the characteristic interfacial properties lead to the formation of this texture. However, very little information regarding the true interfacial properties of zinc alloys is available. Data assimilation is a promising method for inferring material properties; this method combines experimental observations and numerical simulations [3]. However, it incurs large computational costs, as multiple numerical simulations with different material properties and/or computational conditions are involved.

In this study, we accelerated data assimilation for three-dimensional dendrite growth simulations using the phase-field method by employing parallel computing schemes using multiple graphics processing units. We used an efficient data assimilation technique, that is, the local ensemble Karman filter. The accuracy of the assimilation was confirmed via twin experiments. In the near future, we aim to combine time-resolved X-ray tomography [4] and large-scale phase-field simulation to infer the interfacial properties of zinc alloys, which are used as HDG materials.

Key Words: *Weakly Compressible, Consistent Transport, Two-phase Flow, Multi-GPU*

In recent years, the use of GPU as computational accelerator has attracted wide attention. Powerful computing performance and high bandwidth for data transfer are the main features of GPU. In the simulation of incompressible fluid flow, a Poisson equation should be solved implicitly. This poses a great challenge for massively parallel and scalable computing because of the complexity in the iteration algorithms and the slow convergence rate for two-phase flows with a high density contrast. On the other hand, weakly compressible Navier-Stokes equations are becoming a popular alternative for simulation of incompressible fluid flows. A pressure evolution equation can be derived under the low Mach number and isothermal condition. Recently, a weakly compressible scheme with adaptive mesh refinement has been successfully applied to simulate two-phase flows [1].

To address the demand for high-performance large-scale simulation of two-phase flows, a momentum-conserving weakly compressible Navier-Stokes solver with multi-GPU computation is proposed. Following the principle of consistent transport, the Con-CAC-LS solver that involves conservative Allen-Cahn equation and level-set method and the Con-PLIC-HF solver that involves PLIC-VOF and height function method are developed. Combined with the evolving pressure projection method to damp the acoustic wave [2], this solver aims at a robust and accurate computation of violent two-phase flows with a high density ratio, while taking advantage of fully explicit time integration of the weakly compressible Navier-Stokes equations.

For multi-GPU computation, the strong scaling with two types of domain partition is evaluated and a better scalability is exhibited by the 3D partition. The technique for overlapping communication and computation is implemented and discussed. Finally, the conservative solvers are used to simulate the Rayleigh-Taylor instability, milk crown, dam break and liquid jet atomization problems. Accurate and delicate evolution process of the two-phase interface is demonstrated.

Efficient parallel mesh movement based on fast low rank solvers and local remeshing

Youssef MESRI

Computing and Fluids Group, CEMEF, Mines Paris, PSL University, France

Youssef.mesri@minesparis.psl.eu

We propose in this work a framework dedicated to the movement of rigid bodies inside 3 dimensional complex geometries which are discretized with conformal unstructured meshes. Several applications can take benefit from this framework such as shape design and Fluid Structure Interactions (FSI) to name a few. This paper will focus on FSI applications. The displacement imposed on the rigid bodies is smoothly interpolated to the mesh elements inside the domain to deform the whole mesh with respect to the prescribed displacement. The mesh movement is considered to be part of mesh deformation problems. In this work, Radial Basis Functions (RBF) interpolation method is used to deform the mesh. This algebraic interpolation approach is well known for its robustness, but it is too expensive on large scale meshes.

The objectives of this work are twofold: 1- Speeding up the RBF calculations in a large-scale parallel environment. Indeed, the resulting linear system has a good hierarchical matrix structure which is exploited to build a parallel hierarchical low-rank solver to speed up the mesh deformation interpolation. The low-rank approximation is driven by a predefined error tolerance. 2- Combine the RBF computed displacement with local remeshing to prevent mesh invalidity during long term displacements or large deformation. The displacement field is used to predict bad quality elements to be locally remeshed. A metric based on the displacement field is derived to inform the remeshing tool which element is subject to local modification. The remeshing is performed in parallel as well the whole the computation pipeline.

Numerical experiments were conducted on numerous 2D and 3D complex geometries with deep analysis on convergence, mesh quality and performance. The results and performance assessments will be presented.

Key Words: Cartesian Mesh, Eulerian Method, Resin Material,

Resin parts have been widely used as load-carrying components in many mechanical engineering fields. Thus, engineers must deeply consider estimating the mechanical material property and understanding the mechanical response. In many cases, the finite element method (FEM) is employed to predict the mechanical property and response. It is necessary to divide the target component into the mesh for FEM. However, the complicated component and/or whole structure is difficult to divide the mesh, furthermore, high computational cost.

In this study, we propose a structural simulation based on the Eulerian formulation using marker particles [1] for resin materials. The proposed method represents the target components by particles in a fixed Cartesian mesh. As a result, it is possible to avoid the numerical diffusion of the solid interface and the solid internal variables. Furthermore, it is suitable for high-performance computing. The conventional method is applied to the elastic or elastoplastic material under large deformation. Considering this, implementing the material model for resin material[2] based on the elastoplastic formulation.

We demonstrate representative numerical examples to evaluate the validity of the present method. The numerical result is compared with the FEM and/or experimental results from the point of view of the deformed shape and stress value.

Key Words: *Proper Orthogonal Decomposition, Flow Structure, Automobile Aerodynamics*

There are multi objectives in the aerodynamic development of automobiles, which are not only drag reduction but also improvement of running stability, aeroacoustic noise reduction, thermal cooling, etc.. In recent years, with the development of high-performance computing technology, a computational fluid dynamics (CFD)-based multi-objective shape optimization for automobile aerodynamics is being realized. To contribute to actual product development and support design engineers, it is also important to extract useful knowledge for design from the Pareto solutions of the multi-objective optimization. The proper orthogonal decomposition (POD) is a powerful technique for such data mining from the Pareto solutions [1, 2]. Automobile aerodynamics engineers has conventionally discussed the relationship between aerodynamic performance and flow phenomenon focusing on the flow structure and topology around automobile.
Therefore, in this study, we applied the POD to extract characteristic flow structures as the POD modes of time-averaged velocity field from the results of aerodynamic shape optimization for a 1/5 scale sedan-type automobile model [3]. Relationship between extracted flow structures and aerodynamic performances of the automobile model was statistically analysed and the flow phenomena related to the Paleto-optimal aerodynamic characteristics were clarified.
The aerodynamics analysis for each sample of the evolutionary multi-objective optimization had been conducted by using the building cube method (BCM) with the immersed boundary method (IBM). The time-averaged velocity field in approximately 200 samples, analysed during the optimization, were analysed by the POD. As the principal component regression (PCR), regression analysis between the mode coefficients and the objective functions was performed, and the POD modes related to the objective aerodynamic performances were investigated.

Implementation of the Mother-leaf Method on GPU-accelerated AMR Code for Phase-field Computation of Dendrite Growth

Ryosuke Suzuki[1*], Shinji Sakane[1] and Tomohiro Takaki[1]

[1] Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto 606-8585, Japan;
b8123039@edu.kit.ac.jp, sakane@kit.ac.jp, takaki@kit.ac.jp

Key Words: *Phase-field Method, Adaptive Mesh Refinement Method, Mother-leaf Method, GPU Computation, Solidification*

The phase-field (PF) method is the only numerical method that can quantitatively predict dendrite growth. However, it has the disadvantage of a high computational cost because it is based on a diffuse interface model. To accelerate the PF computations, parallel computations have been conducted using multiple graphic processing units (GPUs), which exhibit high parallel processing performance. Alternatively, the adaptive mesh refinement (AMR) method, in which fine meshes are arranged only around the interface, has also been used to improve computational efficiency.

Through the combined use of parallel GPUs and AMR, further acceleration of PF computations for dendrite growth has been achieved [1]. However, because of the use of AMR, the execution time of PF computation for each grid point increases several times as compared to that with a uniform mesh. In the previous study, a block-structured AMR method was used, which offers the advantage of sequential memory access when computing the PF model using a finite difference method [1]. However, the method requires memory access for reading grid-point data on adjacent blocks to compute the outer grid points of the blocks. This process generates multiple branch divergence depending on the position of the outer grid points and the difference level from the adjacent blocks, which degrades the execution rate of the GPU.

In the present study, to solve the degradation of computational speed in the previous reports [1], the mother-leaf method [2] has been implemented on the parallel GPUs code with AMR of a PF dendrite growth simulation. The mother-leaf method reduces the total number of outer grid points of blocks by allocating each block to the parent node of leaf nodes. The computational performance of the developed method has been compared with the results of previous studies [1] to evaluate the improvements in computational efficiency.

The flood poses a great threat to the safety of human lives and properties, when it accompanies floating objects such as driftwood, damage is multiplied [1]. In this study, computational fluid dynamics (CFD) based simulations for the motion and mechanical properties of driftwood are carried out. The cumulant lattice Boltzmann method (LBM) [2] and discrete element method (DEM) are utilized to simulate fluid phase and solid phase respectively. For the interface capturing method, a conservative Allen-Cahn equation is employed to maintain the mass conservation. In order to achieve high performance computing (HPC), CUDA programming and adaptive mesh refinement (AMR) [3] method are applied.

The driftwood capturing experiments in water tank were simulated first for validation. By comparing the snapshots, water height and force, it can be concluded our simulation results show good agreement with experimental results, proving that our method is appropriate for driftwood simulation.

After the validation process, simulations of the actual driftwood disaster happened in Otomo area of Iwate Prefecture were performed. By using AMR method, the number of meshes is reduced by around 78% compared to using uniform meshes. Results showed that accumulation positions of driftwood in simulation have a good agreement with that of real situation.

In conclusion, large-scale simulations of driftwood disasters using GPU supercomputers show that the simulation results exhibit a certain degree of agreement with the actual situations. The simulation method is of great significance for driftwood disaster prediction and prevention.

Key Words: *Tidal current turbines, Lattice Boltzmann method, Actuator line model, GPU*

In numerical simulations of tidal current power generation farms, large-scale CFD simulations with a high-resolution grid are required to calculate the interactions between tidal turbine wakes. In this study, we develop a numerical simulation method for tidal current turbines using the lattice Boltzmann method (LBM), which is suitable for large-scale CFD simulations. Turbines are modeled using the actuator line model (ACL)[1], which represents each blade as a point cloud. In order to validate our LBM-ACL model, we conducted a water tank experiment with two turbines and simulated the same conditions as in the experiment. The time series of the calculated and experimentally measured torques oscillate regularly, which is the effect of the regular waves. The torque of the backward turbine is smaller than that of the upstream turbine, which is due to the velocity deficit of the wake of the upstream turbine. LBM simulations could reproduce the experiment in terms of wake interaction and wave effects on turbine performance, and we confirmed the validity of the LBM-ACL approach. Our LBM-ACL code can be applied for a tidal current power farm, and we demonstrated a simulation for ten tidal current power farm with 80 turbines using 1.48 billion grid points and 16 GPUs Tesla P100 on the multi-GPU system ITO subsystem B at Kyushu University.

Conventional assessment of vehicle aerodynamic performance has been conducted under uniform flow conditions using both experiments in wind tunnels and simulations. However, unsteady aerodynamic forces always act on a road vehicle in the practical environment due to atmospheric turbulence and vehicle motion, which affect the vehicle's steering and fuel consumption. Therefore, there is a need for a method to predict such unsteady aerodynamic forces with high accuracy and to assess the aerodynamic performance of vehicles under practical driving conditions.

In this study, we developed a coupled analysis framework using CUBE, a fluid analysis software developed by RIKEN and Kobe University, and Project Chrono, an open-source vehicle motion analysis software. It can be applied to simulate the situation where vehicle motion and aerodynamic forces interact with each other. Moreover, the real driving environment where the wind fluctuations should be taken into consideration can also be conducted using the current framework. With this framework, we can assess the aerodynamic performance under the practical environment.

Key Words: *Foam formation, Multi-phase-field, Lattice Boltzmann Method, Adaptive Mesh Refinement*

Foam formation is a common phenomenon that occurs daily, such as soap, beer, and sea foams. The phenomenon also occurs in various industries, such as textile, food, and oil recovery. Foam formation simulation is challenging because the liquid film separating gas bubbles is very thin compared to the bubble diameter, and the mechanisms to stabilize the foam formation are complicated. It is difficult to simulate the problem using conventional methods because of the finite resolution to resolve the thin film. As a result, bubble coalescence will occur when multiple interfaces are within a single computational cell, a phenomenon is known as numerical coalesce.

We simulate the foam formation using a multi-phase-field (MPF) lattice Boltzmann method (LBM) with adaptive mesh refinement (AMR). Using the MPF model, multiple bubble interfaces can be simulated within a single cell, preventing the numerical coalesce. The cumulant LBM is employed to simulate the hydrodynamics stably and efficiently using parallel computers. AMR is introduced to simulate the problem efficiently by concentrating the computational cells at the interface regions. The proposed method has been validated and used for large-scale simulation of foam formation with many bubbles. Several cases are simulated to gain insight into the behavior of the foam formation using various surface tension, bubble sizes, and viscosity. This study is expected to help understand the effect of foam formation on heat transfer in a medium in the future.

Key Words: *Coal Gasification, Combustion LES, Thermal Conduction and Cooling, Two-way Coupled Simulation, Supercomputer Fugaku*

In this research, we target one of innovative clean energy systems, i.e. carbon-free coal gasification plant. The coal gasification is one of the key technologies to drastically reduce CO_2 emission from coal fired power generation. Coal is crushed into fine particulate matter and then partially burned into gas in a high-pressure and elevated-temperature environment.

We perform a high-fidelity two-way coupled simulation of combustion turbulent flow and thermal conduction and cooling in a reactor vessel of a laboratory-scale coal gasification facility. We first explain our developed multiphysics and multiscale simulations on the Supercomputer Fugaku, which we call Super-simulation in short. Here a unique parallel coupler, REVOCAP_Coupler, is used to integrate highly parallelized independent solvers such as a FVM-based combustion LES flow solver, FFR-Comb, and a FEM-based thermal conduction and cooling solver, ADVENTURE_Thermal.

The simulation results are quantitatively compared with experimental results obtained from the laboratory-scale experimental facility. We succeeded in quantitatively reproducing the experimental phenomena in the facility with regard to temperature distribution as well as generated chemical components. The developed simulations will be powerful tools to improve the design and operation of actual coal gasification plants.

Key Words: *Flow Field Decomposition, Machine Learning, Distributed Learning, Fugaku*

POD (Proper Orthogonal Decomposition) is the most typical method for decomposing the flow field into the modes [1]. However, since POD reduces the system's dimension by a linear function, it is known that sufficient reproduction accuracy cannot be obtained in a flow field in which advection is predominant, and non-linearity is prominent [2]. Therefore, Murata et al. used a convolutional neural network (CNN) to perform non-linear mode division for a two-dimensional flow field around a cylinder [3]. In this study, this network is expanded to three dimensions, and mode division is performed by large-scale distributed learning on Fugaku.

As a result, it was confirmed that if the time interval of the flow field snapshot data to be learned can be sufficiently small to resolve the oscillation with a short cycle, the reproduction accuracy of the detailed vortex structure of the flow field improves as the number of modes increases. In addition, it was confirmed that the computational performance in distributed learning on Fugaku scales well to about tens of thousands of nodes (million cores) by increasing the number of decomposing modes.

Based on the above results, by using the neural network used in this study, we demonstrate the possibility that the complex vortex structure and short cycle oscillation of a three-dimensional fluid can be reproduced with sufficient accuracy by adjusting the accuracy of the learning data and the number of modes. In the future, we would like to increase the scale of distributed learning further and aim to improve parallel computing performance to decompose with a sufficient number of modes required for the reproduction of the complex three-dimensional flow field.

Key Words: Adaptive Mesh Refinement (AMR), Static AMR, Lattice Boltzmann Method

We developed a block-structured static adaptive mesh refinement (AMR) CFD code for the aerodynamics simulation using the lattice Boltzmann method on GPU supercomputers. The data structure of AMR was based on the forest-of-octrees, and the domain partitioning algorithm was based on space-filling curves (SFCs) [1].

We evaluated the performance of the code and found that, in GPU computing, the SFC-based domain partitioning had a bottleneck on costly halo data communication. To reduce the halo data communication, we introduced the tree cutting approach (Fig. 1, Ref. [2]), which divided the global domains with a few octrees into small sub-domains with many octrees, leading to a hierarchical domain partitioning approach with the coarse structured block and the fine SFC partitioning in each block.

The tree cutting improved the locality of the sub-divided domain, and reduced both the amount of communication data and the number of connections of the halo communication. In the strong scaling test on the Tesla V100 GPU supercomputer, the tree cutting approach showed ×1.82 speedup at the performance of 2207 MLUPS (mega-lattice update per second) on 128 GPUs.

Topology optimization [1,2] is widely used in structural engineering design problems, including automobile frames. To obtain the conceptual structure of an automobile frame from a large area of metal blocks by topology optimization, we need a volume constraint of less than 1% and sufficient element resolution. The building-cube method (BCM[3]) with hierarchical Cartesian mesh has been developed for large-scale industrial simulations for fluid dynamics and also for fluid-structure interaction analysis[4].

Authors have developed a voxel topology optimization framework using finite element analysis under the BCM environment. Topology optimization of billions of elements intended for a vehicle frame subject to a single load case is performed using tens of thousands of processors, and its parallel performance is measured. In this paper, topology optimizations of automobile frame structure subject to multiple load cases are discussed. Torsional and bending load case is assumed to obtain a more robust and realistic design with various directional forces. The optimal shapes of a single load case and multiple load case are compared. Based on these results, we will discuss the characteristics of topology optimization itself that are necessary for the assembly-level manufacturing constraint function to be developed in the future.

Key Words: high-order methods, high performance computing, fluids

High-fidelity simulations of compressible turbulent flows play a crucial role in the development of future technologies. Exascale computing will be a key component in enabling high-fidelity analysis and design but fundamental shifts in computing architectures have introduced challenges into how to best exploit modern hardware. High-order, matrix-free methods have the potential to dramatically improve the efficiency of these simulations by benefiting more from the high computational throughput on modern hardware compared to traditional second-order methods. Unfortunately, modern hardware is changing rapidly and refactoring a code to work efficiently on the latest hardware is becoming increasingly infeasible. In an effort to avoid architecture specific programming, software libraries such as Trilinos and programming models such as Kokkos are important to obtain performance portable implementations.

In this talk, we provide an overview of a performance portable implementation for high-order, entropy-stable spectral collocation schemes for tensor product elements through the use of Trilinos libraries and the Kokkos programming model. We introduce a preconditioned Jacobian-free Newton-Krylov method to drive unsteady simulations of turbulent compressible flow. We also provide a detailed performance analysis of the solver on various CPU and GPU architectures and compare our implementation with methods used for traditional finite volume schemes. We show that these high-order schemes perform better on modern hardware given a metric that includes both time-to-solution and error.

Hyperdimensional, Adaptive Finite Elements Using Camellia and Intrepid2

Nathan V. Roberts

Sandia National Laboratories, 1515 Eubank SE, Albuquerque, NM 87123, nvrober@sandia.gov

Key Words: High-order Finite Elements, Hyperdimensional Meshing, Adaptive Mesh Refinement, Plasma Physics, Vlasov Equation, Space-time Finite Elements

Camellia is a finite element library designed to facilitate rapid development of computationally efficient, hp-adaptive finite element solvers, starting with support for DPG. Intrepid2 is a package within Trilinos upon which Camellia depends for assembly. In Camellia, we have recently added support for meshes beyond 3D, with particular application to the Vlasov equation and space-time finite elements. Meanwhile, in Intrepid2 we have added data structures to support efficient storage of tensor-product data, and implementations of sum-factorized assembly built atop those structures. In this talk, we discuss these capabilities, as well as efforts to combat the curse of dimensionality, with some sample results from space-time Vlasov problems.

Recent and emerging HPC systems change the balance of compute/memory/latency. This has fundamental consequences on choice of data structures and algorithms to accurately and efficiently solve physical problems. Although some existing software exploits structure in high order methods to achieve high performance on modern architectures, it usually comes with compromises such as special-purpose application, incidental complexity and debugging difficulties for users and developers, limited architectural targets, and complex packaging and distribution. libCEED is a new mathematical software library that offers flexible, performance-portable algebra for finite element operators and preconditioning. It offers a simple interface that readily handles real-world complexities such as implicit material models, stabilization/shock capturing techniques, and matrix-free multigrid without compromising performance on various computational device types. libCEED exploits structure in high-order finite/spectral elements in a lightweight package without environment assumptions. In this presentation, we investigate the effect of problem size, polynomial degree, parallelism, and physical complexity on the accuracy, cost, and execution time on CPU and GPU architectures for a variety experiments including compressible turbulent flows.

A Comparison of Different Isogeometric Refinement Strategies for the Solution of 2D Hertzian Contact Problem

Sumit Kumar Das[1]*, Vishal Agrawal[1] and Sachin Singh Gautam[1]

[1]Indian Institute of Technology Guwahati, Assam-781039, India
E-mail address: ssg@iitg.ac.in

Key Words: Hertzian contact, Isogeometric analysis, NURBS, Discretization, Refinement techniques

The finite element analysis (FEA) is considered one of the most popular numerical techniques used to get the solution of a Hertzian contact problem. However, one of its limitations is the utilization of approximate geometry, which causes geometric error in the analysis. This problem can be alleviated by the isogeometric analysis (IGA) technique [1]. This is because the technique uses spline technology to create geometric models. It also provides various refinement options, viz., order elevation, knot insertion, and a combination of the former two, i.e., $k-$refinement for geometric smoothness. The application of IGA to contact problems has gained popularity because of the deliverance of its accurate and robust predictions over FEA [2]. To the best of the authors' knowledge, a comparative assessment of refinement techniques in IGA is not available for the solution of contact problems and hence is the scope for present work. In this contribution, an investigation of several refinement techniques in IGA is presented for the solution of the 2D Hertzian contact problem. In combination with the Gauss-Point-to-Surface (GPTS) formulation, the penalty method is used to incorporate the contact constraints. It is validated that the order elevation and the knot insertion techniques in IGA imitate the $p-$ and $h-$refinement techniques in FEA, respectively. The accuracy of the results improves with the increase in the order of underlying basis functions or new knots in the knot vector, provided the geometry and parameterization are preserved. Further, the numerical results using knot insertion converge to the actual solution faster than the order elevation for each refinement step. The $k-$refinement technique, which utilizes an order elevation process followed by knot insertion, provides better results even with the coarse mesh resolution. The oscillations in the results using this technique reduce faster than the other two techniques. It is concluded that the order elevation and the knot insertion steps within the $k-$refinement technique can be incorporated in a controlled manner to optimize the computational cost and time.

A Discrete Energy Consistent Approach for Implict Dynamic Contact with Displacement and Velocity Constraints

Mike Puso[1]*

[1] Lawrence Livermore Nat'l Laboratory, puso1@llnl.gov

Key Words: Implicit Dynamics, Contact, Stability

Standard time integration schemes such as Newmark's method are well known to have stability issues and chatter in the event of unilateral contact. This is due to inherent smoothness built into these time integration schemes and the lack of control of the energy due to the nonlinear nature of the impact. A large body of literature has been developed to treat these issues and a small survey of the different approaches will be presented. A number of approaches apply Lagrange multipliers and employ a velocity jump (e.g. [1, 2]) in the time integration scheme to handle impulse occuring at impact. Some employ incremental gap forms [3, 2] whilst others apply special techniques to enforce the explicit gap constraint at each time step [4, 5]. Some employ penalty constraints and balance energy at contact release [3]. Several incorporate special schemes to add algorithmic damping to mitigate high frequency noise [4]. This work combines different aspects from previous approaches, includes Lagrange multipliers and yields an algorithm that is provably B-stable in a discrete energy norm. Here, energy is dissipated at impact and the velocity is updated by applying a bilateral constraint to enforce persistency. This process is inherently dissipative but an additional force can be applied to recover the lost energy upon contact release if desired. In fact, the proposed conserving approach only requires two subsequent linear solves at the end of time step to recover lost energy as opposed to the nonlinear solve necessary in [2].

Key Words: Contact mechanics, Lagrange multipliers, AMG

To accurately simulate the geomechanical response of a complex subsurface system, such as an aquifer or a hydrocarbon reservoir, it is critical to capture the behavior of faults and fractures. Several phenomena, such as micro-seismicity and fracture propagation, depend on the nature of these discontinuities. As a result, it is important to account for the complex behavior across these fractures explicitly. From a modeling viewpoint, it is necessary to simulate the influence of the fractures on the mechanical deformation. Dealing with frictional contact problems lies at the core of the challenge [1].

The frictional contact problem is one of the most challenging in the computational mechanics field, since it usually produces a stiff non-linear problem associated with a series of linear systems, that is hard to solve efficiently. We use Lagrange multipliers to enforce the constraint and we focus on two different discretization techniques, one of which is intrinsically stable, while the other requires a stabilization [2].

To solve the saddle-point Jacobian matrices arising from the linearization, we propose a constraint preconditioner where the primal Schur complement is obtained by eliminating the Lagrange multipliers unknowns. Suitable augmentation is presented for the intrinsically stable case. Finally, an optimal multigrid method [3] is applied to efficiently solve the Schur complement. We provide numerical evidences of the robustness and efficiency by solving large size problems from various applications.

Funding was partially provided by TotalEnergies through the FC-MAELSTROM project.

A Smooth Spline-based Contact Approach for Beams: Normal and Tangential Interactions

Celso Jaco Faccio Júnior[1*], Alfredo Gay Neto[1] and Peter Wriggers[2]

Key Words: *Smooth Contact, Normal Interaction, Tangential Interaction*

A frequent strategy to model mechanical contact in a finite element context is to adopt the elements' geometry to formulate the contact interaction. This strategy, however, can lead to numerical difficulties due to ill-defined contact geometries such as sharp corners formed between straight finite elements. To avoid such issues, particularly in the context of beam-to-beam contact, this work proposes a spline-based C^1 continuous contact formulation, able to model beams with circular cross-section. The main advantage of this approach stems from a spline description which guarantees a smooth geometry of the whole structure. The proposed contact formulation starts from a classical finite element mesh that defines the spline control points and leads to a spline-based mesh that is employed to model the contact interaction. Moreover, a consistent strategy is developed to split the spline patches into specific elements, more suitable for the contact interactions. The normal gap definition is based on an approach, first presented in [1] and later expanded in [2] to a spline description. Once the contact scenario and the gap are defined, a nonlinear normal interaction law is introduced. A two-parameter general polynomial law is proposed for the nonlinear normal contact interaction with the objective of modeling a broad range of problems, including the linear penalty case. A normal damping (dissipative) contribution is also included. For the tangential interaction, a specific gap that is geometrically defined by the tangential projection of the relative displacement obtained from two consecutive contact configurations is adopted [3]. With the tangential gap established, a specific rheological model including two sliding devices is used [4] which includes an elastic and a dissipative contribution. Additionally, static and dynamic frictional interactions are considered in the rheological model. Several examples are solved that show the robustness and applicability of the proposed formulation.

A Trust-region Method for solving finite deformation contact problems in Unfitted Finite Element Method

Hardik Kothari[1] **and Rolf Krause**[2]

Euler Institute, Università della Svizzera italiana, Switzerland
[1] hardik.kothari@usi.ch, [2]rolf.krause@usi.ch

Key Words: extended discretization methods, Lagrange mutliplier, multigrid method, contact problems

Unfitted methods simplify the cumbersome task of generating high-quality meshes that fits the computation domain explicitly. In the unfitted methods, structured background meshes are used and the underlying finite element spaces are modified to incorporate the geometrical details of the computational domain. In this work, we consider frictionless contact problems in the context of finite deformation and discretize this problem using an unfitted finite element method. We use the method of Lagrange multipliers to enforce the non-penetration contact condition, where the inf-sup stability of the discretization is ensured by employing the vital-vertex algorithm. Moreover, we also employ a variant of the ghost penalty term to control the gradients of the solution on the cut-elements.

Solving such contact problems in the finite-deformation framework requires minimization of nonlinear energy functional such that the non-penetration condition on the contact boundary is satisfied. Here, we propose to use the trust-region method to solve such a nonlinear constrained minimization problem. The proposed trust-region method provides convergence control and accommodates the constraints naturally in the algorithm. To solve the arising trust-region subproblems, we use a tailored generalized multigrid method that can tackle the linear inequality constraints and the point-wise constraints arising from the convergence control. We show the essential modifications for the smoother to handle the contact and the trust-region constraints, simultaneously. For the transfer operators, we use a so-called pseudo-L^2-projection which is designed specifically for the unfitted finite element framework. Lastly, the robustness and the efficiency of the proposed solution method will be demonstrated and a comparison with the other methods will be made.

Key Words: *Contact, Corotational Beam, Rotation-Free Shell, Cardiovascular*

The mechanics of beam-to-surface contact has important applications in cardiovascular minimally invasive surgery (carotid and intracranial stents, catheters, guide-wires and coils, stent-retrievers for acute stroke treatment, venous filters and other devices to treat venous thrombosis). Surgical planning is still sub-optimal at the patient-specific level and there is a pressing need to provide surgeons with in-silico patient-specific models capable of capturing the complex mechanics of the contact between the device and the vessel. On top of this, the stringent clinical time frame calls for efficient algorithms, able to provide accurate simulations in a short time.

This article builds upon our previous work in rotation-free shell elements [1] and beam to surface contact using corotational beams [2]. The formulation presented in [1] exploits the fact that the thickness to radius ratio of vascular vessels is relatively small and therefore, they can be accurately modelled using shell elements. The rotation-free shell element calculates both the membrane and bending behavior via displacement degrees of freedom for a triangular element, resulting in an efficient formulation to model complex patient-specific geometries while incorporating biologically relevant 3D hyperelastic constitutive models. In [2], the authors presented an efficient beam to rigid surface contact formulation using corotational beam elements. Such elements allow to decompose the deformation into rigid body rotations and small local deformations, which results into an efficient formulation as compared to Total Lagrangian beam models.

This work presents a fully implicit algorithm that couples the contact between the corotational beam element and the rotation-free shell formulation. The new contributions are fully linearized to update the tangent operator and the system is integrated in time via the HHT-α method. The algorithm is implemented using Julia within an on-going open-source development. Overall, a consistent implicit contact dynamics formulation is obtained. Several examples are provided to illustrate the accuracy and robustness of the proposed algorithm.

Key Words: Enriched FEM, IGFEM, non-conforming meshes, contact, Lagrange multipliers, multiple-point constraints

We propose an enriched finite element formulation to address the computational modeling of contact problems and the coupling of non-conforming discretizations in the small deformation setting. The displacement field is augmented by enriched terms that are associated with generalized degrees of freedom collocated along non-conforming interfaces or contact surfaces. The methodology follows from our previous work on the Interface-enriched Generalized Finite Element Method [1, 2]. The enrichment strategy effectively produces an enriched node-to-node discretization that can be used with any constraint enforcement criterion; this is demonstrated with both multiple-point constraints and Lagrange multipliers, the latter in a generalized Newton implementation where both primal and Lagrange multiplier fields are updated simultaneously. The *node-to-node enrichment* ensures continuity of the displacement field—without locking—in mesh coupling problems, and to transfer fairly accurate tractions at contact interfaces—without the need for contact stabilization—is demonstrated by means of several examples. In addition, we show that the formulation is stable with respect to the condition number of the stiffness matrix by using a simple Jacobi-like diagonal preconditioner.

Consequences of third-body thickness on first-bodies

Olivier Bouillanne[1,2*], Guilhem Mollon[2], Aurélien Saulot[2], Sylvie Descartes[2], Nathalie Serres[3], Guillaume Chassaing[3] and Karim Demmou[3]

[1] LaMCoS, Univ. Lyon, INSA-Lyon, CNRS UMR5259, F-69621, France

Key Words: *third-body, fretting, friction, flow regime, contact*

Fretting is a tribological phenomenon generated by two parts in contact, called first-bodies, undergoing a relative movement of small amplitude. In some dry contacts, as in the case of fretting, the relative motion between the two first-bodies generates third-body particles. This third body plays several roles in the life of the contact and notably participates in transmitting loads and accommodating velocities [1]. The understanding of the influence of the third body flow is a prerequisite to the writing of wear models taking into account the entire tribological triplet, constituted of the two first-bodies, the third body, and the loading system.

The MELODY software, developed at LaMCoS [2], allows modeling the third body (Figure 1). Between two bodies, one rigid and the other deformable, a collection of deformable grains is generated, then subjected to normal pressure and shear. Numerical results show that the third body can present several aspects and flow according to several regimes (plastic, granular, agglomerated, etc.) depending on the values assigned to two parameters: stiffness and cohesion between particles. These different flow regimes greatly influence the stresses undergone by the first bodies and therefore their wear. During the lifetime of the contact, the thickness of the third body can vary greatly. We thus ran a campaign of numerical simulations in order to analyze the influence of the third-body thickness on the stresses undergone by the first bodies, and on their variations in time and space.

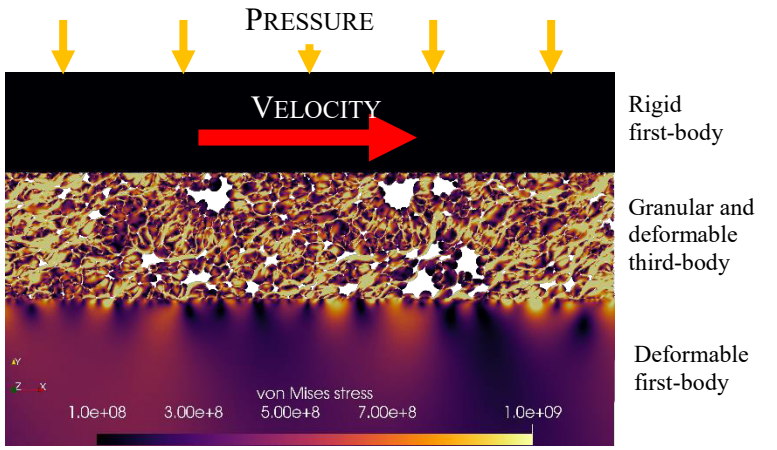

Figure 1 : Simulation with 700 deformable particles submitted to compression and shear. The lower body is deformable. The color indicates the constraints of von Mises.

Consistent Coupling of 1D Cosserat Beams and 3D Solid Bodies: From Embedded Fibers Towards Contact

Alexander Popp[1*] and Ivo Steinbrecher[1]

[1] Institute for Mathematics and Computer-Based Simulation (IMCS),
University of the Bundeswehr Munich, Werner-Heisenberg-Weg 39, 85577 Neubiberg, Germany,
e-mail: alexander.popp@unibw.de, web page: www.unibw.de/imcs-en

Key Words: *Nonlinear Beam Theory, Contact Mechanics, Mixed-Dimensional Coupling*

In this contribution, we first present a consistent coupling method for fully embedding arbitrary curved one-dimensional (1D) Cosserat continua (i.e., beams) into three-dimensional (3D) solid volumes, as e.g., in fiber-reinforced materials [1]. The beams are explicitly modeled with 1D geometrically exact beam finite elements, while the surrounding solid volume is modeled with 3D continuum (solid) elements. The translational and rotational degrees of freedom of the beams are coupled to the solid, thus requiring a suitable definition of a representative rotation tensor field within the solid domain [2]. An objective, i.e., frame invariant, embedded mortar-type approach is presented to enforce the kinematic coupling constraints between the beam and solid elements on inevitably non-matching and mixed-dimensional meshes. We demonstrate optimal rates of spatial convergence and showcase the capabilities of the proposed method for various applications.

As a second step towards increasingly complex beam-to-solid interaction scenarios, the mortar-type coupling approach is extended to the 1D-2D case, i.e., the attachment of beams onto solid surfaces, well-known from biomedical devices such as endovascular stent grafts. Additional challenges arise due to the natural existence of a discrete field of surface normal vectors, which must be properly dealt with when formulating the coupling constraints to avoid unphysical internal stresses and to guarantee exact conservation of both linear and angular momentum.

Finally, our recent research efforts regarding the most general beam-to-solid interaction scenario of unilateral contact are highlighted. While beam-to-solid volume coupling and beam-to-solid surface coupling could rely exclusively on a consistent formulation in the undeformed reference configuration, we must now carefully consider finite deformations and relative motions including finite sliding of beams across solid surfaces. Consistent linearization and its crucial importance for nonlinear solver robustness within implicit dynamics as well as the use of various state-of-the-art discretization techniques for the solid bodies, e.g., NURBS-based isogeometric analysis [3], will be illustrated along with challenging applications from engineering practice.

Key Words: Contact Mechanics, Mortar Methods, High Performance Computing, Domain Decomposition, Finite Elements

Computational contact mechanics provide insight into various physical phenomena, e.g. frictionless contact, frictional sliding, or wear problems just to name a few. Although mortar methods [1] are widely considered the favorite approach due to their variational consistency, high accuracy and outstanding robustness, the accurate evaluation of mortar terms and their linearizations comes at a high computational effort and cost. While we have already proposed scalable iterative solvers for contact problems [2], the cost for evaluating the mortar terms might become dominant or even prohibitive at large scale. While the parallelization of the finite element evaluation is well established to speed-up simulations, the evaluation of mortar terms requires special care in a parallel computing environment.

In this presentation, we study the impact of the curse of dimensionality onto the overlapping domain decompositions of the volume and interface discretizations and its effect on parallel scalability and the overall time to solution. As a remedy, we then develop load balancing schemes for static and dynamic contact problems to optimally distribute computational work to all available hardware resources of parallel computing clusters [3]. Furthermore, we outline a geometrically motivated ghosting strategy based on cartesian bins to reduce the storage and parallel communication of the master side of the contact interface. We demonstrate weak and strong scalability of the proposed algorithms in the context of three-dimensional static and dynamic contact problems and discuss load balancing and ghosting strategies for various practical scenarios.

[3] National Formosa University, No.64, Wunhua Rd., Huwei Township, Yunlin County 632, Taiwan, e-mail: natt.mta@gmail.com

Key Words: *Wear particle, Contact mode, Friction, Interface*

Methodology:
This paper studies the effect of the diameter and the number of the wear particle on the contact mode and friction coefficient at the contact interface under 3-body contact conditions. When the particle and two surfaces are in contact under the 3-body contact conditions, the friction coefficient (μ_s) is the sum of surface-to-surface friction (μ_{ss}) and surface-to-particle friction (μ_{sa}) of solid contact, which can be calculated from three-body friction model [1]. The main cause of wear on the contact surface is the solid friction, so the contact behavior at the interfaces can be obtained from the changes in the surface contact area (A_{ss}) and particle contact area (A_{sa}) [2]. The results of an extensive set of simulations are then used to obtain the curve-fit expressions for the film thickness [3,4].

Results:
The results show that the friction coefficient increases with increasing particle diameter (x_a) and the number of particles per unit area (η_a), and decreases with increasing speed parameter (U). When the wear debris is too large or its concentration is too high, the contact model of the interface is easily transferred into the 3-body S-P contact model, which can produce an excessive friction coefficient. Controlling the size and concentration of wear debris can effectively increase the lifetime of components.

Conclusions:
This paper estimates the tribological performances of interface contacts using a 3-body contact model. The effects of size and concentration of particles on the contact model are analyzed. The proposed 3-body model is validated by comparing to the results obtained from the other existing model. This work is helpful to understand the contact mechanism transitions, the wear process during running-in in mechanical components, as well as the mixed lubrication mechanisms.

First-order Primal-dual Algorithm for Quasi-static Unilateral Contact Problem with Coulomb Friction

Yoshihiro Kanno

The University of Tokyo, kanno@mist.i.u-tokyo.ac.jp

Key Words: Coulomb Friction, Complementarity Problem, First-order Method, Second-order Cone

Recently, accelerated first-order methods have received significant attention for solving large-scale optimization problems in data science. First-order methods do not use the second derivatives of the functions in an optimization problem, and their computational cost per iteration is cheap. By incorporating an acceleration scheme, the number of iterations required by a first-order method can be reduced considerably [4]. Such an accelerated first-order method may possibly be efficient also for diverse problems in computational mechanics. For instance, it was demonstrated through the numerical experiments that an accelerated proximal gradient method developed for elastoplastic incremental problems outperforms a conventional second-order optimization method [5]. The author proposed an accelerated Uzawa method for frictionless contact problems [3].

This paper presents an accelerated first-order method for quasi-static problems with the unilateral contact and the Coulomb friction. The method is designed based on a primal-dual algorithm [1]. Major computational efforts for each iteration is solution of a system of linear equations and projections of variables onto the friction cones. We use a preconditioned conjugate gradient method for the former. The latter can be highly parallelized. It is shown in the numerical experiments that the proposed method outperforms a regularized and smoothed Newton method for second-order cone complementarity problems [2].

Key Words: Quarter Space, Edge, Semi-Analytical Method, SAM, Contact Mechanics

The elastic quarter space problem is commonly encountered in practical mechanical systems such as the contact of rail wheels, cam followers, gears and roller bearings. In these mechanisms the contact limit is so close to the free edge that the edge effects cannot be neglected or ignored. Another situation where edge effects modify the materials response is in the nanoindentation or indentation test (where the mechanical properties of the samples are sought up to the ends of the free edges). For these different contact cases, the Hertz assumptions are no longer valid, so a quarter space model enables to better translate the physical reality. The quarter space problem was first investigated by Shepherd [1]. This problem is very difficult and complex to solve analytically, several techniques have been developed by researchers. Among them Hetenyi [2] ingeniously proposed a technique of overlapping half space, which allowed to obtain an approximate numerical solution with an acceptable precision. Inspired by the Hetenyi's technique Guilbault [3] has proposed a new method of resolution. This paper presents a new quick and convenient method for solving the finite space problem based on the Guibault's method. Its validation was carried out by comparison with the finite element method and the literature.

Key Words: *Thermomechanical Contact, Mortar Method, Acceleration Techniques, Partitioned Solution*

Thermomechanical coupling is of the most relevant multi-physics problems from the perspective of mechanical engineering. When contact is involved, the coupling emerges from the heat transfer across the contact zone and the dissipation of the frictional work into heat. As a result, the temperature evolution can trigger harmful changes in the material and interface properties, for instance, softening of the surrounding material and variations of the coefficient of friction. The wide range of applications that call for predictions on thermomechanical contact problems has fostered several investigations in the topic over the last decades. Solution approaches to this class of problems can be divided into monolithic and partitioned solutions. Monolithic schemes have superior stability and robustness, at the cost of higher complexity in the construction and solution of the system of equations [1]. On the other hand, (strongly) partitioned solution schemes provide significant simplifications of the implementation and may take advantage of several numerical techniques already developed for mechanical and thermal problems. However, this approach may lack convergence properties, namely concerning the iteration between fields [2]. This pitfall of partitioned solution strategies has motivated the development of acceleration techniques for coupled problems, typically studied in the absence of contact interaction [3].

Leveraging the significant body of literature on these techniques, we aim to accelerate the partitioned solution of thermomechanical contact problems. The state-of-the-art literature identified relevant convergence acceleration techniques based on the ease of implementation in partitioned solution schemes and numerical performance. These strategies are implemented in the in-house partitioned nonlinear finite element solver, equipped with a mortar-based discretisation of contact. The computational efficiency of each candidate is benchmarked using numerical examples with varying degrees of thermomechanical coupling at the contact interface. The present work enables the identification of advantageous alternative solution procedures for coupled contact interaction, that recover the solution of the monolithic approach, retain the simplicity of the partitioned schemes and exhibit competitive computational cost.

Plastic zone analysis of nanoindentation for unique constitutive properties of elastoplastic materials

Ziyi Shen[1], Qipu Jia[1], Jiao Li[1], Ruipeng Dong[1], Yongchao Liu[1], and Xu Long[1*]

[1] School of Mechanics, Civil Engineering and Architecture, Northwestern Polytechnical University, Xi'an 710072, People's Republic of China
[*]E-mail address: xulong@nwpu.edu.cn

Key Words: *Nanoindentation; Plastic Zone; Dimensionless Analysis.*

Nanoindentation has been used to evaluate the mechanical properties of the bulk, coating, or film materials at micro- and nano-scales as an advanced mechanical testing technique. Accurate and continuous measurements of the applied load on the indenter can be achieved at micro-Newton accuracy as a function of the indentation depth at the nanometer level. The major advantage of the depth-sensing indentation technique is the lack of requirements for the size and geometry of the material samples. Indentation experiments have been performed to evaluate mechanical properties and residual stresses of various types of materials. The nanoindentation responses from different types of indenters are closely associated with the elastoplastic stress–strain responses of isotropic materials.

It is challenging to describe the evolution of the plastic zone underneath the indenter during nanoindentation, and it is recently known to be crucial to establish a constitutive model that features the plastic properties of the substrate materials based on their indentation responses. Using molecular dynamics and axisymmetric finite element (FE) simulations in this study, we show that the plastic zone shape in the elastoplastic materials under a three-sided pyramide-shaped Berkovich indenter is hemispherical in a broad range of length scales. Dimensional analysis is performed to derive dimensionless functions regarding the radius of the hemispherical plastic zone, considering the critical factors of the load–penetration depth (P–h) curve. By focusing on the loading and the complete unloading stages after completing extensive FE simulations, polynomial functions are proposed by associating the instantaneous and residual plastic zone radii with constitutive parameters, such as Young's modulus, the hardening exponent, and the ratio of the representative stress and the reduced modulus.

As the main objective of this work, we discussed the use of the proposed dimensionless functions to obtain the unique constitutive properties of materials, especially the plastic parameters. We used three reverse algorithms to demonstrate that three elastoplastic materials with similar P–h curves could have significantly different plastic properties. The predicted P–h curves and stress–strain relationships indicated that slight differences in the P–h curves led to significant differences in the stress–strain relationships for all three reverse algorithms. The plastic zone radius represents a crucial parameter in the reverse analysis for predicting the unique plastic parameters of materials. Thus, the proposed dimensionless function of the residual plastic zone radius is essential to obtaining the relation between the evolution of the plastic zone radius and the unique plastic parameters of materials.

[2] Universite Catholique de Louvain, Institute of Mechanics, Materials and Louvain-la-Neuve, Belgium, jean-francois.remacle@uclouvain.be

Key Words: X-MESH, contact mechanics, variational inequality, membrane, sharp interface

Contact problems are governed by inequality constraints, which have been at the core of many research during the past decades [1, 2]. Most of these methods are quite efficient in modeling the inside of the contact zone, however only a few of them are able to sharply model the contact front (contact zone boundary). Yet, a sharp representation of the contact front is necessary to get optimal convergence rate, as it was shown by [3] for instance.

In this work, an efficient way to model sharp contact front is proposed, based on the X-MESH approach which was originally introduced in [4] to model phase-change fronts. The key idea is to move the nodes of a finite element mesh to have a time continuous, sharp representation of the contact front. These nodes movements allow to model topological change of the contact front, including coalescence and splitting, without remeshing or changing the mesh topology. Some finite elements may eventually reach zero measure, but we show in this work that this can be properly tackled.

The method could be applied to any contact problems, but we chose to illustrate its capabilities on several 1D and 2D quasi-static membrane problems in small perturbation. In particular we show that the X-MESH method allows to recover optimal mesh convergence rates, and how it allows to model complex topological changes of the contact zone.

Key Words: Vibration modes; Fluid-Structure Interaction; Added-mass; Coaxial cylinders, Narrow annulus

This work deals with the fluid-structure interaction problem of two coaxial cylinders separed by a thin fluid layer. The inner cylinder is flexible and is imposed a displacement corresponding to the vibration mode of an Euler-Bernoulli beam. Assuming a narrow duct as in [1], we carry out a new theoretical approach to obtain an analytical expression of the fluid added-mass matrix. This new formulation applies to finite size cylinders and encompass all classical types of boundary conditions. We show that the coefficients of the matrix depend on the aspect ratio of the flexible cylinder, the confinement of the duct and the characteristics of the imposed vibration mode.

To assess the validity of the theoretical predicitons, we perform numerical simulations with the open-source code TrioCFD [2]. In this code, the fluid-structure interaction problem involving moving boundaries is solved using an Arbitrary Lagrange-Eulerian technique. We show that the theoretical predictions are successfully corroborated by the numerical simulations, for all types of classical boundary conditions, for different confinements, and for different aspect ratios of the vibrating cylinder.

In engineering, phenomena of fluid-structure interaction play an important role. A prominent example is aeroelasticity, where, e.g., the behaviour of elastic airplane wings has to be included in the design process in order to maximize the aerodynamic performance. But not only in aerospace engineering, also in other engineering areas one can find further examples: the blood flow through flexible arteries in bio-engineering, the deformation of wind turbine blades in energy engineering, the flexible hulls of ships exposed to wind and water in naval engineering, or the movement of flexible piston rings in automotive engineering.

In the presented work, the coupled problem is solved by time-continuous stabilized space-time finite element methods. Building on previous studies on time-dependent flow problems [1], the time-continuous simplex finite elements (C-SST) are applied on the fluid side, using an unstructured triangulation of the space-time domain. Following a boundary-conforming approach, the deformation of the coupling interface is treated via a pseudo-elastic approach [2]. On the solid side, we focus on simplified models, i.e., rigid-body or beam models, solved in the manner of time-continuous prismatic space-time finite elements (C-PST), where the spatial discretization is extruded in time, leading to a structured discretization in time. The overall solver is presented along with numerical results to underline its potential.

Key Words: FSI, Isogeometric Analysis, Immersed Boundary Method, Microswimmers

According to Purcell's scallop theorem, microswimmers need to break the time-reversal symmetry to achieve net body motion in a Newtonian fluid at low Reynolds numbers. For biological microswimmers, this is typically achieved through changes in their body shape, using flagella locomotion or, more commonly, combining both [1]. For artificial microswimmers made of interacting individual particles, the time-reversal symmetry is broken through cycles of non-reciprocal variations of the relative distances between particles. Numerical simulations of this type of microswimmers are carried out in very recent works with simplistic models, assuming far-field flow interaction between particles and representing the fluid through the Oseen's tensor [2]. In this work, we solve the fluid-structure interaction (FSI) problem with the Isogeometric Divergence-Conforming Immersed Boundary Method (IDCIBM) [3], where we include the Navier-Stokes equations for the description of the fluid motion and the constitutive equations of a Neo-Hookean material for the solid phase. The interactions between particles are controlled from the software package ESPResSo [4], taking advantage of its wide variety of already implemented short and long-range interacting forces. In the IDCIBM the Eulerian velocity-pressure pair is discretized using divergence-conforming B-splines, which leads to inf-sup stable, H1-conforming, and pointwise divergence-free Eulerian solutions. This numerical approach allows us to simulate microswimmers made of interacting deformable particles with no restriction on the separation distance. Furthermore, the methodology includes deformable particles, which is one more step to more realistic simulations.

Key Words: *Fluid-structure interaction, Tuft Visualization, Inverse problems*

A tuft is a strip of yarn or string attached to an aircraft wing or a car surface. Tuft flow visualization is a broadly used technique for capturing the flow pattern around an object and studying the dynamics of a fluid system [1]. This study aims to recover the velocity magnitude and direction of fluid flow from the deformation of a tuft. The deformation of the tuft depends on the geometry, material properties, and applied forces. Applied forces are related to the velocity of the fluid. An ABS (acrylonitrile butadiene styrene) strip was used as a tuft, and its deformation was measured. The experiment was conducted in an open water flume, and the deformation was measured by comparing images. The experiment was also simulated using a two-way coupled fluid-structure interaction model [2]. The tuft was modeled as a nonlinear shell (large deformation). The computational model was validated, and a series of experiments were developed to correlate the fluid velocity and the tuft deformation. Furthermore, the validated simulation was used to analyze a series of conditions varying by tuft geometry and fluid velocity. These results were used to create a regression model that determines velocity based on deformation. Preliminary results show that the velocity of a fluid flow increases nonlinearly as the deformation of the ABS tuft increases. It can also be observed that the regression model has a range of accuracy, and outside this range, the results are not reliable. On the other hand, using a variety of geometries and materials simultaneously increases the model's validity range.
Measuring the velocity of a fluid based on deformation enables measurements to be taken more efficiently in a variety of conditions. For example, in remote areas of the world where the equipment to measure wind speed is not available, or in the case of plumbing where measuring the velocity in pipes requires invasive equipment.

Water Wave Interaction with a π-shape Floating Breakwater by Scaled Boundary FEM

Abstract

The principal aim of the current study is to examine a Scaled Boundary Finite Element Method (SBFEM)-based model to analyze the interaction problem between the water waves and moored floating breakwaters with sharp edges. Regarding the increasing employ of rectangular cross-section floating breakwaters with vertical side plates to their down-wave and up-wave sides (π-shaped floating breakwaters), they are used as a practical basis to examine how the model works. By comparing the present solutions to those from existing literature, without changing the mesh density compared to previous simulations used in simple configurations, the accuracy and generality of the present model in the complex configurations are evaluated. It is demonstrated that as the proposed model is a semi-analytical method, unlike conventional numerical methods, there is no need to refine the mesh around sharp corners, which can considerably save the computational time, effort, and cost in large solution domains.

A Residual based a Posteriori Error Estimators for Algebraic Flux Correction Scheme

Abhinav Jha[1*]

[1] Postdoctoral Researcher, Applied and Computational Mathematics, RWTH Aachen University, Schinkelstraße 2, 52062 Aachen , jha@acom.rwth-aachen.de

Key Words: A posteriori estimator, Steady-state convection-diffusion equations, Algebraic flux correction (AFC) schemes, SUPG finite element method, Energy norm

Non-linear discretizations are necessary for convection-diffusion-reaction equations for obtaining accurate solutions that satisfy the discrete maximum principle (DMP). Algebraic stabilizations, also known as Algebraic Flux Correction (AFC) schemes, belong to the very few finite element discretizations that satisfy this property. Results regarding the convergence of the scheme [1] and efficient solution of the nonlinear system of equations [2] have been obtained recently..

The talk is devoted to the proposal of a new residual based a posteriori error estimator for AFC schemes. We derive a global upper bound in the energy norm of the system which is independent of the choice of the limiter in the AFC scheme. We also derive a global upper bound by combining the estimators from [3] and the AFC schemes. Numerical simulations in 2d are presented which support the analytical findings.

Key Words: Unfitted FEM, Level Sets, Approximate Delta Functions, Shifted Boundary Method

We introduce a new way to implement Dirichlet, Neumann, or flux boundary conditions on level sets of approximate distance functions. The proposed approach can be interpreted as a diffuse interface version of the shifted boundary method (SBM) for continuous finite element discretizations of conservation laws on unfitted meshes [2, 3]. We impose the interface conditions weakly by substituting them into surface integrals, which we approximate by volume integrals (as in continuum surface force (CSF) implementations of surface tension in finite element level set methods for incompressible two-phase flows [1]). The calculation of volumetric interfacial terms requires (i) construction of an approximate delta function [5] and (ii) extrapolation of the immersed boundary data into quadrature points. We accomplish these tasks using a level set function, which is given analytically or evolved using the algorithm proposed in [4]. A globally defined averaged gradient of this approximate distance function is used to find the nearest point on the implicitly defined interface. The normal and tangential derivatives of the numerical solution at that point are calculated using the interface conditions and interpolated values. As in classical SBM approaches, extrapolation back to the quadrature points is performed using Taylor expansions. Numerical results are presented for a suite of new 2D test problems with fixed and moving interfaces.

Key Words: *High-order Finite Element Method, Space-Time, Discontinuous Galerkin, Shock Dynamics, Solid Mechanics, Implicit Methods, Unconstrained Minimization, Regularization*

Accurate and robust high-order discontinuous finite element formulations and numerical implementations for flows with discontinuities is a long-standing challenge, which so far has not been resolved satisfactorily. All known methods use shock-capturing, and require introduction of numerical diffusion to regularize the solution in the vicinity of discontinuities, typically in the form of ad-hoc filtering algorithms, non-linear limiters, hyper-/entropy-viscosity, flux-corrected procedures, etc. Recently, a new approach has been developed in [1], named the "*Moving Discontinuous Galerkin with Interface Condition Enforcement*" (MDG-ICE). MDG-ICE is designed to avoid using numerical dissipation, by incorporating the mesh motion into the global non-linear implicit iterative procedure. The method is capable of implicitly resolving wave patterns, detecting solution and derivative discontinuities and "fitting" the mesh to align with such solution features. This enables construction of a truly high-order discontinuous finite-element framework.

In this work, we focus on an extension of the MDG-ICE method to represent shocked solid dynamics. The response of solids is represented with an appropriate closure equation for the Cauchy stress tensor in a hypoelastic formalism. This work considers the Jaumann corotational stress rate [2]. The main challenges are the derivation of jump conditions for non-conservative deviatoric stress equations and how to properly incorporate plasticity effects. We show that our MDG-ICE discretization of this solid dynamics model is capable of delivering exceptionally accurate solutions. A set of 1D-in-space (2D space-time) test problems [2,3] featuring the interaction of solid rods (fliers) with elasto-plastic shock responses are demonstrated, as well as an initial demonstration of 2D-in-space (3D space-time) Taylor anvil impact.

Key Words: Shock hydrodynamics, Shifted boundary method, Multi-material, Lagrangian/Eulerian/ALE, interfaces

We present a new algorithm for high-order numerical simulations of multi-material Lagrangian hydrodynamics. The discretization is based on the finite element method by [Dobrev et al, SISC, 2012], which is combined with the idea of the shifted interface approach, originally proposed in [Scovazzi et al., Int J Numer Methods Eng., 2019]. The proposed interface representation provides three major properties. First, the material interface is represented as a sharp jump, i.e., there is no artificial material mixing in the interface region. Second, the curved interface is obtained without any computations in cut elements or similar geometry-based calculations. This allows to maintain the computational efficiency and generality of the finite element discretization. Third, the method can achieve high-order convergence when the flow around the interface is smooth.

The shifted interface approach falls into the category of immersed/embedded finite element methods. Integrals over the material interface are approximated by integrals over surrogate mesh faces. These face integrals take into account the distance between the positions of the interface and the face. This distance is represented as a global high-order finite element function whose zero level set represents the material interface. The distance function is advected with the material velocity, resulting in representation of curved interfaces inside curved mesh elements. In the limit of fitted interfaces, the additional integrals disappear. We will present initial results on standard 2D and 3D benchmarks, obtained by our extension of the Laghos shock hydrodynamics mini-application.

Invariant-Domain Preserving Approximations for the Euler Equations with Tabulated Equation of State

Bennett Clayton[1*], Jean-Luc Guermond[1], Bojan Popov[1], Eric Tovar[1]

[1] Department of Mathematics, Texas A&M University 3368 TAMU, College Station, TX 77843, USA

Key Words: Compressible Euler equations, tabulated equation of state, maximum wave speed, Riemann problem, Invariant-domain preserving approximation, composite waves

This work is concerned with the approximation of the compressible Euler equations supplemented with an equation of state that is either tabulated or is given by an expression that is so involved that solving elementary Riemann problems is hopeless. A robust first-order approximation technique that guarantees that the density and the internal energy are positive is proposed. A key ingredient of the method is a local approximation of the equation of state using a covolume ansatz from which upper bounds on the maximum wave speed are derived for every elementary Riemann problem. This work is documented in [1].

Key Words: Multi-Scale Problems, Multiphysics Problems, Fluid Structure Interaction, Turbomachinery, Wells Turbine, Wave Energy

A 3D Fluid Structure Interaction (FSI) unsteady simulation is performed using Finite Elements Method and a strongly coupled approach with an in-house built software on a flexible Wells turbine blade.
Flexible blades could represent a practical and promising technological solution to enhance the performance of Wells turbines, by passively adapting the shape of the blade profile to the alternating direction of the air flow in a Wells turbine for an Oscillating Water Column plant. Additionally, the adoption of flexible blades in air turbines could lower the cost of the manufacturing process by selecting low-cost materials, and consequently reduce the cost per kilowatt of the device.
The main objective of the paper is to propose a design of a Wells turbine with flexible blades, inspired by boat sails, by observing and exploiting the passive morphing behaviour of thin structures in immersed high Reynolds flows. To achieve that, we perform a 3D FSI simulation of a Wells turbine with flexible blades.
A secondary claim of the work is to evaluate the dynamic response of the structure, as well as the eventual occurrence of unexpected aeroelastic effects due to the positive feedback between the fluid and the structure. The analysis can provide useful insights both about the feasibility of the proposed design and about the performances of the proposed flexible blades with respect to the classical technology.
The simulations are carried out using the Residual Based Variational MultiScale (RBVMS) method to solve the Navier-Stokes equations, the Total Lagrangian formulation (TL) for the structural non-linear elastic problem, and the Solid Extension Mesh Moving Technique (SEMMT) to move the mesh and avoid a continuous remeshing of the computational domain.

Key Words: Shifted Boundary Method, Embedded finite elements, unfitted finite elements, immersogeometric finite elements

The Shifted Boundary Method (SBM) belongs to the class of unfitted (or immersed, or embedded) finite element methods and was recently introduced for the Poisson, linear advection/diffusion, Stokes, Navier-Stokes equations, and many additional problems [**?**, **?**]. By reformulating the original boundary value problem over a surrogate (approximate) computational domain, the SBM avoids integration over cut cells and the associated problematic issues regarding numerical stability and matrix conditioning. Accuracy is maintained by modifying the original boundary conditions using Taylor expansions. Hence the name of the method, that *shifts* the *location* and *values* of the boundary conditions. When considering the application of the SBM to incompressible flows with moving boundaries or free surfaces, spurious pressure oscillations in time may result from a discrete change of the total volume of active fluid over a time step. To avoid this issue, a weighted SBM is proposed, in which the variational form of the equations is weighted by the elemental volume fraction of active fluid [**?**]. The proposed weighted SBM (or W-SBM) induces small mass (i.e., volume) conservation errors, which converge quadratically in the case of piecewise-linear finite element interpolations, as the grid is refined. We present an extensive set of two- and three-dimensional tests to demonstrate the robustness and accuracy of the method.

[3] Rice University, MS 321, 6100 Main Street, Houston, TX 77005, USA, E-mail: tezduyar@tafsm.org

Key Words: Kirchhoff–Love shell model, Hyperelastic material, Out-of-plane normal stress, Out-of-plane deformation mapping, Neo-Hookean material model, Fung's material model

A shell formulation based on the Kirchhoff–Love shell theory and isogeometric discretization was introduced in [1]. It has the advantage of not requiring rotational degrees of freedom. Extension to general hyperelastic material can be found in [2, 3]. We are introducing a hyperelastic extended Kirchhoff–Love shell model with out-of-plane normal stress. We present the derivation of the model, with focus on the mechanics of the out-of-plane deformation. To determine the out-of-plane stress, we solve the linear-momentum-balance equation in the out-of-plane direction. Accounting for the out-of-plane normal stress distribution in the out-of-plane direction affects the accuracy in calculating the deformed-configuration out-of-plane position, and consequently the nonlinear response of the material. The improvement is beyond what was achieved with the new model's precursor [3] by accounting for the out-of-plane deformation mapping. By accounting for the out-of-plane normal stress, the traction acting on the shell can be specified on the upper and lower surfaces separately. With that, the new model is free from the "mid-surface" location in terms of specifying the traction. We also present derivations related to the variation of the kinetic energy and the form of specifying the traction and moment acting on the upper and lower surfaces and along the edges. We present test computations for plate bending, plate saddle deformation, and pressurized cylindrical and spherical shells.

A Unified Framework of Navier-Stokes Cahn-Hilliard Models with Non-Matching Densities

Marco ten Eikelder[1*], Kris van der Zee[2], Ido Akkerman[3] and Dominik Schillinger[1]

Key Words: Navier-Stokes Cahn-Hilliard equations, mixture theory, thermodynamic consistency

Over the last decades, many diffuse-interface Navier-Stokes Cahn-Hilliard (NSCH) models with non-matching densities have been proposed, see e.g. [1, 3, 4]. Even though these models claim to describe the same physical phenomena, they are distinct from one another. The aim of this talk [2] is to present a unified framework of NSCH models that brings all of these models together. The core principles of the framework are the following:

1. there is only one system of balance laws based on continuum mixture theory that describes the physical model.
2. there is only one natural energy-dissipation law that leads to quasi-incompressible NSCH models.
3. variations between the models only appear in the constitutive choices.

We additionally aim to indicate and rectify inconsistencies of existing volume-averaged velocity based models with respect to mixture theory. Furthermore, we identify the mobility to be of degenerate type and show that a non-degenerate mobility leads to an incompatibility in the limit of the single-fluid regime.

Added-Mass Partitioned Algorithms for Fluid-Structure Interactions

William D. Henshaw[1*] **and Donald W. Schwendeman**[2]

[1] Rensselaer Polytechnic Institute, Troy, NY 12180, USA, henshw@rpi.edu
[2] Rensselaer Polytechnic Institute, Troy, NY 12180, USA, schwed@rpi.edu

Key Words: fluid-structure interactions, added-mass, partitioned algorithms, overset grids

In this talk we give an overview of some fluid-structure interaction (FSI) algorithms that we have developed to solve problems with light structures where added-mass and added damping effects are large. Traditional partitioned algorithms for FSI often have difficulty for light solids and require multiple sub-iterations per time-step to remain stable. The problem is especially acute for incompressible flows and light bodies due to the effective infinite speed of sound in the incompressible fluid. The new numerical schemes we have developed, called Added-Mass Partitioned (AMP) algorithms, are partitioned algorithms that require no sub-iterations, are fully second-order accurate, and remain stable even in the presence of strong added-mass and added-damping effects. We have developed AMP algorithms for a variety of FSI regimes involving compressible and incompressible flows coupled to rigid bodies, beams and bulk solids [1, 2, 3, 4, 5]. The details of the AMP schemes differ for the different FSI regimes but a common theme is to develop novel numerical interface conditions that embed important properties of the solution. For example, for compressible fluids or solids, characteristic information is used, while for incompressible flows a balance of accelerations is enforced. These schemes have been implemented on moving and deforming overlapping grids using the Overture framework.

Key Words: *Flow-Driven Energy Harvester, Partitioned iterative method, Fluid-Structure Interaction, Piezoelectricity*

The piezoelectric effect transforms electrical energy into mechanical energy and vice versa. Piezoelectric materials can thus be used to harvest energy from mechanical vibration. Flow-driven energy harvesters, which harvest energy from flow-induced vibration, have attracted attention. This type of harvester has been widely investigated in the aerospace community.

Flow-driven energy harvesting is a complex problem with coupling among the host structures, piezoelectric materials, surrounding fluid, and electric circuits. For numerical evaluation of the harvester, coupled analysis is needed. Although there have been some numerical studies on flow-driven piezoelectric energy harvesters [1], many of them introduce simplifications and detailed numerical simulations have been rarely conducted.

In our previous work, we developed FEM-based fluid-structure-piezoelectricity coupled analysis [2], where we employed a partitioned approach, which allows to use existing solvers. In the present study, we integrate circuit analysis into the coupled analysis to consider piezoelectric energy harvesters and to calculate generated energy by the harvesters. We show a two-dimensional numerical simulation on limit cycle oscillation of a cantilevered beam where piezoelectric energy harvesters are implemented. Then, the relation between the placement of the harvesters and the scavenged energy is investigated.

Key Words: fluid-structure interaction, turbulent flow, patient-specific heart modelling

We present recent work on computational fluid-structure interaction with contact and turbulent flow, in the context of patient-specific simulations of the blood flow in the left ventricle of the heart. The mathematical model of the intraventricular blood flow and its interaction with the mitral and aortic valves presents challenges in terms of a complex geometry, turbulent flow, a deforming domain, and fluid-structure interaction with contact. The numerical method is based on an Arbitrary Lagrangian-Eulerian approach [1], where the blood and the valve tissues are modelled in one single computational mesh, and the implementation of the method is designed to be efficient on massively parallel computing platforms.

Such simulations have the potential to be part of the standard workflow in the clinic, for example, to support diagnosis and treatment of heart disease. Through simulation, the blood flow can be investigated in great detail and properties of the blood flow can be computed which cannot be measured by imaging techniques, such as the local blood pressure and mechanical stresses. To analyze the mechanical stresses in the blood we use the triple decomposition of the velocity gradient tensor [2], by which shear flow can be separated from straining flow and rigid body rotational flow. The level and extent of different types of mechanical stresses can lead to an elevated risk for thrombosis events. Hence, a detailed analysis of simulation data could contribute to the risk assessment of clinical interventions.

Further, the triple decomposition of the velocity gradient tensor can be used to analyze the stability of turbulent flow, hence, to characterize the smallest scales of the blood flow in the ventricle [3].

Key Words: Stokes Flow, Flexible Filaments, Large-Deformation Beam Elements, Beam Contact, Boundary Element Method, Graphic Processing Units (GPUs).

The dynamic response of flexible filaments immersed in viscous fluids is important in cell mechanics, as well as other biological and industrial processes. In this talk, we propose a parallel computational framework to simulate the fluid-structure interactions in large assemblies of highly-flexible filaments immersed in a viscous fluid. We model the deformation of each filament in 3D with a C^1 geometrically-exact large-deformation finite-element beam formulation and we describe the hydrodynamic interactions by a boundary element discretization of the Stokeslet model. We incorporate a contact algorithm that prevents fiber interpenetration and avoids previously reported numerical instabilities in the flow, thus providing the ability to describe the complex evolution of large clouds of fibers over long time spans. In order to support the required long-term integration, we use implicit integration of the solid-fluid-contact coupling. We address the challenges associated with the solution of the large and dense linear system for the hydrodynamic interactions by taking advantage of the massive parallelization offered by Graphic Processing Units (GPUs), which we test up to 1000 fibers and 45000 degrees of freedom.

We validate the framework against the well-established response of the sedimentation of a single fiber under gravity in the low to moderate flexibility range. We then reproduce previous results and provide additional insights in the large to extreme flexibility range. Finally, we apply the framework to the analysis of the sedimentation of large clouds of filaments under gravity, as a function of fiber flexibility. Owing to the long time spans afforded by our computational framework, our simulations reproduce the breakup response observed experimentally in the lower flexibility range and provide new insights into the breakup of the initial clouds in the higher flexibility range.

Key Words: Compressible flow, Fluid–structure interaction, Non-matching interface, Isogeometric analysis, Hybrid fluid–structure interaction, Aircraft buffeting, Arbitrary Lagrangian–Eulerian

Aircraft buffeting is an aeroelastic phenomenon characterized by random pressure oscillations impacting on the horizontal stabilizer caused due to the turbulent airflow in the wake of the wing during the different flight missions. This unsteady dynamic loads acting on the stabilizer over a longer duration can reduce its structural fatigue life. Computational modeling of aircraft buffeting has been challenging due to the aerodynamic nonlinearities and complex aircraft structural components. To numerically model and study the effects of aircraft buffeting, a high-fidelity fully-coupled compressible flow fluid–structure interaction (FSI) framework is developed in this work. The FSI methodology is developed to handle the different non-matching discretizations at the interface and a projection method is used for the transfer of kinematic and traction data between the fluid and structure subdomains. Finite element based Navier–Stokes equation of compressible flow and the isogeometric analysis (IGA) based rotation-free Kirchhoff–Love shell structural formulation are considered to model the physics involved. The method is validated for its accuracy through a benchmark problem and is applied to simulate flow around full-scale aircraft and the buffeting of its horizontal stabilizer. A novel hybrid FSI methodology is also developed specifically in the application to model aircraft buffeting. The FSI framework is also extended to model the aircraft maneuvers based on arbitrary Lagrangian–Eulerian (ALE) approach to simulate realistic time-dependent flight paths and study the effects of unsteady loads acting on the horizontal stabilizer of the aircraft.

Key Words: Cardiac modeling, Electrophysiology, Fluid-structure interaction, Multiphysics

We propose an integrated computational model of the human heart [1], comprising three-dimensional descriptions of electrophysiology, active and passive mechanics and hemodynamics, resulting in an electrophysiology-fluid-structure interaction bidirectionally coupled model. We incorporate the effect of external circulation with a lumped parameters model [3]. We explicitly describe the interplay between the different phenomena occurring within the heart. We rely on the monodomain equation for cardiac electrophysiology. Muscular activation is described with the model presented in [2]. Passive mechanics is modeled in the hyperelastic framework using Guccione and Neo-Hooke models [3]. We use incompressible Navier-Stokes equations in ALE framework for blood dynamics, with the RIIS method for of valves [4]. We rely on a staggered scheme for time discretization. All coupling terms are treated explicitly, but for fluid-structure coupling, treated implicitly with a monolithic approach [5]. We discretize in space with the finite element method. Simulations on a realistic human left heart showcase the ability of our model to reproduce physiological behavior. This project has received funding from the ERC under the European Union's Horizon 2020 research and innovation programme (grant agreement No 740132, iHEART - An Integrated Heart Model for the simulation of the cardiac function, P.I. Prof. A. Quarteroni).

Key Words: *Multibody Aircraft, Separation, Compatibility, Aeroelasticity*

Multi body aircraft can significantly improve the dynamic and tactical characteristics of aircraft by the combining and separating of multi-body structure. This concept has been applied to ammunition and carrier rockets maturely and with promising benefits for application of cluster unmanned aerial vehicles (UAV) and reusable launch vehicles (RLV). Different from the conventional aircraft, multi-body aircraft no longer restrict and contact each other after separation. The interference effect of flow field in separation process will lead to significant nonlinearity in aerodynamic and separation dynamic characteristics. With the improvement of flexibility and layout complexity of modern aircraft, additional aerodynamic force caused by elastic deformation in the separation process can no longer be ignored, which further complicates the separation system[1-5]. For analysing the influence of aeroelastic effect on separation process of multi-body aircraft, a shrapnel-like aircraft is selected as an example, the time-domain fluid-structure interaction (FSI) method based on overset grid is adopted and separation process of multi-body aircraft system at different initial angle of attack (AOA) is analyzed in this paper. Where separation compatibility under different relative position conditions is divided into safety and effectiveness, which is discussed respectively and compared with simulation results based on rigid body dynamics. The results show that the deformation of structure is dominated by low-order bending modes under the consideration of aeroelastic effect. As time marching, the influence of elastic deformation on the trajectory develops incrementally, which has an influence on separation compatibility, which cannot be ignored. Influence caused by AOA of carrier craft on the sub-craft trajectory changes monotonously along the z-axis direction, while influence caused by AOA of sub-craft on the compatibility tends to be consistent. The work of this paper will provide a reference for the design and control of cluster like multi-body aircraft.

Key Words: Vertical-axis wind turbine, Tsunami shelter, Space–Time Variational Multiscale method, ST Isogeometric Analysis, NURBS mesh generation

We present space–time (ST) computational methods and flow analysis for a vertical-axis wind turbine (VAWT) that has been proposed to also serve as a tsunami shelter. Much of this research has been reported in [1]. In this presentation, we focus on the computational methods. Computational challenges encountered in flow analysis of wind turbines in general include accurate representation of the turbine geometry, multiscale unsteady flow, and moving-boundary flow associated with the rotor motion. The tsunami-shelter VAWT, because of its rather high geometric complexity, poses the additional challenge of reaching high accuracy in turbine-geometry representation and flow solution when the geometry is so complex. We address the challenges with an ST computational method that integrates three special ST methods around the core, ST Variational Multiscale (ST-VMS) method, and mesh generation [2] and improvement methods [3]. The three special methods are the ST Slip Interface (ST-SI) method, ST Isogeometric Analysis (ST-IGA), and the ST/NURBS Mesh Update Method (STNMUM). We present computations for the 2D and 3D cases. The computations show the effectiveness of our ST and mesh generation and relaxation methods in flow analysis of the tsunami-shelter VAWT.

Key Words: Fluid–structure interaction, split-step scheme, semi-implicit coupling, hemodynamics, incompressible flow, non-Newtonian fluid

The interaction of incompressible flows and elastic structures plays a central role in numerous applications in biomedical and general engineering and has thus been a very active area of research during the recent years. Advances in the field have enabled patient-specific fluid–structure interaction (FSI) simulations in the cardiovascular and respiratory context, greatly increasing the impact of numerical tools on diagnostics, treatment, device design and deployment. However, the ever increasing model complexity and high computational demand still pose great challenges even to modern supercomputers.
In this context, we present a partitioned FSI algorithm involving incompressible flows of non-Newtonian fluids and three-dimensional continua [1]. Fluid velocity and pressure are decoupled using a pressure Poisson equation and extrapolation in time, leading to an iteration-free time-splitting (or split-step) scheme allowing for equal-order interpolation, which was originally developed for flows of non-Newtonian fluids on fixed grids [2]. Similar to [3], this setup allows for added-mass stable semi-implicit FSI, merely coupling fluid pressure and structure displacement iteratively. To further boost performance, we enforce Robin interface conditions and apply an interface quasi-Newton method [4].
The framework is showcased considering the blood flow through a patient-specific geometry of an iliac bifurcation and an idealised setup of human phonation, both using parameters in the physiologically relevant range.

[3] Rice University, MS 321, 6100 Main Street, Houston, TX 77005, USA, E-mail: tezduyar@tafsm.org

Key Words: Ventricle, Heart valve, Aorta, Medical image, Space–time method, Isogeometric discretization, Inflow stabilization, T-spline discretization

We address the computational challenges of and present results from ventricle-valve-aorta flow analysis. Including the left ventricle (LV) in the model makes the flow into the valve, and consequently the flow into the aorta, anatomically more realistic. The challenges include accurate representation of the boundary layers near moving solid surfaces even when the valve leaflets come into contact, computation with high geometric complexity, anatomically realistic representation of the LV motion, and flow stability at the inflow boundary, which has a traction condition. Much of this research has been reported in [1]. The challenges are mainly addressed with the space–time (ST) computational method "ST-SI-TC-IGA" [2]. The ST-SI-TC-IGA integrates three special ST methods around the core, ST Variational Multiscale (ST-VMS) method [3]. The three special methods are the ST Slip Interface (ST-SI) [4] and ST Topology Change (ST-TC) [5] methods and the ST Isogeometric Analysis (ST-IGA) [3]. The Constrained-Flow-Profile Traction [1], as a special method, provides flow stability at the inflow boundary. The computation with the LV-valve-aorta model shows the effectiveness of the ST-SI-TC-IGA.

Novel aircraft designs must be compliant to crashworthiness certification requirements. One requirement is to investigate the behaviour of the aircraft exposed to the hydrodynamic loads expected in a planned emergency landing on the water, commonly known as ditching. Contrary to an unexpected and unprepared crash on water, ditching is characterized by the level of preparation prior to the impact. Low approach speeds, a nose-up position of the aircraft, the consideration of the sea state and the direction of the wind as well as the cabin preparation are pursued by the pilots and the crew in order to reduce the impact loads and decelerations to increase the survivability of the occupants and to allow their subsequent evacuation [1].

Aircraft manufacturers can apply diverse methods to demonstrate compliance with respect to ditching requirements. Nevertheless, computational numerical approaches in combination with detailed aircraft models allow for the analysis of the global kinematics of the aircraft, and for the investigation of the local airframe structural integrity. The numerical simulation of ditching is very challenging, because the fluid moves at considerably high velocity and the structure undergoes large nonlinear deformations due to high hydrodynamic loads. For this kind of coupled analysis, different numerical methods were investigated; mainly mesh free Lagrangian methods such as the coupled Finite Element-Smoothed Particle Hydrodynamics on one hand or the Arbitrary Lagrangian Eulerian methods [2]. The coupling between the fluid modelled with SPH and the structure is based on a node to surface contact interface, while the Coupled Euler-Lagrange computational approach uses an embedded contact interface between the fluid (ALE formulation) and the structure. A flexible reinforced bottom-aircraft panel made of a skin, frames and stringers in aluminium alloy and modelled with bi-linear quadrangular shell elements under guided ditching conditions was considered in previous work [3]. Detailed results obtained for the different computational approaches are compared here in terms of global and local time histories.

Comparison of Actuator-Disk Based LES and RANSE Predictions in Farm Flow Simulations

Yu-Cheng Hsu and Shiu-Wu Chau*

National Taiwan University, Taiwan, 10617, chausw@ntu.edu.tw

Key Words: *LES, RANSE, Actuator Disk, Wind Farm, Wake*

The wind farm flow simulations are compared between RANSE and LES predictions in this paper, where an actuator disk model is employed in describing the interactions between the incoming airflow and the wind turbine rotor.

This paper proposes a simplified nonlinear wake model that fills the technical gap between the low-cost and less-accurate linear formulation and the high-cost and high-accuracy large eddy simulation, to offer a suitable balance between the prediction accuracy and the computational cost, and also to establish a robust approach for long-term wind farm power prediction. A simplified actuator disk model based on the momentum theory is proposed to predict the wake interaction among wind turbines along with their power output. The three-dimensional flow field of a wind farm is described by the steady continuity and momentum equation coupled with a k-ε turbulence model, where the body force representing the aerodynamic impact of the rotor blade on the airflow is uniformly distributed in the Cartesian cells within the actuator disk.

This paper also develops a large eddy simulation (LES) approach to predict wind farm flows. The standard Smagorinsky model with Mason damping function is used for modeling the subgrid-scale stress. The governing equation is discretized by a finite volume method, where a SIMPLE algorithm is adopted. The bounded-central differencing scheme with a hyper-tangent blending function is proposed in the convection term approximation. An actuator disk method is employed to model the impact of rotor on the incoming airflow. A synthetic inflow formulation is applied to simplify the specification of the inflow boundary condition. The proposed LES framework is implemented in an in-house code, WIFA3D-LES.

The Horns Rev wind farm is selected as the target site to examine the wind farm flow characteristics predicted by both approaches.

Enhanced vortex-induced vibration of two side-by-side circular cylinders at Re = 1000

Yosua Heru Irawan[1*], Syed Ahmad Raza[2] and Ming-Jyh Chern[3]

[1] National Taiwan University of Science and Technology, Taipei 106335, Taiwan, d10803806@mail.ntust.edu.tw

Key Words: vortex-induced vibration, VIVACE, side-by-side, direct-forcing immersed boundary

Vortex-induced vibration (VIV) of bluff bodies such as a circular cylinder is one of the most attractive fluid-structure interaction (FSI) topics. When dealing with the multiple cylinders, the VIV responses for both cylinders are relatively complex. Recently, a number of studies have focused on enhancing the VIV phenomena for energy harvesting devices such as VIVACE (Vortex-Induced Vibration for Aquatic Clean Energy). In the present work, three-dimensional numerical simulations of two side-by-side vibrating cylinders are performed at Re = 1000. This study has been performed using a direct-forcing immersed boundary (DFIB) method. The numerical simulations are conducted in the range of reduced velocity $2 < U_R^* < 10$. The vibration responses of the two cylinders are studied for a range of gap ratios $1 < g^* < 3$. In addition, the fixed circular cylinder is placed in front of the vibrating cylinder to enhance VIV responses.

It was found that the side-by-side cylinders with $g^* = 1 - 1.2$ produce a higher vibration amplitude much larger than the response of a single cylinder in the initial excitation region. In the lock-in region, almost all side-by-side cylinders produce smaller vibration amplitudes than the single-cylinder response. A fixed circular cylinder in front of the vibrating cylinder increases the vibration amplitude in the lock-in and desynchronization regions without changing or shifting the lock-in frequency range. The wake interaction from the fixed cylinder in front of the vibrating cylinder produce this enhanced VIV response.

Key Words: *Finite Element Method, Incompressible Navier Stokes Equation, Shark Denticle, Variational Multiscale Large Eddy Simulation.*

The unique geometry of the microstructure on the shark-skin surface, known as denticles, is the main reason sharks can swim at high speed [1]. In order to discover the relationship between the complicated denticle structures with the associated flow pattern, we perform a series parameters study, including the drag force analysis and flow stability study under different denticle geometry. In this research, the incompressible Navier Stokes (N-S) equation is chosen as the fluid model; the Galerkin finite element method with variational multiscale method (VMS) [2][3] is adapted. The VMS aims to stabilize the instability due to the advection in the N-S equation, as well as introduces the fine-scale terms that act as the large eddy simulation (LES) in the fluid model. The framework was implemented under the open-source finite element platform, called FEniCS [4]. We first perform the numerical testing on the flow over a sphere and a bionic shark-skin structure to investigate the flow pattern under different Reynolds number, which validates the effectiveness of the proposed framework. Then, a parameter study is employed for different shark species with associated unique shark denticle geometry. The drag-reduction effects among different shark-skin are revealed, and can be used as a reference for future design on the bio-inspired structure.

Key Words: General pressure equation, Immersed boundary method, fluid-structure interaction

The general pressure equation-based method[1] is fully explicit, and the method does not require either solving the pressure Poisson equation nor executing sub-iteration for incompressible flow simulation. However, few numerical validations of general pressure equation method are available, especially under complex flows like fluid-structure. In this work, general pressure equation based method is used to conduct numerical simulations of flows with embedded solid object modeled by the immersed boundary method[2, 3, 4, 5]. Several fluid-structure interaction test problems are used to demonstrate the capability of the current approach. The simulations are conducted on GPU cluster using MPI and CUDA[1, 6].

Key Words: Flow Control, Plasma Actuator, Dielectric Barrier Discharge, Vortex Generator, Computational Fluid Dynamics

Abstract: An airfoil is a shaped surface that produces lift and drag when moving through the air, such as an airplane wing, tail, or propeller blade. Stall is a physical phenomena in which lift falls quickly due to a large angle of attack (AOA) surpassing the critical value. The fundamental reason for this is that the boundary layer flow above the airfoil separates early, resulting in vortices in the separated flow that account for the majority of the top airfoil surface. Dynamic stall is a complex fluid dynamics problem that occurs on an airfoil when the angle of attack exceeds the static stall limit during rapid, transient motion. In this study, a dielectric barrier discharge (DBD) plasma actuator was used to control the dynamic stall of an oscillating NACA0012 airfoil. In the current study, the following four cases were investigated based on different frequency of DBD : **(A)** 2KHz, **(B)** 3KHz, **(C)** 4KHz, and **(D)** 6KHz. Overall, instantaneous results and supplementary movies have been provided to demonstrate the effect of DBD to help better understand vortex patterns affected by different plasma parameters. The line plasma DBD can improve the lift-drag coefficient ratio of an airfoil during pitching since it can reduce drag during upstroke and downstroke. In terms of numerical results, it is recommended that using high-frequency increases the lift-drag ratio and delays stall in the complete stroke.

Key Words: *k-ω SST turbulence model, OpenFOAM, NACA 4412, aerodynamic wing kits*

In the past few years, the use of computational fluid dynamics (CFD) to increase downforce on superbikes has been a part of the winning strategy for racing teams. This study aims to find the highest lift-to-drag (L/D) ratio for aerodynamic wing kit configurations with various angles of attack (AoAs) and wind speeds. Based on the SIMPLE algorithm, the k-ω SST turbulence model has been chosen to solve Reynolds-averaged Navier–Stokes equations using OpenFOAM CFD software. All cases using NACA 4412 as the basic airfoil with a wingspan of 0.6 m are able to comply with the technical regulations revised by the Fédération Internationale de Motocyclisme (FIM). The benchmark validation is based on numerical comparison between OpenFOAM and JavaFoil software. Case 0 contains a partial fairing with a wing for grid independence study. The converged results of the near-wall y-plus in the range 0.01 to 2 have been applied to the rest simulations to improve the accuracy of viscous sublayer. Case 1 contains a complete superbike with wings and a rider. According to the results of Case 1, Case 2 uses the highest L/D ratio of -37 degrees as the upper fixed-wing and adds another lower wing placed at an appropriate position. In Case 3, we replaced non-parallel wings with parallel wings. Case 4 uses the highest L/D ratio above all cases, and modifies the 3D model by using a closed wing and obtains L/D ratios in accordance with the FIM regulations. In conclusion, in Case 3, the AOA of -41 degrees parallel wings has the highest L/D ratio. Based on the results, the L/D ratio in Case 4 is -0.2, and the lift coefficient is -0.06. Compared with the lower wing, the upper wing provides higher downforce. Further study aims to visualize the vortex generation using various vertical wing struts based on Case 4. Subsequently, the popularization of aerodynamic wing kits will contribute to the safety of superbike driving.

[*1] Email: joydesti@gmail.com, [1] Email: mjchern@ntust.edu.tw

Key Words: *Savonius wind turbines*, *aerodynamic performance, tip speed ratio, direct-forcing immersed boundary model*

There are two methods for accounting for rotor rotation in the computational domain of a fluid flow equations when conducting numerical simulations to predict the aerodynamic performance of Savonius wind turbines: rotor with constant angular velocity and rotor in an inertial reference frame with variable rotor angular velocity [1,2]. So far, a number of numerical studies have been carried out to investigate the performance of the Savonius rotor using a constant angular velocity approach. However, there is a lack of detailed descriptions about the systematic investigation of azimuthal increments per time step and the number of turbine revolutions impact on the accuracy of CFD simulations results at different tip speed ratios. The purpose of this study is to simulate a three-dimensional model of a Savonius rotor in order to evaluate its aerodynamic performance and to investigate computational parameters such as azimuthal increment and the number of turbine revolutions effect on the accuracy of simulation results at different tip speed ratios. The prominent performance parameters such as instantaneous dynamic torque coefficient (C_t) and power coefficient (C_P), were investigated for each case using a direct-forcing immersed boundary (DFIB) numerical model. A few azimuthal increment angles are investigated and the best value is selected. Furthermore, the steadiness of simulation results is determined in relation the number of turbine rotations. The study found that the azimuthal increment per time step is highly dependent on the tip speed ratio. The present results provide insight into the systematic relationship between azimuthal increments and the number of turbine revolutions on the accuracy of the Savonius rotor simulation results at different tip speed ratios.

Force Performance and Vortex Structure of Flapping Foil in Unsteady Ground Effect at Moderate Reynolds Number

Jiantao Zhang[1*] **and Takashi Nakamura**[2]

[1] Tokyo Institute of Technology, Tokyo, Japan, zhang.j.am@m.titech.ac.jp
[2] Tokyo Institute of Technology, Tokyo, Japan, tnakamur@depe.titech.ac.jp

Key Words: flow-structure interaction, flapping foil, ground effect

In this presentation, a symmetrical foil with combined heaving-and-pitching motion in the unsteady ground effect, that is, close to a solid boundary, at moderate Reynolds number is numerically investigated with varying flapping frequency, f, but fixed amplitude. It is naturally expected that the distance between the foil pitching axis and the ground, d, would make a significant influence on the force performance and vortex structure on flapping foil, compared with that in unbounded freestream[1]. To quantitatively evaluate the effect of d, an acceleration-based velocity corrected immersed boundary method [2] is adopted after being validated with previous experimental and numerical results in literature. With the assistance of numerical simulation, we find that the time-averaged force in streamwise direction increases monotonically as the distance between foil pitching axis and ground decreases. Meanwhile, with decreasing distance d, the time-averaged force in transverse direction changes from a lift force to a suction force, causing a equilibrium altitude[3]. The time evolution of force in transverse direction shows a sudden decrease due to the blockage effect and recirculation. By varying the Reynolds number from 1000, which is large enough making the viscous effect negligible[4], to 50, the force performance is deteriorated with increasing viscosity due to the interaction between trailing edge vortex and boundary layer vortex.

Key Words: Immersed boundary method, Boundary velocity error, Streamline penetration, Blood flow

The immersed boundary method (IBM) has attracted growing interest in the computational fluid dynamics (CFD) research community due to its simplicity in dealing with moving boundaries in fluid-structure interaction (FSI) systems [1]. We present a study on streamline penetration, velocity error and consequences of a FSI solver based on an iterative feedback IBM. In the FSI, the fluid flows are solved by the lattice Boltzmann method; the solid structure deformation is solved by the finite difference method, and an iterative feedback IBM is used to realize the interaction between fluid and structure. The iteration can improve the no-slip and no-penetration boundary conditions at the fluid-solid interface. Four benchmark cases are simulated to study the reduced velocity error and its consequences: a uniform flow over a flapping foil, flow-induced vibration of a flexible plate attached behind a stationary cylinder in a channel, flow through a two-dimensional asymmetric stenosis and a one-sided collapsible channel. Results show that the iterative IBM can suppress the boundary-slip error and spurious flow penetration on the solid wall. While the iterative IBM does not have significant effect on the force production and structure deformation for external flows, it significantly improves the prediction of the force distribution and structure deformation for internal flows. The increased computational cost incurred by the iteration can be largely reduced by increasing the feedback coefficient. This study will provide a better understanding of the feedback IBM and a better option for the CFD community.

Key words: Immersed Boundary—lattice Boltzmann method, wall modelled large eddy simulation and fluid—structure interaction.

ABSTRACT

The wall modelled large eddy simulation (WMLES) in the immersed boundary--lattice Boltzmann method (IB—LBM) is examined by considering two benchmark validations, i.e., flow around a hull of submarine and cylinder. Specifically, the diffusive wall model proposed by Shi et al. is incorporated into the IB—LBM solver to model the high Reynolds number turbulent flow. To maintain the numerical stability, two collision models, i.e., multiple-relaxation-time (MRT) and recursive regularized (RR), are implemented. The performance of these models in the WMLES is examined and compared by considering both the prediction of aerodynamic force and flow fields. It is found that diffusive wall model is capable to achieve excellent results for turbulent flow modelling involving fluid—structure interaction. The two collision models give close results for the aerodynamic force, but the MRT collision model shows spurious non-physical oscillations in the flow field, making the RR collision model a better choice for the high Reynolds number turbulent flow modelling.

Wall Model-Based Diffuse-Interface Immersed Boundary Method for Simulation of Incompressible Turbulent Flows

Key Words: *Immersed boundary method, Diffuse-interface, Wall model, Turbulent flow*

In this work, a method is proposed to simulate the high Reynolds number turbulent flows by combining the diffuse-interface immersed boundary method (IBM) with two wall models. In this method, two auxiliary layers (a series of Lagrangian points) are set outside the wall: the reference layer and the enforced layer. The wall model is applied at the reference layer to calculate the wall shear stress and the boundary condition is implemented at the enforced layer. When implementing the boundary condition, the implicit velocity correction-based IBM is used. This process requires the velocity at the enforced layer. To calculate the velocity at the enforced layer, the momentum equation is integrated along the normal direction of the wall to link the tangential component of the velocity to the wall shear stress predicted by the wall model, and the normal component of the velocity is approximately reconstructed by the parabolic distribution. In addition, Reichardt's law combined with Spalding's formula is utilized to determine the integral length. In this method, the distances between the two auxiliary layers and the wall (Δ_F and Δ_1) are two very important parameters, and Δ_1 further determines the value of the integral length Δ_P. Numerical results show that these two parameters will greatly affect the results and their values should be preferably changed together with the thickness of the boundary layer. Overall, the locations of auxiliary layers are affected by the grid size and the Reynolds number, and they should be as close as possible to the wall. But, due to the limitation of the influence range of the Dirac delta function, which will interfere with the calculation, the distance between the two auxiliary layers should not be too small. This is to avoid the overlapping of the interpolation range between the Lagrangian points of the two auxiliary layers. So how to resolve the contradiction between the limitation of the influence range of the interpolation function and the thin thickness of the boundary layer close to the leading edge still needs further study.

Key Words: *Acoustic-structure coupling, Pump-pipeline System, Pressure Fluctuation, FEM Dynamic Model*

The coupling effects of the acoustic and structure on dynamic response of the petrochemical pump-pipeline system are investigated by the dynamic modeling and numerical analysis. An actual equipment that consists of two centrifugal pumps, two valves and spatially arranged pipes is aimed to build its FEM dynamic model with the acoustic-structure coupling effect. The FEM modeling involves shell finite element for the structure and 3-D acoustics element for the sound field inside the pipes and the pumps. The vibration characteristics of the pump-pipeline system, including modal and amplitude frequency response, are obtained from the numerical analysis. The numerical results are in good agreement with actual test data, thus validating the presented model. It is found that the dynamic response of the pump-pipeline system under different influence factors are substantially different. The pressure fluctuation of pump fluid possess the significantly interactional influences on the dynamic characteristics of the pipe. Small pressure fluctuation could impact the acoustic-structure coupling system, resulting in remarkable changes in the dynamic characteristics of the pipeline. The effects of sound velocity and the density of fluid on structural dynamic behaviours and the corresponding mechanism are discussed.

Dynamic Mode Decomposition of Lead-Bismuth Eutectic Turbulent Flow in a Wire-Wrapped Single Rod Channel

Xielin Zhao[1*], and Jinxiong Zhou[1]

[1] School of Aerospace, Xi'an Jiaotong University, Xi'an 710049, China,
zhaoxielin2013@stu.xjtu.edu.cn

Key Words: *Dynamic Mode Decompostion, Wire-Wrapped Rod Fuel, Lead-Bismuth Eutectic, URANS*

Lead-Bismuth Eutectic (LBE) alloy has been used as coolant for next generation liquid metal fast reactor. The thermal-hydraulics as well as flow-induced vibration of wire-wrapped rod bundles are primary concerns for fast reactor safety design. This calls for accurate and fast fluid field simulation and prediction for wire-wrapped rod fuel assembly, yet it remains a challenge due to the complex geometries and high Renolds number flow in wire-wrapped rod channel. This work presents a data-driven dynamic mode decomposition (DMD) method applied to the turbulent flow in a single wire-wrapped rod channel. The time-series data of fluid velocity and pressure were modelled and collected by using URANS turbulence model. Model analysis was performed over the snapshot matrix and DMD modes were obtained. The DMD modes were then used to construct a reduced-order system for fast fluid field reconstruction and forecasting. The correctness and feasibility of the method was demonstrated and compared with ground truth CFD simulation results. Our method offers a fast and reliable approach for reduced-order modelling of turbulent flow in wire-wrapped rod fuel assemblies.

Study on the behavior of bubbles colliding with hydrophilic and hydrophobic curved walls

Key Words:*Bubble; Wettability; Collision; Liquid film drainage*

The research on the behavior and influencing factors of bubble collision has always been one of the focuses of scientific research. Its application in industrial fields such as mineral flotation and gas film drag reduction is of great scientific value. This work focuses on the effect of curved wall on bubble impact behavior. The impact process of bubbles colliding with hydrophilic and hydrophobic curved wall under different radius of curvature was measured by high-speed camera technology, and the effects of wettability and radius of curvature on bubbles colliding with solid curved wall were analyzed. The results show that when the bubble collides with the hydrophilic curved wall, it will bounce many times until it leaves the curved wall; The larger the radius of curvature is, the less the number of jumps will be. In addition, a theoretical model is established to predict the liquid film drying time, which is mainly related to the initial distance, curved wall curvature radius, bubble diameter, liquid viscosity and critical fracture thickness. The prediction error is less than 5.0%. The prediction results accord with the experimental results. This model can be used to predict and analyze the drainage time of bubble impacting hydrophobic curved wall liquid film, so as to provide a certain theoretical basis for related projects.

Key Words: Underwater Explosions (UNDEX), Fluid-Structure Interaction (FSI), Isogeometric Analysis (IGA), Peridynamics, Computational Fluid Dynamics (CFD), Composites

Blast loading of structures continues to pose challenges with respect to the resolution of fluid and structural response, especially in 3D. Additionally, the naval industry has specific interest in problems involving underwater blast-structure interaction. Shallow underwater blasts from explosive charges result in a high pressure gas region expanding into ambient pressure water and a resulting shock which propagates in the immersing fluid. This bubble collapses due to momentum driven overexpansion. Cavitation in water also influences structural response in water compared to other fluids. Air and underwater blast subject immersed structres to extreme loading, resulting in complex deformation and damage behavior. A new coupled immersed-IGA-peridynamic framework is used to addresss these challenges.

In this work, the performance of an air-blast immersed-isogeometric-peridynamic density primitive reduced-energy formulation is studied in three dimensions and subsequently modified for the computation of underwater blast phenomena. Initialized domains consisting of fluid materials satisfying both the ideal gas equation of state in the air-blast case and Jones-Wilkens-Lee (JWL) equations of state in the underwater blast case in a density primitive reduced-energy compressible flow formulation are evolved using an immersed method. Solid materials are introduced as immersed particle solids, and explosive charges are introduced as immersed particle fluids. The focus of this study is on the detonation of Trinitrotoluene (TNT) in air and 1,3,5-Trinitro-1,3,5-triazinane (RDX) in water. Improvements in artificial viscosity discontinuity capturing tailored for JWL materials and ideal gas are shown to effectively stabilize the formulation.

Fluid (background and foreground) is coupled to peridynamic solids using a strong coupling as well as a penalty based approach. Penalty based coupling shows significant improvement in the deformation in coupled solid materials. In the interest of efficiency in 3D, scenarios which involve thin structures use Elastic and Kirchoff-Love shell formulations for solids. This framework couples code built on PetIGA and Petsc to modified versions of Peridigm. Additionally, a microplane concrete model is implemented in Peridigm for use in the air-blast study.

Expansion of explosive gas products results in under-integration as particles spread. Long-time stability of immersed detonation charges is aided through mass-preserving quadrature volume update on all im-

mersed fluid domains, naturally implemented in the density primitive formulation. This development is coupled with artificial viscosity based discontinuity capturing as well as JWL specific discontinuity capturing to form a robust framework for air and underwater blast structure computations. One dimensional water shocks and underwater detonations are demonstrated to agree with benchmark results. A collection of underwater 1D and 3D examples are provided to illustrate the performance of the new methodology.

Key Words: *Granular Impact, Solid–granular Interaction, Continuum–discrete Coupling*

Granular impact – the dynamic intrusion of solid objects into the granular material – is a common phenomenon in many geotechnical engineering problems, such as dynamic compaction and rockfall protection. Still, however, it remains a significant challenge to efficiently simulate the granular impact dynamics as it involves rapid and complex interactions between the intruder and grains. So far, these intruder–grain interactions have been modeled by either a purely discrete (e.g. [1]) or a purely continuum method (e.g. [2]). However, their computational efficiency is sub-optimal due to the grain-by-grain representation of granular materials in a purely discrete method, or an extremely small time-step restricted by the high stiffness of the intruder in a purely continuum method. In this presentation, we introduce a hybrid continuum-discrete method which seeks to strike the balance between discrete and continuum methods for granular impact dynamics. Our method couples the material point method (MPM), which can efficiently simulate granular materials as continua, and the discrete element method (DEM), which can efficiently model the solid intruder as a rigid body. The method is validated by simulating laboratory test of a solid sphere dropped onto loose dry sand. Through a number of parameter studies, we also identify key factors for successful simulations of granular impact dynamics using the hybrid continuum–discrete method.

A New Assumed Deformation Gradient Approach to Mitigating Volumetric Locking in Explicit Material Point Methods

Yidong Zhao[1*], Chenfanfu Jiang[2] and Jinhyun Choo[1]

[1] KAIST, South Korea
E-mail addresses: ydzhao@hku.hk, jinhyun.choo@alumni.stanford.edu

Key Words: Material Point Methods, Volumetric Locking, Assumed Deformation Gradient

The material point method (MPM) is commonly used to simulate large deformations in various types of nearly incompressible materials such as water and undrained soils. When applied to nearly incompressible materials, however, standard MPM schemes suffer from volumetric locking – overly stiff behavior accompanied with erroneous strain and stress fields – due to their use of low-order basis functions and many integration points. To date, several classes of approaches have been put forward to address volumetric locking in MPM. However, the existing approaches require significant modifications of the basis functions, governing equation, or the time-integration scheme, making it onerous to apply them to standard explicit MPM schemes. In this talk, we present a new approach to mitigating volumetric locking in MPM, which features an unprecedented combination of simplicity, efficacy, and generality for a class of standard explicit MPM schemes. The key idea is to combine the assumed deformation gradient ($\bar{\boldsymbol{F}}$) method [1], which was originally developed for finite element methods, with a standard projection operation in MPM. The approach has two significant advantages: (i) it does not require any modification of the existing basis functions, governing equation, or the time-integration scheme, and (ii) it can be applied to any types of nearly incompressible materials. Numerical examples will demonstrate that the new approach is effective for two popular MPM interpolation schemes – the generalized interpolation material point (GIMP) and B-spline methods – and for various types of nearly incompressible materials including a Newtonian fluid, hyperelastic solid, and an elasto-plastic solid.

Key Words: *MICP, Galerkin Finite Element Method, BCHM model, Return Mapping Algorithm*

Ground improvement techniques involving chemical additives are often energy-intensive and unsustainable due to the environmental distress caused by them. Sustainable biocementation processes such as microbially induced calcite precipitation (MICP) can overcome the drawbacks of traditional ground improvement techniques[1]. Capturing the underlying coupled mechanisms in the biocementation process requires the knowledge of diverse fields of bio-chemo-hydro-mechanics. Modeling such a complex phenomenon is imperative for the successful implementation of the stabilization technique in the field. The existing coupled models on biocementation are chiefly intended to validate the observed behavior of laboratory-scale biocemented specimens[1]. This scenario demands the need to develop a coupled bio-chemo-hydro-mechanical (BCHM) model for field simulations. The BCHM model was developed with finite element and backward Euler finite difference approximations in space and time. The Galerkin weak formulations are derived for the mass balance equations of the coupled model. The advective-governed transport phenomena are accommodated with the Petrov-Galerkin formulation. An overall kinetically controlled reactive model is implemented to reproduce the urea hydrolysis and associated chemical kinetics[1]. The reduced permeability of the biocemented soil is accounted in terms of its effective porosity, using the modified Kozney-Carman equation[2]. The fixed point iteration method is implemented for bio-chemo-hydraulics to deal with the nonlinearity in the balance equations. The mechanical constitutive response of biocemented soil is simulated using a micromechanical framework. The von Mises and Drucker-Prager plasticity models were adopted for the biocement and soil particle phases, respectively[3]. The integration of plasticity models was carried out using a return mapping algorithm[3]. The Newton Raphson scheme is considered for the finite element implementation of elastoplastic models. The fully coupled nonlinear finite element problem is solved in a staggered approach using the developed MATLAB routine. The contour plots of biomass and chemical concentrations and precipitated calcite content are generated. The iso error maps are acquired for the inspection of the error behavior of the integration algorithm. The considered elastoplastic models predicted improvement in mechanical strength of biocemented specimen. A complete bio-chemo-hydro-mechanical behavior of the two-dimensional geometry is captured.

Hyperelastic Model for Geomaterials: Its Significance in Coupling with Plasticity for Finite Strain

Yuki Yamakawa[1*], Akiyoshi Ueda[1], Kanta Sakamoto[1]

[1] Tohoku University, 6-6-06, Aramaki-aza-Aoba, Aoba-ku, Sendai 980-8579, Japan

Key Words: *Geomaterials, Hyperelasticity, Cam-clay plasticity, Anisotropy, Finite strain*

This study is aimed at developing a formulation of hyperelastic model for geomaterials and combining it with plasticity. Several existing representative isotropic hyperelastic models with pressure-dependent bulk and shear moduli are reformulated to extend them to finite strains [1–4]. To be compatible with the framework of multiplicative finite strain elastoplasticity, the stress versus the elastic strain relation, together with the fourth-order elastic tangent moduli tensor, in the description relative to the intermediate configuration is derived for each of the hyperelastic models. Their spatial and material descriptions are also derived. A systematic parametric study with a particular focus on the pressure-dependent property of the elastic moduli is performed to examine and compare the constitutive response of the hyperelastic models under typical cases of simple shear and triaxial compression. Significant differences in the hyperelastic responses depending on the types of model are observed in the analysis. Notably, some models exhibit unexpected unreasonable decrease in stress in the process of triaxial compression.

The hyperelastic models are then combined with plasticity. The Cam-clay plasticity with rotational hardening is adopted as a specific prototype model for geomaterials exhibiting induced anisotropy. A formulation of the elastoplastic model based on the multiplicative framework, as well as a stress-point algorithm using fully implicit return-mapping scheme, is developed [5]. Numerical examples are presented to demonstrate the significance of hyperelastic model in the analysis of elastoplasticity. The analysis result reveals that the property of hyperelastic model has significant influences not only in the responses of elastoplastic model but also in the computational aspect to ensure stable analysis.

Multiphysics finite element analysis of intermediate-depth earthquakes

Craig Foster[1*], Sheng-Wei Chi[1], Ashay Panse[1] and Yeji Lee[1]

[1] University of Illinois at Chicago, 3085 Engineering Research Facility, 842 W. Taylor St., Chicago, Il 60607 USA, fosterc@uic.edu

Key Words: *intermediate-depth earthquakes, extended finite element analysis, phase transformation, thermo-mechanical*

While less common and less studied than shallow earthquakes, intermediate-depth earthquakes comprise around 90% of deep earthquakes and cause significant damage and casualties. Defined here as earthquakes that occur between 50-350 km depth, the mechanisms that drive them are still not completely understood. Extreme pressures preclude the frictional sliding that dominates shallower events, and low void ratios suggest that fluid pressure probably does not play a major role. Because these events cannot be observed directly, a combination of small-scale experiments, numerical modelling, and seismological data represents the best approach at understanding these events.

A leading hypothesis is that mineral phase transformation at high pressure and temperature densifies the material, leading to local normal stress drops and damage zones that can nucleate dynamic fractures [1,2]. Heat generation from the fracture may increase the rate of phase transformation, aiding in a runaway reaction that can generate an earthquake.

We model a subducting plate in central Japan using a thermo-mechanical extended finite element method. The finite element model includes slab plasticity as well as a phase transformation based on the stress and temperature. This leads to a densification of the “undeformed” state as well as heat production. Fracture is initiated at bounding surface, which in later version of the model will be stress and temperature dependent. Initially, we try to fit the model to small-scale experiments conducted at GSECARS beamlines at the Advanced Photon Source. We then apply the model to see whether tremors resembling earthquake records can be generated.

Key Words: *Multiscale modelling, finite element method, discrete element method, normal fault rupture, soil-foundation interaction*

A multiscale approach [1] that couples the finite-element method (FEM) and the discrete-element method (DEM) is employed to model and analyse the earthquake fault rupture-soil-foundation interaction (FR-SFI) problem. In the approach, the soil constitutive responses are obtained from DEM solutions of representative volume elements (RVEs) embedded at the FEM integration points so as to effectively bypass the phenomenological hypotheses in conventional FEM simulations. The fault rupture surfaces and shear localization patterns under normal faults with or without foundation atop have been well captured by the multiscale approach and verified with available centrifuge experimental [2] and numerical results [3]. By examining the responses and microstructural evolutions of local RVE packings, it is found that the RVEs located in- or outside the shear bands behave distinctly, and may change their stress states from initial at-rest to active in the normal fault case. The micromechanics study also sheds lights on the capability of heavy foundations in protecting the superstructure as a result of rupture surface diversion.

Numerical study on the hydrate rich sediment behaviour during depressurization

Sahil Wani [1*], Rahul Samala[2], Ramesh Kannan Kandasami[1] and Abhijit Chaudhuri[2]

[1] Department of Civil Engineering, Indian Institute of Technology Madras, Chennai, India,
*ce20d750@smail.iitm.ac.in
[2] Department of Applied Mechanics, Indian Institute of Technology Madras, Chennai, India

Key Words: Gas pressure, depressurization, multi-phase flow, saturation, THMC

Natural gas hydrates have been investigated for past several years as a potential resource for commercially producing gas. The stable condition for the formation of gas hydrates sediments i.e., high pressure and low temperature generally occurs in deep-sea and permafrost regions. The methane gas extraction from the hydrate-bearing sediments was carried out by drilling and using various dissociation methods. The dissociation methods include thermal injection, depressurization, and chemical injection, which will cause a significant loss of solids in the pore space of geomaterials after extraction. The loss of solids will eventually reduce the reservoir strength, leading to borewell wall collapse, causing subsurface landslides (Collett et al., 2002).

The behavior of gas hydrate sediments is governed by coupled Thermo-Hydro-Chemo-Mechanical (THMC) response during the gas extraction process. In this study, in order to understand the coupled behavioral response of hydrate rich sediments, a 2D hydrate reservoir is simulated (using a multi-phase numerical schema) and analysed under axis symmetric conditions. The initial results suggests that the rate of change of gas pressure near the well bore decreases with the increase in the duration of the extraction. Further, the maximum settlement occurs near the seabed level while the rate of settlement decreases with time. The maximum shear stress generally occurs near the well bore which results in associated maximum volumetric strains. Thus, the continuous gas extraction results in highly porous medium which is stabilized primarily due to the geomechanical changes.

Key Words: *Phase-field Method, Rock Friction, Micromechanics, Nonlinear Yield Criterion*

A micromechanics-enhanced phase-field model (MicroPFM) proposed by You et al. (2021) recently is capable of better describing lower scale (mesoscale) features of fracture in quasi-brittle rocks, for instance microcrack growth and frictional sliding along the lips of microcracks. However, on the one hand, the frictional dissipation in this homogenization-based model vanishes, and this counterintuitive behavior was accused of using associative flow rule in the evolution of inelastic strain (Ulloa et al, 2022). On the other hand, the involved linear yield function in the MicroPFM underestimates rock strength under no or low confining pressure. Driven by these problems, we first present a new dissipation mechanism during frictional sliding of microcracks at the mesoscale, and then build a macroscopic phase-field model grounded in various microstructure mechanisms by using the energy equivalence principle. Several validation cases spanning two different scales confirm that the frictional dissipation can be retrieved by an appropriate Helmholtz free energy function, where even an associative flow rule is employed. Furthermore, by specifying the frictional dissipation coefficient, a suit of nonlinear yield criterion is proposed to uniformly capture the crack initiation, peak strength and fault slip envelops of rock. Three examples corresponding to Beishan granite, Lac du Bonnect granite and Carrara marble respectively are investigated to show desirable predictive capability of the proposed nonlinear yield criterion, in particular, when the tension cut-off behavior is involved.

Earthquakes are among the deadliest and costliest natural hazards. Earthquakes are associated with unstable slip on surfaces of discontinuities within the Earth's crust, known as faults. The faulting process involves not only rate- and state-dependent frictional sliding along a fault but also complex evolution of discontinuous geometry such as kinking, branching, and intersecting of faults. Further, fault rupture often gives rise to off-fault damage, which cannot be readily captured by discrete approaches to fault geometry and need to be defined separately through a supplementary bulk constitutive relation. For these reasons, numerical simulation of fault rupture dynamics has long been a notoriously challenging problem in computational mechanics and geophysics alike. Here, we present a phase-field approach to computational modeling of fault nucleation, growth, and propagation, which is built on recent phase-field formulations for quasi-static shear fractures with frictional contact [1, 2]. Compared with existing approaches for the same purpose, the phase-field approach has two main advantages: (i) it can handle complex geometry of faults without any topology-tracking algorithms, and (ii) it can capture both fault propagation and off-fault damage in a unified way. We have verified the new phase-field method using the problem of an anti-plane dynamic rupture on a strike–slip fault, comparing its results with those from a discontinuous approach, namely, the finite element-spectral boundary integral scheme [3]. We then demonstrate the capabilities of the phase-field method for modeling fault propagation problems that involve complex features from kinking and intersecting to off-fault damage.

Prediction of Rate-dependent Mechanical Behaviour of Toyoura Sand Employing a Newly Proposed Visco-plastic Constitutive Model

Siddharth Pathak[1], Mousumi Mukherjee[2*]

Response of soil under medium to high strain rate loading has been of consideration for several military and civilian applications such as air blasts and explosions, projectile penetration, dynamic compaction, pile driving and rapid load testing of piles etc. The mechanical behaviour of sand has been noticed to differ significantly in transient tests with strain rate ranging between 10^{-5}/s to 1/s or even higher [1]. Such rate effects may further vary with density state of the sand and applied level of confinement. Rate effect in sand is generally manifested by an apparent enhancement of soil strength and stiffness primarily due to suppressed particle re-arrangement, increased viscous and inertial effects associated with the higher ranges of strain rate. For modelling and design of geotechnical applications involving medium to high strain rate loading, it becomes imperative to consider the rate-dependent constitutive response of the soil. The rate-dependent material models are often formulated within a general framework of elasto-viscoplasticity involving Perzyna [2] type overstress concept. In this regard, recently Mukherjee et al. [3] proposed a 3D non-associative overstress model, which incorporates both shear and volumetric strain based hardening/softening response and aptly captures some of the key features observed during experiments on sand involving higher strain rates. Such behavior includes strength enhancement with distinct peak followed by rate induced softening and reduced compression; however, the predictability of the proposed model was examined for a limited triaxial test data on coral and silica sand, and primarily focused on strain localization phenomena under biaxial loading condition.

In the present study, the visco-plastic model proposed by Mukherjee et al. [3] has been further assessed over different ranges of confining pressure and strain rate in reference to the drained triaxial experimental results available for Toyoura sand [1, 4]. The influence of strain rate on peak strength, friction angle and strain at peak strength has been analyzed in detail based on the model predictions at three different density states. An increase in peak shear strength of around 60% has been observed for dense Toyoura sand over four orders of magnitude increase in the logarithmic scale of strain rate; whereas, such increase has been limited to 40% and 20% in case of medium dense and loose state, respectively. The corresponding increase in the peak friction angle has been found to be around 20-15% for a change in density state from dense to loose one. However, the rate-induced enhancements noted in both the peak shear strength and friction angle has been observed to remain nearly independent of the level of confinement, except for loose state where such enhancement is more pronounced at lower confinements. For dense state, the strain at peak strength increases with increasing strain rate indicating a delayed peak; whereas, an early peak has been observed for medium dense to loose Toyoura sand at higher rates implying decrease in the magnitude of strain at peak strength.

Stochastic Homogenization of Large Deformation Plasticity in Porous Brittle Solids

Lars Blatny[1*], Henning Löwe[2], and Johan Gaume[1,2]

Key Words: Material Point Method, Microstructure-Based Modeling, Gaussian Random Field, Finite Strain Elastoplasticity, Porous Brittle Solids

Porous brittle solids such as rocks, snow and foams exhibit complex mechanical behavior whose origin can be linked to deformation mechanisms on the microstructural level. Understanding the intricate mechanics of such materials is crucial to the modeling of, e.g., avalanche release processes and earthquakes. Upscaling of elasticity and yielding of arbitrary microstructures using the Finite Element Method (FEM) has become a standard procedure. However, numerical methods to study the transition from small to large deformation situations involving irreversible deformations are still rare. Treating such large deformations is feasible for materials with particulate microstructures using the Discrete Element Method (DEM), but most porous media cannot be approximated by such granular geometries. The lack of flexible computational techniques for these materials prevents the development of accurate homogenized constitutive models.

In this work, we use the Material Point Method (MPM) to investigate large deformation mechanics of porous brittle solids characterized by irregular and bicontinuous microstructures where a segmentation into grains and bonds would be ambiguous. Such microstructures are obtained artificially by level-cutting Gaussian Random Fields (GRF), allowing specific structural properties such as the solid volume fraction to be defined beforehand. This GRF-based scheme facilitates a computationally efficient generation of an ensemble of geometrically different microstructures for each set of prescribed structural properties. Finite size effects are minimized by averaging over different realizations for given structural properties. We demonstrate the usability of our stochastic-numerical approach by examining microstructures with a wide range of porosities under compression. We study the full deformation including the microstructural collapse and packing, going beyond yielding and failure onset. Considering ensembles of microstructures, the uncertainty in the stress-strain response is quantified and related to the error in the numerical discretization.

Snow slab avalanches release due to crack propagation within a weak snow layer buried below a cohesive snow slab. In 1979, McClung [1] described this process assuming an interfacial and quasi-brittle shear failure for the weak layer. This model fails to explain observations of propagation on low angle terrain and remote avalanche triggering. To address this shortcoming, Heierli et al. [2] adapted in 2008 the anticrack concept developed for porous rocks to weak snow layers. In 2018, Gaume et al. [3] showed that mixed mode shear-compression failure and subsequent volumetric collapse (anticrack) of the weak layer were necessary ingredients to accurately model propagation mechanisms, thus reconciling apparently conflicting theories. More recently, large scale simulations based on the Material Point Method (MPM) and field observations revealed a transition from slow anticrack to fast supershear crack propagation [4]. This transition, which occurs after a few meters suggests that a pure shear model should be sufficient to estimate the release sizes of large avalanche release zones.

Motivated by this new understanding, we developed a depth-averaged MPM for the simulation of snow slab avalanches release. Here, the weak layer is treated as an external shear force acting at the base of the slab and is modeled as an elastic quasi-brittle material with residual friction. We first validate the model based on simulations of the so-called Propagation Saw Test (PST) and comparing numerical results to analytical solutions and 3D simulations. Second, we perform large scale simulations and analyse the shape and size of avalanche release zones. Finally we apply the model to a complex real topography. Due to the low computational cost compared to 3D MPM, we expect our work to have important operational applications for the evaluation of avalanche release sizes required as input in hazard mapping model chains. Finally, the model can be easily adapted to simulate both the initiation and dynamics of shallow landslides.

Key Words: *Snow, Avalanches, Computational Mechanics, MPM, DEM*

Snow is a complex material which can sustain stresses like a solid or flow like a fluid depending upon the load it is subjected to. Snow avalanches result from a complex stick to slip failure mechanism in a layered snowpack. Once in motion on a mountain slope the collective behavior of snow particles lead to complex and transient flow dynamics. Quantitative and accurate prediction of slope failure, avalanche release sizes, run-out distances and impact pressures can be based on numerical solution of partial differential equations as well as appropriate constitutive models. Over the last 2 decades, the increase in computational capabilities and the development of advanced numerical models enabled the relaxation of several simplifying assumptions. These models contributed to a significant improvement of our understanding of snow and avalanche mechanics. Here, selected and recent numerical methods for computational snow and avalanche mechanics at high strain rates are presented. Particular emphasis is placed on the Discrete Element Method and the Material Point Method for application at different scales. At the scale of snow microstructure, combining X-ray computer tomography or stochastic microstructure reconstruction techniques with numerical mechanical models has allowed to gain crucial insights into the mechanics of snow under various loading modes. Through homogenization techniques, these numerical results helped to develop constitutive snow models. At the mesoscale, numerical models for large deformations allowed to reproduce (anti)crack propagation mechanisms involved in snow slab avalanche release. At the slope scale, recent models were able to simulate both avalanche release and flow in three dimensions in a unified manner. Additional applications and developements include avalanche impact pressures, wave phenomena, snow-vehicle interaction, avalanches in forested terrain and depth-averaged modeling. Suggestions for future research include more complex rate-dependent constitutive models for dry and wet snow, modeling wet slab and glide-snow avalanches which could become more frequent due to global warming, the effect of spatial variability of snow mechanical properties, as well as model inter-comparisons.

Key Words: *Discrete element method, Dry-slab avalanche, supershear crack propagation.*

Avalanche accidents mainly occur due to dry-snow slab avalanches. Their release is a multi-scale process which starts with the formation of a localized failure in a highly porous weak snow layer underlying a cohesive snow slab, followed by rapid crack propagation within the weak layer. Finally, a tensile fracture through the slab leads to its detachment. The dynamic process of crack propagation which affects the size of avalanche release zones, is still rather poorly understood. Here, we use a 3D discrete element method (DEM) to numerically simulate fracture mechanical tests commonly called Propagation Saw Tests (PSTs) and analyze fracture dynamics using a micro-mechanical approach. Using cohesive and non-cohesive ballistic deposition, we numerically generate a highly porous, brittle weak layer underneath a dense cohesive slab. First, our DEM model is used to reproduce precisely the PST behavior extracted from experiments based on Digital Image Correlation. Our results show that a stationary crack propagation speed regime appears if the snow column is long enough. Elastic moduli of the slab and weak layer as well as weak layer shear strength are key variables influencing crack propagation by affecting the critical crack length for the onset of crack propagation, and the crack velocity. Our results highlight the effect of these mechanical parameters on the propagation distance required to obtain a steady-state regime and their implication on dry-snow slab avalanche release. In addition, our numerical experiments show the apparition of a so-called supershear crack propagation regime for steep slopes in which the crack velocity becomes intersonic. Overall, our results lay the foundation of a comprehensive study on the influence of snowpack mechanical properties on the fundamental processes of slab avalanche release.

Modelling Roll Waves and Erosion-Deposition Waves in Snow Avalanches with the Material Point Method

Xingyue Li[1*], Betty Sovilla[2], Nico Gray[3] and Johan Gaume[1,2]

Key Words: *Roll Waves, Erosion-Deposition Waves, Snow Avalanches, MPM*

Roll waves can lead to severe flow variations and deep flow depth, which have been one of the key concerns in many artificial and natural flows composed of water and/or granular materials [1]. Recently, surges called erosion-deposition waves have been identified from dry granular flows [2]. Compared to roll waves which have moving material between the wave crests, erosion-deposition waves have completely stationary regions between individual crests. Although frequently observed from experiments and field events, roll waves, erosion-deposition waves and their transitions are challenging to be modelled under real-scale conditions involving complicated terrain and flow dynamics. In this study, we simulate the roll waves and erosion-deposition waves in snow avalanches by using the material point method (MPM) and an elastoplastic constitutive model based on critical state soil mechanics. In particular, a snow avalanche at Vallée de la Sionne (VdlS) in Switzerland is modelled with consideration of bed erosion. The properties of the simulated snow are firstly calibrated with the deposition depth of the VdlS avalanches measured with a laser scanner. The dynamic behaviour of the avalanche is then analysed in terms of the different waves, the flow depth evolution at a fixed location, as well as the temporal and spatial evolution of the flow velocity. It is observed that both roll waves and erosion-deposition waves are naturally captured from the simulated avalanche. The flow depth evolution from the simulation shows satisfactory agreement with the field data measured with FMCW radar. The model is also able to recover the spatial evolution of the wave activity from release to deposit, which was measured in the field experiment using a radar. With both the numerical and field investigations, this study offers new perspectives on wave behaviour and provides a validated numerical approach for exploring waves in granular flows like snow avalanches.

Key Words: Multiscale MPM×DEM, granular flow, free-surface, avalanches

Snowpack can be characterized as a loose granular assembly of cohesive non-spherical particles, whose shape and size can greatly vary depending on meteorogical conditions and depth of the considered snow layer. Recent discrete elements (DEM) simulations of centimetric snow samples [1] have highlighted a complex mechanical response, including strong strain-softening and volumetric collapse. Moreover, these features are sensitive to the wide variety of microstructural patterns observed in snow. Avalanches, on the scale of a mountainslope, involve large deformations and can propagate over hundreds or thousands of meters. For modelling such large scale processes, while preserving proper account of microstructural effects on snow mechanical response, a double-scale MPM×DEM approach is proposed (where MPM stands for Material Point Method). Hence, MPM performs the resolution of large scale free-surface flows by relying on a rheology obtained from a homogenized numerical constitutive law (HNCL). Each Gauss point embeds its own "realistic" microstucture handled by a DEM approach. The HNCL is expected to capture the complex mechanical behavior of the material in a more robust and realistic manner than any macroscopic analytical constitutive model. Our coupling strategy differs from another recent MPM×DEM implementation [2], in particular with respect to the periodic boundary conditions [3] used at the DEM scale. Benchmark simulation results (slump tests) will be presented to evaluate the approach. Then, typical slab-weak layers systems involved in slab avalanche release will be modeled. The influence of initial snow microstructure will be investigated using 3D microtomographic images of different snow samples as inputs for the DEM samples.

Key Words: Snow Slab Avalanche Release, MPM, Elastoplasticity, Critical State Theory, Anticrack, Supershear, Crack Propagation

The release of snow slab avalanches starts with the failure of highly porous weak layer buried beneath a cohesive slab leading to mixed-mode crack propagation along the slope. The first modelling attempt of the process date back to 1979 with a pure shear weak layer fracture assumption proposed by McClung [1]. Later, Heierli [2] extended the concept of anticrack, to account for weak layer volumetric collapse and subsequent slab bending. Recent advances [3] reconciled these approaches and have shown the existence of a supershear crack propagation regime leading to intersonic propagation speeds [4].

Here, based on the Material Point Method, finite strain elastoplasticy and critical state theory, we report a transition from sub-Rayleigh anticrack to supershear crack propagation involving the Burridge–Andrews mechanism. The existence of this transition is further confirmed by full-scale avalanche analyses. By accounting for slab fracture, we highlight that soft slabs can prevent supershear transitions to occur. In addition, it is shown that crack branching in the slab can either occur from top to bottom in the case of slow propagating anticracks or from bottom to top for supershear cracks. Through a sensitivity analysis, we investigate the conditions for crack arrest or so-called 'en echelon' slab fracture. Full 3D simulations reveal interesting propagation and release patterns related to the interplay between cross-slope and down/up-slope propagation and slab tensile failure. This enables to analyse slab fracture modes at crown, flanks and staunchwall of the avalanche. These findings allow us to reach a next step in our understanding of the release mechanics in order to predict avalanche release shapes and sizes.

New Perspectives for the Elasto-Plastic Modelling of Snow

Gianmarco Vallero[1*], Monica Barbero[1], Fabrizio Barpi[1], Mauro Borri-Brunetto[1] and Valerio De Biagi[3]

[1] Politecnico di Torino, corso Duca degli Abruzzi 24, 10129 Torino (Italy)

Key Words: Snow Mechanics, Constitutive Model, Elasto-Plasticity

Modelling the mechanical behaviour of snow for laboratory or in situ conditions requires advanced constitutive relationships that are able to account for large inelastic deformations, viscosity, rate dependency, material and geometrical non-linearities, etc. All these aspects characterize the response of a snow element with respect to external actions and strictly depend on the peculiar properties of snow at the micromechanical scale, such as: the presence of bonds between grains (sintering), the effect of the temperature gradient on the grain shape (metamorphisms), etc.

Therefore, the elasto-plasticity theory was largely adopted for snow mechanics purposes, often starting from models originally conceived for soils (e.g., the modified Cam-clay) [1, 2]. The existing models have often a limited range of application only for some specific types of snow (e.g., rounded grains or faceted crystals) while new ones need to be more general. For instance, in the new elasto-plastic models for snow, the yield locus is required to be highly deformable and also capable of varying its shape to follow different stress paths both in the deviatoric and in the meridian plane.

In this work we analyse the possibility of adopting a tailored version of the Bigoni-Piccolroaz yield function for snow [3]. Moreover, we introduce three hardening/softening laws for snow that consider the effect of: i) irreversible volumetric deformations, ii) bonding/degradation processes, and iii) rate dependence. Finally, we depict some concepts related to the numerical implementation of these topics in the framework of a continuum model for snow developed for Finite Element (FE) analyses.

The effects of precipitation particle shape on snowpack

Takahiro Tanabe[1]

[1] National Research Institute for Earth Science and Disaster Resilience, 1400 Takadan, Tokamachi, Shinjo-shi, Yamagata, 996-0091, JAPAN, tnabe@bosai.go.jp

Key Words: *Precipitation particle shape, Snowpack, Discrete element Method*

Snowflakes reflect meteorological information in the sky such as the temperature and degree of supersaturation, and their shape is formed by the balance of them. These shapes affect not only how the snow falls (*e.g.* snow-fall speed [1]), but also how the snowpack is formed. Although these shape differences of precipitation-particle are negligible after mechanical- and thermal-induced metamorphosis in snowpack, it causes differences in the mechanical property of snowpack in the early stage of them. In addition, it is said that some kinds of precipitation-particle from cyclone form weak layer within the snowpack, which causes a potential occurrences of surface avalanches over broad area simultaneously [2].
Our interest is to understand the snowpack properties caused by the differences of precipitation-particle and environmental conditions from the granular scale. For examples, the effects on snowpack with/without rimed snow crystal and with/without wind. In nature, it is difficult to observe the desired precipitation-particles freely in controlled environmental setting. In order to solve these problems, numerical granular sedimentation experiments with non-spherical grains are conducted. Clump particles constructed by spheres are employed to resemble precipitation-particles in discrete element method (DEM) [3]. To make granular packing, free fall of clumps are simulated with changing the shape of clumps and initial conditions (initial orientation and initial velocity/rotational velocity) as parameters.

Key Words: *Granular materials; Contact force chains; Machine learning; Artificial neural network*

There is a dearth of machine-learning investigations of the micro-mechanics of granular soils. The micro-mechanics deals with the mechanics of granular materials at the micro-scale (often particle scale) or meso-scale and is contrasted with the macro-mechanics which focuses on the macro-scale behavior measured at the laboratory sample scale or field scale. In this paper, a novel investigation of the contact force chains (CFC) in quasi-statically sheared granular materials using machine learning methods is conducted. An artificial neural network (ANN) based on discrete element method (DEM) simulation data is developed and applied to predict the anisotropy of CFC in an assembly of spherical grains undergoing a biaxial test. Five particle-scale features including particle size, coordination number, x- and y-velocity (i.e., x and y-components of the particle velocity), and spin which all contain predictive information of the CFC are used to establish the ANN. The results of model prediction show that the combined features of particle size and coordination number have a dominating influence on the CFC estimation. An excellent model performance manifested in a close match between the rose diagrams of CFC from the ANN predictions and DEM simulations is obtained. In addtion, some preliminary results of the prediction of the constitutive response of granular materials using the machine learning method are also presented. Our ongoing work includes the direct prediction of the inter-particle contact forces of a real granular material (such as sand) based on the micro computed tomography input, and the machine learning based constitutive modelling of granular materials.

Predicting Pile Bearing Capacity with Machine Learning

Yago F. Gomes*[1] and Dimas B. Ribeiro[1]

[1] Aeronautics Institute of Technology, São José dos Campos, Brazil

Key Words: Standard Penetration Test, Pile Capacity, Machine Learning

For the past years, machine learning (ML) techniques have been applied to several engineering areas, including geotechnics. Although there are studies dedicated to pile capacity prediction, many gaps still remain in this research field, like the use of few ML techniques, datasets with few examples and poor variety of soils. To fill some of these gaps, this work presents an application of ML techniques for predicting the bearing capacity of precast concrete pile foundations.

The raw dataset, collected from the literature, contains 165 load test results and its respective SPT sounding data. Four datasets based on different semi-empirical methods and one aggregating all inputs were created and used to train seven different ML algorithms. The leave-one-out cross validation approach was used for training and testing, for its ability to better explore the information within the dataset. We use the root-mean-square deviation (RMSE) and the coefficient of determination (R^2) as metrics to evaluate the ML techniques. The table below summarizes the best results obtained from the study, comparing some of the tested ML techniques with classical semi-empirical methods from the literature.

Random forest (RF) presented best performance for both R^2 and RMSE, followed by k-nearest neighbor (KNN). The best semi-empirical method was [1] with respect to R^2, the only one that overcame linear regression (LR). [2] and [3] presented the worst performance. One can also notice that the semi-empirical methods presented high RMSE comparing to all other techniques. It is worth commenting that RF was the best technique not only in the presented table, but in most tests varying input combinations and datasets. After testing alternatives for KNN, we concluded that the best approach is simply weighting point distance.

Method	R^2	RMSE
RF	0.770	635.96
KNN	0.762	651.24
[1]	0.756	1443.11
LR	0.728	708.25
[2]	0.660	896.10
[3]	0.614	922.34

From these results, one can conclude that ML techniques are capable of modeling this type of problem. We suggest for future works the investigation of different input combinations, using information like the cone penetration test (CPT), and including other types of piles.

Key Words: *Strain Space Multiple Mechanism Model, Soil-Structure System, Seismic Response, Inherent Anisotropy*

Consideration of inherent anisotropy is crucial to gaining an improved understanding of the behavior of granular materials. Inherent anisotropy is thought to arise from the preferred particle arrangement and contact orientation of granular materials during sedimentation. Although inherent anisotropy of granular materials has been a subject of extensive investigation for almost 40 years, only a limited number of studies have investigated the effect on the dynamic behavior of soil-structure systems during earthquakes [1].

This study aims to investigate the inherent anisotropy's effect numerically on the seismic response of soil-structure systems using the strain space multiple mechanism model that has been extended to account for inherent anisotropy [2]. In the proposed model, three parameters have been introduced to control the degree of inherent anisotropy and its principal direction. Considering the design case studies of port structures [3], the following soil-structure systems are picked up for consideration: breakwater, sheet-pile quay wall, and gravity type quay wall.

The seismic response analyses for the sheet-pile and gravity type quay walls demonstrate that the consideration of inherent anisotropy affects not only the horizontal displacement of the structure but also the excess pore water pressure in the liquefiable deposits. In the case of the breakwater, the vertical strain of the liquefiable layer below the breakwater is affected by inherent anisotropy, resulting in a different amount of breakwater settlement. The above analysis results indicate that the effect of inherent anisotropy cannot be ignored in evaluating the dynamic behavior of soil-structure systems during earthquakes.

Key Words: *Partially Saturated, Liquefaction, Effective Stress Analysis, Underground Structure*

Background

In recent years, a large number of the unsaturated soil structures such as embankments and slopes were severely damaged due to the multi geotechnical hazards induced by rainfall and earthquake (2004 Niigata-ken Chuetsu Earthquake, 2018 Hokkaido Eastern Iburi Earthquake, etc). Numerical analysis considering the characteristics of unsaturated soil is a promising approach to analyse the effects of combined disasters. Hence, an effective stress analysis method for analysis of both unsaturated and saturated porous media and the transition from unsaturated to saturated soil is developed. This study shows validation of the developed analysis method and its application.

Modelling for unsaturated soil

To consider the characteristics of unsaturated soil, simplified three-phase effective stress analysis was conducted. This method uses the equivalent bulk modulus of fluid considering the degree of saturation and the specific moisture capacity assuming that the pore air pressure equal to atmospheric pressure [1][2]. The suction is defined as the negative value of the pore water pressure, and it is related to the increase in the initial value of the yield surface.

Validation analysis and application to multi geotechnical hazard

To validate the developed analysis method, 1D leaking test and the quasi 1D non-steady seepage flow through soil was idealized. The numerical results reproduce the spatial and temporal distribution of pore water pressure.

Furthermore, the seismic behaviour of an underground structure surrounded by unsaturated and saturated liquefiable ground with three different ground water level, were estimated as examples for comparison. Non-linear response of the reinforced concrete, the relationship between stress and strain for concrete and rebars, is considered as well.

The pore water pressure in unsaturated layer increases, and a part of the unsaturated layer near the ground water level changed into saturated soil. The deformation of the underground structure is larger at the boundary of the unsaturated and saturated layers.

Conclusion

The following conclusions are obtained: (1) the proposed method of incorporating the characteristics of unsaturated soil is verified, (2) the simulation well represented the seismic behaviour of the excess pore water pressure and the deformation of the RC structure in unsaturated layer on liquefaction.

Key Words: *Suction Bucket Foundation, Effective Stress Analysis, Monotonic and Cyclic Loading, Wind and Wave Resistant Stability*

Suction bucket foundations have been attracting attention in recent years as a foundation method for offshore wind power facilities. To investigate the foundation stability against wave loading, Nielsen et al. carried out monotonic and cyclic loading tests using a small-scale mono bucket foundation installed in water-saturated dense sand [1]. Ueda et al. performed two-dimensional effective stress analyses to examine the foundation's wave-resistant stability; the seismic behavior was also investigated through shaking table tests in a centrifugal field [2]. However, the effect of different bucket dimensions (e.g., bucket diameter) on wave-resistant stability has not been thoroughly investigated.

The present study aims to numerically investigate the bucket dimension effect on the foundation's wave-resistant stability using two-dimensional effective stress analyses under undrained and partially drained conditions. A number of combinations of different monotonic and cyclic horizontal loads are applied for two types of suction bucket foundations with different bucket diameters installed in a liquefiable sandy deposit. Whereas the buckets are modeled as linear beam elements, the strain space multiple mechanism model [3] is used to consider the nonlinear response of the ground with pore water pressure increase during the cyclic loading.

Referring to Nielsen et al. [1], the computed inclination angle of the foundation after the combined loading is organized as a contour map on the drawing where the horizontal axis is the amplitude of monotonic loading while the vertical axis is the amplitude of cyclic loading. It is noted that both axes are normalized by the ultimate load obtained from pushover analyses (i.e., drained monotonic horizontal loading). The contour maps demonstrate that the bucket diameters affect the inclination angle under wave loading. Preparing such contour maps for foundations with different bucket dimensions makes it possible to easily and visually evaluate the degree of foundation inclination under any combination of monotonic and cyclic loads.

Key Words: *high-performance simulation, solid-fluid analysis, soil liquefaction, Cycliq constitutive model*

This study develops an efficient solid-fluid coupled simulation method of soil liquefaction analysis, based on the GEOSX open-source, multiphysics simulator. Solid-fluid analysis is achieved through an explicit FEM-FVM coupling routine. The CycLiq constitutive model is implemented for the simulation of soil liquefaction behavior, based on the cutting plane stress integration algorithm and the three-dimensional mapping rule. LEAP-UCD-2017 centrifuge shaking table tests are simulated to validate the soil liquefaction analysis method. Moreover, an underground tunnel model with large-scale gravel piles is simulated to demonstrate the simulation ability of 10 million degrees of freedom solid-fluid coupled dynamic liquefaction analysis. The efficiency and scalability of the high-performance solid-fluid coupled analysis method is evaluated by varying the scale of the analysis model. The results highlight that proposed method can significantly expand soil liquefaction analysis capability in terms of both problem size and solution fidelity.

Key Words: *Liquefaction resistance, Underground Structure, Seismic Response Analysis*

This study investigates the importance of appropriate liquefaction resistance simulation for underground structure seismic response analysis in liquefiable ground. A series of numerical simulations are conducted using solid-fluid FEM with two constitutive models for soil liquefaction analysis. The first constitutive model is the original CycLiq model proposed by Wang et al. (2014) which is able to provide good simulation for the post-liquefaction behavior of sand, but tends to underestimate liquefaction resistance at low cyclic stress ratio. The second model is proposed based on the original CycLiq model to enhance the description of the liquefaction resistance. These two models are first used in the simulation of the centrifuge shaking table test conducted by Zhu (2021) for validation. Upon validation, the models are used in the simulations with different input peak acceleration amplitudes (PGA) to evaluate the influence of the models' ability to appropriately reflect liquefaction resistance on the seismic response analysis of underground structures. The analysis results show that these two models can produce similar response of underground structure in liquefiable ground within a certain range of PGA. However, the original model overestimates the response of underground structure at low PGA and underestimates it at high PGA, compared with the modified model. The results suggest that it is important for constitutive models to accurately reflect the liquefaction resistance of sand when simulating the seismic response of underground structures. The influence of liquefaction resistance on the seismic response of above ground structure needs to be further studied.

Key Words: *Multi-segmented rigid bodies, Liquefaction, 3D effect of dynamic SSI*

Three-dimensional effect of dynamic soil-structure interaction (SSI) on liquefiable ground critically matters in the embankment containing the underpass structure. Damage closely related to this effect has been reported in Mid Niigata Prefecture Earthquake in 2004 [1] and the 2016 Kumamoto Earthquake [2]. In these earthquakes, the joint openings of the box culverts occurred due to the liquefaction of the foundation ground; the damage patterns have been unstructured.

A three-dimensional model of a road embankment containing a box culvert with joint was fabricated on liquefiable ground. Its seismic behaviour was investigated with geotechnical centrifuge of 50G. To visualize the foundation ground under the culvert, a half-section embankment-culvert model was used. The longitudinal section was observable from the front.

The testing result reproduced the past-reported joint opening: joint opened as if it was inclining toward the culvert-mouth as liquefaction progressed. The 4 locations of the excess pore water ratios directly under the culvert-mouth, the joint, and the shoulder and the centre of embankment were respectively compared. The measured results indicated that the excess pore water ratios under the culvert exceeded that under the embankment in each point, and its ratio under the joint exceeded under the culvert-mouth; they can be categorized as 3D effect of dynamic SSI.

In summary, liquefaction is more likely to occur in the foundation ground directly under the culvert. This different progress of the liquefaction under the culvert and the embankment seems to amplify the joint opening of the box culvert. In the future, we plan to conduct reproductive analysis to verify whether this interesting response can be confirmed in the numerical analysis.

ACKNOWLEDGEMENT

This work was supported by JSPS KAKENHI Grant Number 21K14241.

Seismic response of sheet-pile structures in liquefiable soils: Stochastic modeling and validation

M.T. Manzari[a*] and M. A. ElGhoraiby[a]

[a] George Washington University, Washington, DC, USA
* corresponding author: manzari@gwu.edu

Abstract:

Design of sheet-pile walls in granular soils is traditionally based on limit equilibrium analysis approaches that are known to be highly over-conservative. An alternative approach that has gaining much popularity in recent years is to use nonlinear elastoplastic analyses that more accurately account for the initial state of soils and the soil-pile interaction. However, majority of the modeling tools available in engineering practice are limited to simplified constitutive models that are unable to properly simulate the cyclic response of soils. Even when more advanced constitutive models are available, their performance has been evaluated against limited number of element tests that cover a narrow range of densities and initial stresses and target specific stress and strain paths that might not be representative of what the soil experiences in its interaction with structures. To address these shortcomings, there is a need for systematic evaluation of constitutive models and numerical modeling techniques against high quality experimental data that cover a wide range of initial stresses, soil densities, and stress/strain paths. Here, seismic response of a sheet pile wall embedded in a liquefiable soil is used to demonstrate the versatility of such a systematic approach. The sheet-pile wall was first designed by conducting a series of nonlinear finite element analyses that considered the coupled response of the pore fluid and soil skeleton and included a critical state elastoplastic model of soil skeleton that was thoroughly calibrated against element test data performed on the selected soil. Seismic performance of the designed sheet-pile wall was then predicted for a large number of target seismic motions. Following these blind predictions, a scaled model of the system was tested in a geotechnical centrifuge. The measured response of the wall was found to be remarkably close to the blind prediction. The computational model, initially validated against the element tests and the centrifuge experiment, was then used in a series of stochastic finite element analyses to assess the response of the system for a wide range of seismic motions and soil densities. The analysis results were compared to extensive experimental results obtained in the course of an ongoing international collaborative research project, Liquefaction Experiments and Analysis Projects (LEAP)[1]. The capabilities and limitations the computational model in capturing the response of the sheet-pile wall structure over a wide range of densities and base motion intensities and frequency contents are discussed.

A coupled BCHM model for MICP treatment in soil

Xuerui Wang[1a*], **Udo Nackenhorst**[1b]

[1] Leibniz University Hannover, Appelstr. 9a, 30167 Hannover, Germany,
[a]xuerui.wang@ibnm.uni-hannover.de, [b]nackenhorst@ibnm.uni-hannover.de

Key Words: MICP, BCHM Coupling, Multifield Problem, FEM

Microbially induced calcite precipitation (MICP) provides potential of developing sustainable methods for improving the engineering properties of soil. MICP treatment in soil can cause complex interactions among different fields, by which ureolytic bacteria are utilized to catalyze urea hydrolysis, producing ammonium and carbonate ions. With the presence of calcium, calcite can be precipitated. In soil, the filling of calcite in the pore spaces can reduce the porosity as well as permeability. Besides, calcite act as binding material among the solid grains which can improve the mechanical stiffness and strength.

In the present study, a coupled bio-chemo-hydro-mechanical (BCHM) model is developed with the aim on a better understanding of coupling effects involved in MICP. In this model soil is considered as saturated porous media. The computational domain is a representative elementary volume (REV), in which the solid phase and the liquid phase are considered. In the liquid phase, multi-component transport is considered and described by reactive mass transport equations. The governing equation for the flow process is derived based on the mass conservation of the liquid phase. The couplings between the mechanical and hydraulic fields are incorporated in the mass balance equations for solid and liquid phases. The decrease of permeability following the MICP induced porosity reduction is considered using a modified Kozeny-Carman equation. Modified Cam-Clay model with combined volumetric-deviatoric hardening is adopted to describe the elasto-plastic behaviour of the soil. The increase of stiffness and strength is considered with the calcite-contents-dependent increase of elastic modulus and extension of the yield surface. Besides, the degradation of calcite bonds is considered by introducing a degradation parameter. The model is solved by the finite element method (FEM) based on the open source code OpenGeoSys (OGS). To consider the multifield problem, subsystems for reactive mass transport (BC), flow process (H) and deformation process (M) are defined, respectively. These subsystems are solved iteratively using a staggered scheme [1]. The couplings are considered by defining the dependency of the parameters and variables from different subsystems.

This model has been applied to simulate experiments from different literature sources. The experimentally observed mass and permeability variations in space and time, increase of mechanical stiffness and strength, and the dilatancy behaviour during MICP can be well captured in the model.

Analysis of coal fluidization mining with continuous-discontinuous element

Jing Li[1], Chun Feng[2] and Yiming Zhang[1*]

[1] School of Civil and Transportation Engineering, Hebei University of Technology, Xiping Road 5340, 300401 Tianjin, PR China

[2] Institute of Mechanics, Chinese Academy of Sciences, Beijing 100190,PR China

Key Words: Fluidized mining, filling rate, filling rate

Comparing to traditional mining methods, in-situ fluidization mining[1] is a promising method for reducing ecological influence. During fluidization mining, coal gangue will be separated from ores and filled back to the excavation region, which greatly reduces strata deformation, depending on the filling rate. Numerical simulations can help the engineers to evaluate the strata deformation and optimize the designs with affordable costs. In this work, a continuous-discontinuous element method[2] is adopted for simulating the coal in-site fluidization mining-filling processes, which is a coupled finite-discrete element methods with explicit integration formulation. The theory of "equivalent mining height" is used to define the backfill mining height. The results partly reveal the influence of filling rate on the strata deformations, surface subsidence and rock burst.

Key Words: *thermal stresses, multiscale analysis, eigenstrains, constraints, concrete beams*

Temperature changes in concrete structures result in thermal stresses that may cause cracking. As for concrete beams, these stresses originate from thermal eigenstrains, constrained or prevented at three different scales of observation, namely, the microstructural scale of the concrete material, the cross-sectional scale, and the macrostructural scale of the beams.

The multiscale nature of the thermal stresses is quantitatively addressed by establishing the scale transition (i) from cement paste, sand, and aggregates to the material scale of concrete, (ii) from the material scale of concrete to the cross-sectional scale of the beam considered, and (iii) from the cross-sectional scale to the macrostructural scale of the beam. This mode of analysis is applied to quantifying the fluctuations of microstructural stresses of the concrete constituents for rectangular concrete beams, subjected to thermal loading. Sensitivity analyses, with respect to different heating speeds, different concrete constitutions, different internal relative humidities, and different geometric dimensions of the beams are carried out. This provides better understanding of thermally-induced degradation of concrete structures and helps to improve their durability by optimization of the concrete mixture and improvement of the thermal boundary conditions.

A coupled implicit MPM-DDA for soil-structure interaction problems

Ryota Hashimoto[1*], Bodhinanda Chandra[2] and Kenichi Soga[3]

[3] University of California, Berkeley, Davis Hall, Berkeley, CA, USA, soga@berkeley.edu

Key Words: *Material Point Method, Discontinuous Deformation Analysis, Implicit Scheme, Soil-Structure Interaction*

Numerical analysis of the soil-structure interaction problems in a large deformation range is important to understand both the failure mechanisms and the post-failure behaviors of slopes and earth structures. For this purpose, coupled continuum-discrete analysis methods have been developed intensively during the last decade. Those methods mainly employed particle-based methods (e.g., Smoothed Particle Hydrodynamics and Material Point Method) for the modelling of large deformation of soil and discrete element methods (e.g., Distinct Element Method and Discontinuous Deformation Analysis) for the modelling of structures and rigid bodies, where the contacts between them are considered [1, 2].

The previous methods often use an explicit time integration and/or a staggered coupling scheme that alternately runs the continuum method and the discrete method while exchanging the forces and the kinematics. This is owing to the explicit time integration scheme used in the particle methods and/or the Distinct Element Method. However, when we analyze the pre-failure process that is often quasi-static as well as the post-failure behavior, the explicit scheme often exhibits large computational costs due to the limitation of time increment size.

In this study, we newly developed a coupled analysis method of the implicit Material Point Method (MPM) for soil and the Discontinuous Deformation Analysis (DDA), which is an implicit type of discrete element method for structure. The contact between the MPM and the DDA is formulated based on the penalty method, and the equilibrium of the whole system is solved monolithically. Since the Newmark type implicit time integration is used in both MPM and DDA, the fully implicit feature is retained also in the coupled analysis. The developed method was applied to a simulation of a benchmark experiment [3] and the validation was investigated.

Key Words: Discrete element method, Irregular-shaped, Signed distance field, Contact potential, Spherical harmonics.

This work develops a signed distance field (SDF)-based contact approach to the discrete element method (DEM) for modeling generic irregular-shaped particles. It is proposed to implement particle models from an SDF-based generic interface that provides an SDF function and a surface projection function. The signed distance is positive inside particles, and vice versa; thus the zeroth isosurface of SDF represents particle surface. With particle surface discretized into a set of nodes, the node-to-surface algorithm is adopted for contact detection, namely, by checking the distance signs of the surface nodes of one particle with respect to another. Then, the energy-conserving contact theory is adopted to derive the contact interaction forces, with the contact potential defined on each intruding nodes. Based on the SDF-based contact framework, particle models are developed based on classical geometries, including poly-super-ellipsoid, poly-super-quadrics, spherical harmonics, and polyhedron; and the existing level set particle model is also integrated. In addition, a weighted spherical centroidal Voronoi tessellation-based scheme is developed for particle surface discretization and reconstruction. Example DEM simulations are provided to verify and demonstrate the capabilities of the proposed SDF-DEM framework. The computational aspects, including the memory consumption and computational efficiency of the approach and aforementioned particle models, are discussed.

An Improved Extended Material Point Method to Model Shear Band Evolution and Large Deformation Post-failure Behaviors

Yong Liang*, Bodhinanda Chandra and Kenichi Soga

Department of Civil and Environmental Engineering, University of California, Berkeley, CA, 94720, United States

Key Words: Extended Material Point Method, Localization detection, Frictional Self-contact, Shear Band, Large Deformation

An improved XMPM formulation is proposed to simulate the evolution of shear bands and post-failure behaviors with large deformations (e.g. landslide). The XMPM introduces a localization search algorithm based on the theory of bifurcation to predict the initiation and propagation of shear band. To deal with the dynamic frictional contact mechanism between the generated shear planes, a formulation of self-contact is integrated into the XMPM framework. In addition, a hybrid implicit-explicit description of discontinuity is considered by employing the level-set method and a point cloud approach to ensure the smoothness of the discontinuity surface during localization propagation. Several numerical examples have been investigated to assess the accuracy and demonstrate the capability of the proposed XMPM approach in simulating the shear band evolution of different engineering problems in both 2D and 3D. The proposed formulation is proven to exhibit minor sensitivity with respect to mesh refinements in predicting the shear-band path. Further research should focus on improving the efficiency and stability of the XMPM solver by considering parallelism and high-order spatial and temporal approximation. It is also interesting to investigate the connection between weak and strong discontinuity in large deformation problems, as well as a variable frictional contact model taking into account the material cohesive and dilatancy characteristics.

Assessment of Macro and Micro level Heterogeneities for Characterizing Mechanical Behavior of Sand in Biaxial Test employing DEM

Madhu Sudan Negi[1*] and Mousumi Mukherjee[2]

[1] Research Scholar, IIT Mandi, India, d20013@students.iitmandi.ac.in ([*]Corresponding Author)

Key Words: *Macro and micro level, Heterogeneity, Biaxial test, Representative volume element (RVE), Wall-based measurement, Sand*

Discrete element method (DEM) is widely used to examine the mechanical behaviour of granular assemblies, like sand, under various loading conditions by performing numerical simulations replicating different laboratory tests. While simulating various element tests from such particle-based methods, it is often required to estimate magnitudes of field variables, such as stresses and strains, which are essentially defined based on a continuum assumption. In this regard, either a wall-based global estimation or a representative volume element (RVE)-based local assessment is often adopted. Wall-based estimation predicts an overall response of the specimen which takes into account only the particle to wall contacts. As a result, such wall-based estimation of field variables is often influenced by the boundary effects arising due to the concentration of stresses and voids around wall boundaries [1], which can be identified as a source for macro level heterogeneities. On the contrary, RVE is considered to be statistically representative of the specimen under consideration. Further, it must be large enough so that an increase in the size will not change the estimated field variables and should exclude any possible macro level heterogeneities. In addition, an RVE should not be too small such that it starts to depict micro level heterogeneities, such as the development of unrealistic localized zones of various field variables due to consideration of only limited number of particles within the RVE [2]. However, deciding the optimal extent of the RVE to avoid such macro or micro level heterogeneities requires a systematic analysis.
In the present study, biaxial test simulations are performed employing DEM with non-circular particles of realistic particle size distribution [3]. Subsequently, an analysis has been carried out to assess the influence of the aforementioned macro and micro level heterogeneities in reference to the characterization of mechanical behavior of the specimen from a chosen RVE configuration. In this regard, a series of simulations have been carried out by generating various RVE configurations with different diameter and volume coverage over the specimen. It has been observed that the wall-based estimation predicts higher stresses and unrealistically higher volumetric strain, particularly at the larger strain levels, in comparison to the RVE-based estimations. However, it is interesting to note that increasing the volume coverage of RVE can predict stresses in the range of wall-based stress estimates. In order to establish a better mechanical characterisation, it has been proposed that the RVE should evolve with the continued deformation maintaining a constant volume fraction coverage in reference to the deformed configuration of the specimen. Further, it is suggested that the RVE should occupy a maximum of 90% volume of the specimen in order to avoid any possible boundary effects and can still be able to capture its overall mechanical behavior. However, when a local variation of field variables is of interest, RVE of smaller diameters can be employed. In such cases, depending on the average particle size of the granular assembly, the diameter of the RVE should be selected ensuring that it is small enough to aptly capture the local variation of field variables and at the same time, large enough to avoid any micro level heterogeneity.

Detailed Statistical Properties of Cell-Based Packing Structure in Elliptic Particle Systems

Xiaoyu Jiang[1*] and Takashi Matsushima[2]

Key Words: Granular Microstructure, Cell-Based Description, Elliptical Particle, DEM

The ubiquity of granular material in nature and in human society makes it important to model, however we are still far from understanding its complex and rich behaviors. One of the difficulties is that the macroscopic granular material properties are sensitive to microscopic structural characteristics. In two dimension, the granular structure can be described in terms of *cell* [1], which is the smallest closed loop in force chains. Recent works revealed the evidence of structural self-organisation and universal statistical properties of cell structure in systems composed of circular particles [2, 3]. On the other hand, particle shape has a great effect on the evolution of granular local structures [4], to which careful attention should be paid.

In this study, we performed numerical simulations, using Discrete Element Method (DEM), to investigate the detailed statistical properties of cell-based packing structure in two dimensional elliptical granular packings. Granular systems of elliptical particles with different particle aspect ratio (quantifies by the ratio of particle long axis to short axis) and intergranular friction, were slowly compressed isotropically into a marginally jammed and mechanically stable state. We found that: (1) The mean coordination number ranges from 3 in very rough particles to 5.5 in very smooth particles which agrees with isostatic theory of non-circular particles. The transition from circular particles to non-circular particles appears when the aspect ratio is less than 1.5. (2) Being different from the result of circular particles system, the initial condition before compression slightly affects the resulting solid fraction in equilibrium even after removing rattlers (floating particles with one or no contact). This may be due to the orientational clustering of elliptical particles [4]. (3) The mean cell volume for each cell order in elliptical particles packs can be interpreted by the extended regular polygon cell model in which the upper and lower bound relations are obtained by the long and short axes of ellipses, respectively.

Our results not only confirm the usefulness of cell-based approach in understanding and modelling the granular materials, but also encourage further using of cell-based approach in non-circular particle systems.

Key Words: *granular avalanches, Discrete Element Method, Power-law*

Avalanches of geomaterials often cause serious damage to downstream area. When the material contains sufficient water, it flows as a fluid, which is called debris flow or mudflows depending on the material type, and its behaviour is investigated as the continuum fluid mechanics framework. On the other hand, when the material is under unsaturated condition, the flow behavior is more like a dry granular flow in which constituent geological grains move individually with mutual interaction [1]. As a result, particles in front of the flow are widely scattered and reach much farther than the mass flow. The evaluation of such '*particle runout*' is important to assure the safety of the downstream area [2].

This study attempts to clarify the particle runout of dry granular chute flow from statistical behaviour of granular materials. We performed a series of 2D Discrete Element simulations for non-circular particles of different particle properties such as particle size, shape, restitution coefficient and friction. We found that (1) the centre of the mass of the deposition tends to be independent from grain shape and size, (2) the distribution of the particle location at the final deposition has a tail of more like a power-law type than an exponential type, and (3) the power-law exponent is affected by the particle size but not affected by the length of the slope. These findings are in accordance with the previous experimental results [3]. The first finding is related to the fundamental rigid block runout model in which the equivalent friction $\mu = H/L$, where H is the height of the slope and L is the horizonal mass runout [4]. As for the finding (2), a simple particle runout model by assuming the Maxwell-Boltzmann type distribution as the initial particle eject speed cannot explain the resulting power-law distribution, and more detailed statistics of individual particle motion should be investigated.

kajiyama@yamaguchi-u.ac.jp

Key Words: *DEM, Angle of repose, Contact force*

Binary granular mixture is composed of two different size particles. The skeletal structure that governs mechanical properties of this material can be divided into three types according to large particle content. These were defined as “Small particle skeletal structure” seen when large particle content is low, “Large particle skeletal structure” found when large particle content is high and “Intermediate skeleton structure” [1]. The authors have been investigating the mechanical properties of binary granular mixtures of large particles with special shapes. In this research, skeletal structure of binary granular mixture composed of large cylindrical particles such as coral gravel and small particles was investigated. First, the angle of repose experiment was reproduced by DEM. Then, three types of skeletal structures were identified from the relationship between the angle of repose and large particle content. This allowed us to evaluate large particle content V_L^b%, which is the boundary between small particle skeletal structure and the intermediate structure, and large particle content V_L^a %, which is the boundary between the intermediate structure and the large particle skeletal structure. Furthermore, the internal structure in the intermediate skeletal structure was analysed from a microscopic point of view.

Based on DEM analysis results, the relationship between the angle of repose and large particle content was analyzed. The boundary large particle content V_L^b% was 15.7%, and V_L^a% was 84.5%. Angle of repose begans to rise from V_L^b, increased to V_L^a, and above V_L^a, the result was same as result of only large particle content (100%). Since this tendency was the same as that of the experiment using the actual material, it was considered that the simulation performed could essentially reproduce the actual experiment. [2].

Here, the contact force equivalent to the own weight of one small particle of $6.99 \times 10^{-3} N$ was used as the reference value, and the relationship between the proportion of contacts below the reference value and the angle of repose was analyzed. With V_L^b% as the boundary, the ratio increased as the angle of repose increased. It shows a transition to the intermediate skeletal structure in which the number of contacts that transmit large contact force of large particles increases as content of large particles increases. This indicates that the number of contacts that transmit small contact force of small particles has increased.

Key Words: *Unsaturated Soil, Failure Analysis, Material Point Method*

Water infiltration induces many natural hazards, e.g. slope failures, landslides and embarkment collapses. In particular, torrential rains have recently become more intense than before probably due to climate change. To simulate such hazards, particle methods have recently become popular, and, among them, the solid-liquid coupled material point method (MPM) has accomplished a remarkable progress in the area of computational geomechanics. This particular MPM is separated two types: one for saturated soil and the other for unsaturated soil. Especially for the MPM for unsaturated soil, it is essential to represent the decrease in shear resistance of soil by the transition from unsaturated to saturated sates by infiltration.

However, in most of the coupled solid-liquid MPM algorithms for unsaturated soil [1], the liquid phase is assumed to be weakly compressible, and as results often cause pressure oscillation. Also, this assumption requires a high computational cost due to the large bulk modulus of water when explicit time integration is adopted. Although several scholars [2] have proposed semi-implicit MPMs, which are empowered by the fractional-step method to overcome this problem, and proved its effectiveness, few studies have so far been made at enhancing it to deal with failure of slopes with unsaturated soil.

In this study, we develop a semi-implicit MPM to properly express the mechanical behavior of unsaturated soil based on Biot's mixture theory. The new contribution of this study is the incorporation of the fractional-step method into the MPM to solve the pore water pressure implicitly, which improves the numerical stability and computational efficiency. Several numerical examples are presented to demonstrate the capability and performance of the proposed method. In particular, a validation analysis is carried out using a model experiment of infiltration-induced landslide.

Key Words: Bi-disperse Granular Material, $\mu(I)$ Rheology, Size Segregation, Discrete Element Method

Size segregation is commonly observed in granular systems when the difference of component sizes is sufficiently large [1]. The bi-disperse granular system is the simplest system to investigate this phenomenon. In some previous contributions, it was found that the rheological properties of bi-disperse flows fall in the $\mu(I)$ rheology framework established for monodisperse ones [2], although the quantitative effect of segregation (different components) on flow mobility was not fully clarified [3][4].

In this work, we computationally explore the rheology of size-binary, steady dense flows on a slope using the two-dimensional discrete element method. A series of simulations are carried out for various assemblies of circular particles of identical total volume with different size ratios ($1.5 \leq S_r \leq 5.0$) and bulk volume fraction of large particles ($0.3 \leq V_r \leq 0.7$). The particles are randomly placed on an inclined rough plane ($17^\circ \leq \theta \leq 25^\circ$) with a periodic boundary setting in the streamwise direction and are let flow under the gravitational force until they reach a steady condition where the depth profile of the flow velocity, stress components, volume fraction and large particle fraction (f^L) is regarded as constant with some fluctuations. Then we take a time average of such variables for different depths to investigate their correlation in the framework of the $\mu(I)$ rheology model.

Our results show that (1) the bulk shear friction ($\mu = \tau/\sigma$) and the particle fraction ϕ are roughly but not perfectly described in $\mu(I)$ rheology model by using the generalized inertial number (I) proposed by [3], where the representative particle size is defined by the volume average of the large and the small particles size, where similar results were also reported in [5], (2) the deviation of the observed results is mainly caused by the shear friction and the particle fraction at the quasi-static limit (μ_0 and ϕ_0, respectively) to be a function of f^L. Based on the second result, we modeled the functions $\mu_0(f^L)$ and $\phi_0(f^L)$, which gives better predictions of μ and ϕ.

florince-tm@ynu.jp,
rahmat.kurniawan@si.itera.ac.id,

Crushable soils such as volcanic soils, carbonate sand or decomposed granites whose grains are easily break under foundation pressure, especially, large magnitude of stresses under pile tips. When the grains are crushed, particle size distribution (PSD) varies followed by higher compressibility of these soils. Pile foundation's settlement in crushable soils tends to be increased. Nonetheless, design code for bearing capacity of pile in crushable soil is still unavailable leading to a lot of difficulties for engineers to have an appropriate foundation design. This paper introduces a constitutive model for soils which takes account of the breakage mechanics including the evolutions of PSD and the compressibility due to grain crushing. The model is implemented in a finite element code to simulate a past experiment of pile penetration in crushable soil. Finally, parametric studies are carried out to investigate bearing capacity of piles in crushable soil.

Key Words: *MPM, Elasto-plasticity, Sediment flow, Landslide, Transition between solid and fluid, Actual terrain model*

In the last two or three decades, there has been consecutive interest in numerical simulation of damage caused by slope disaster such as landslides and mudslides triggered by earthquakes. It is, however, difficult to represent the collapse and subsequent sediment flow that are transitioned from the elasto-plastic and/or damage behavior of soil. To predict such a transitional behavior between solid and fluid states of soil, a single constitutive model for either solid or fluid is inappropriate and multiple models representing individual states should be properly combined.

To tackle this issue, we explore the novel constitutive model capable of representing the transition between solid and fluid states and discuss its applicability to the analysis of sediment flow induced by earthquakes using an elaborate terrain model. The model is formulated by the combined use of the Jaumann velocity-based hypoelastic-plasitc constitutive law of Dunatunga et al. [1], which is equipped with the μ-rheological model for granular flow proposed by Jop et al[2], and the standard Newtonean viscous model, and is implemented into the material point method (MPM). The resulting analysis tool has a capability to simulate collapse of soil structures and a sediment flow stemming from and ceasing at sedimented states.

After the basic performance of the proposed constitutive model is validated, several numerical examples are presented to demonstrate the capability in reproducing the transitional behavior from/to the sedimented state to/from the sediment flow. Also, to clarify the mechanism of sediment flow under the influence of seismic force and predict the subsequent sedimented state, we conduct a simulation of the landslide in the grounds of the Ebisu Circuit, which was caused by the Fukushima earthquake on February 13, 2021 using an actual terrain model with the detailed 0.5 meter topography data.

Key Words: *MPM, FEM, 3D-2D hybrid, Submarine landslide, Tsunami*

Submarine or/and subaerial landslides sometimes cause a series of hazardous events, such as the severing of submarine cables and pipelines, obstacles obstructing the operation of resource development facilities, and large-scale tsunamis. The damage caused by such a tsunami has been considered globally, and the loss of life has also been significant. However, the process of such an event is not well understood partly due to multiple physical phenomena simultaneously interacting (the collapse of the seabed, the interaction between soil and water). Conventional approaches make it difficult to predict the behaviours of soil and seawater with high accuracy. Therefore, it is necessary to develop novel numerical methods to evaluate the complex interaction between solid and liquid. For this purpose, we have proposed an MPM-FEM hybrid method [1] for expressing the complex interaction between solid and liquid, in which the MPM [2] is applied to the governing equation of the solid phase by the Lagrangian description, whereas the stabilized FEM [3] is applied to that of the liquid phase in the Eulerian frame. Since several numerical examples have demonstrated performance and capability of our proposed method, we will apply it to reproduce natural disaster on a large scale in this study. The tsunamis induced by submarine landslides that happened in Palu Bay, Sulawesi Island, Indonesia, in 2018 are our first target to simulate. However, using complete 3D computations to simulate the propagation of offshore waves require high computational costs and not suitable for large-scale and long-duration simulations. In this context, the 2D shallow-water equation has been widely used for simulating large-scale offshore wave propagation [4] because of its lower computational costs compared to full 3D computation. Since 2D approach is preferable in this respect, we will also develop a novel scheme that can couple with 3D and 2D domains for reproducing the whole process of tsunami induced by submarine landslides. The results of this study will help elucidate the mechanism of landslide-triggered tsunamis and are expected to contribute to the development of effective strategies for disaster prevention and mitigation.

Key Words: DEM, rockfall, polygonal particles, shape effects

Rockfall events are a gravity-driven mass movements with limited volume but high energy and mobility. They are a significant hazard in mountainous regions and along engineered slopes with substantial potential for destruction (e.g. [1]). Mitigation of rockfall damage requires accurate prediction of potential rockfall trajectories and motion behavior. While various simulation methods have been proposed over the years, the common approach in discrete element simulations is to use round particles, see e.g. [2]. However, as real particles in rockfall events are rarely round but often angular and sharp-edged, round particle methods cannot accurately describe rockfall events. The dynamics of rigid bodies are heavily affected by the shape of the bodies as a competition of sliding, rolling, and even bouncing. Only recently have simulations begun to consider polygonal or polyhedral particles, e.g. [3], but they are still limited to a coarse selection of particle shapes. Up to now, no systematic study on the effect of particle shape in rockfall events has been performed.

With this research, we want to address this shortcoming by investigating the dependency of the motion behavior and runout distance of polygonal particles on the corner number and elongation for different initial orientations and slope angles using a two-dimensional discrete element method based on [4].

Key Words: 3D MPM, multi-phase and multi material flows, gravity-driven mass movements, cascading natural hazards

Gravity-driven geophysical flows such as rock, ice and snow avalanches impacting large bodies of water bear the risk of causing cascading natural hazards. Such cascading hazards may include rock or snow avalanches followed by lake outburst floods. To evaluate the resilience of existing protection measures and to define adaptation strategies for the future, it is necessary to have instruments to asses the danger potential of such events. However, the numerical modelling of process chains is a challenging task, as multiple materials with differing properties and phases are interacting in the process. During such events, diverse physical processes such as fracturing and multi-phase mixing or impact, for instance with water, are common. In state-of-the-art operational models, these processes are usually not considered due to difficulties in their mathematical formulation and in the assessment of the respective parameters.
In order to address the challenges of simulating complex cascading processes of gravity-driven mass movements, we use a newly developed numerical model [1, 2] based on the 3D Material Point Method (MPM) and finite-strain elastoplasticity theory. Using this MPM framework, we analyse the flow of rock and snow avalanches in complex terrain and their interaction with mountain lakes by performing fully three dimensional simulations. As a case study, we present preliminary results of simulations of the "Salezer" snow avalanche in Davos, Switzerland. At this site, a snow avalanche was artificially released on January 15th 2019, impacting Lake Davos. In our simulations we use the snow conditions present on that day and the original release area mapped by a photogrammetric drone survey. We compare macroscopic flow features, e.g. the runout and deposition, of the simulated avalanche to the observations of this well-documented event. Furthermore, using different snow conditions and release areas, we identify critical scenarios endangering the infrastructure, touristic sites or inhabited areas in the vicinity of the avalanche track and the lake.

Key Words: *Biaxial shearing, granular material, microscopic mechanism, particle rotation, numerical simulation*

Validation and/or calibration of distinct element method (DEM) models is usually performed by comparing element test simulation results with the corresponding stress-strain relationships observed in the laboratory [1]. However, such validation procedure performed at the macroscopic level does not ensure capturing the microscopic particle-level motion [2]. Thus, the reliability of DEM model may be limited to some stress paths and may not hold when the material response becomes non uniform for example when shear bands develop. In this study the validity of the DEM is assessed by comparing numerical result with experimental data considering both particle-scale behavior (including particle rotations) and macroscopic stress-strain characteristics observed in shearing tests on granular media. Biaxial shearing tests were conducted on bi-disperse granular assemblies composed of around 2700 circular particles under different confining pressures. Particle-level motions were detected by a novel image analysis technique. Particle rotations are observed to be a key mechanism of the deformation of granular materials. The results from this study suggest that to properly calibrate DEM models able to capture the mechanical behavior in a more realistic way particle scale motions observed in laboratory experiments along with macroscopic response are necessary.

Mathematical models play an important role in understanding drying processes in sawn timber and in the development of new drying schedules for kiln (i.e. air-circulation) drying of timber[1]. An experimental validation of such models is essential for their use in commercial applications. X-ray computed tomography (CT) is a non-destructive measurement method, which, in combination with suitable image-processing algorithms, allows for the reconstruction of the wood's fibre orientation[2], the observation of moisture content changes in wood during drying[3], and quantification of the deformations also experienced by wood during drying. Swedish sawmills use drying schedules for air-circulation drying that consist sequentially of heating, capillary, transition, diffusion, conditioning, and cooling regimes. The aim of the current study was to perform an experimental validation of a recently developed three-dimensional numerical model[4] based on moisture content and deflection data obtained through X-ray CT[5] and an image-processing algorithm[3]. The numerical model consists of two individual models that are determined in sequence: a moisture transport model based on a single-Fickian approach and a model that can simulate the visco-elastic and hygro-mechanical behaviour of wood. The experimental validation of the numerical model was determined using CT-data obtained during the kiln drying of a piece of sawn timber using a drying schedule provided by a local sawmill in the north of Sweden. The validation considered the transition, diffusion, and conditioning regimes since these are associated with moisture diffusion in wood. The objective of the study was to use the CT-data not only in the experimental validation, but also in the development of the model's geometry, the reconstruction of the fibre orientation, pith detection, and the definition of the simulation's initial states, boundary condition and moisture, temperature, and dry-density dependent material parameters. The validated model was used to analyze the effect of the conditioning regime on the moisture content and tangential stress development within the timber's cross section.

Investigation of Chemical Elements Influence on Tracheid Effect by ICP-MS

Yi-Jen Chen[1*], Tzu-Yu Kuo[2], Wei-Chung Wang[3]

Engineering Building I, National Tsing Hua University, Taiwan 30013
Republic of China
[1] s109033549@m109.nthu.edu.tw [2] asmit.com@msa.hinet.net
[3] wcwang@pme.nthu.edu.tw

Key Words: *Tracheid Effect, Sapwood, Heartwood, Chemical Elements, Inductively Coupled Plasma Mass Spectrometry (ICP-MS)*

Tracheids provide not only structural support but also transport water as well as inorganic salts for the wood, in particular, the conifer. The direction of tracheid determines the direction of the fiber. To measure the direction of the fiber, tracheid effect was used to measure the in-plane angle, α, and diving angle on the wood surface. Both α and β were determined by the elliptical shape of a laser speckle dot [1]. Based on the tracheid effect, the three-dimensional fiber orientation scanning system (3D FOSS) was developed in the Photomechanics Laboratory at National Tsing Hua University (NTHU), Taiwan [2] . Images of laser speckle on sapwood and heartwood can be obtained respectively. It is possible to predict the modulus of elasticity (MOE) of the wood by employing the values of α and β. By comparing the predicted and material testing results of the MOE of the Japanese cedar, the tracheid effect was found being influenced by density, crack, roughness, etc.

Based on experimental investigation performed at NTHU, it was observed that different shapes of laser speckle of sapwood and heartwood were not caused by the diving angle. This observation was confirmed by using the scanning electron microscope. The difference of laser speckle shape may be possibly caused by organic or inorganic compound in cell wall or lumen of the tracheid. Therefore, in this paper, inductively coupled plasma mass spectrometry (ICP-MS) was employed to measure inorganic compound in sapwood and heartwood of Japanese cedar. By using the ICP-MS, samples are injected and lead to a plasma source to become ionized and analyzed. Hence, the ICP-MS has excellent selectivity and sensitivity as well as high accuracy. Content ratio and type of inorganic material can also be rapidly detected by the ICP-MS. Therefore, the ICP-MS is an effective method to observe distribution differences and trends of chemical elements between sapwood and heartwood.

The preliminary results obtained at NTHU show that the content ratio of inorganic material trend of potassium and magnesium between sapwood and heartwood of the Japanese cedar have high correlation. Therefore, characteristics of heartwood of Japanese cedar have strong relationship with the potassium and magnesium. Further results will be reported in the Congress.

Key Words: *wood, moisture transport, moisture induced stresses, moisture induced failure*

Wood and wood-based products exhibit a strongly moisture-dependent behavior. Thus, knowledge about the wood moisture condition in a timber component is essential to predict its mechanical behavior during its service life. Not only stiffness and strength properties are highly dependent on the wood moisture content but also diffusion coefficients, density, specific heat capacity and the thermal conductivity. In addition, wood interacts with the surrounding climate, resulting in dimensional changes and stresses which may lead to critical conditions due to deformation caused by the non-uniform expansion coefficients. Therefore, modern prediction tools, which are able to describe these effects, can be of great benefit for the development of new wood-based products. Especially if these products exhibit complex geometries and are made of materials with different moisture characteristics. Such products have to be tested in varying climate conditions. Transport mechanisms below the fiber saturation point were described by Fortino et al. [1]. Three coupled differential equations describe bound water, water vapor and energy conservation. Free water exists above the fiber saturation point with the corresponding transport mechanisms described in Perre and Turner [2]. Values of the free water content can be much higher than those of bound water and water vapor. Thus, within the areas, where the switch from the transport mechanisms below the fiber saturation point to those above occur, high gradients can exist. To deal with these high gradients in terms of the finite element method different procedures like upstreaming and mass lumping described in Eriksson [3] were used. A three-dimensional Abaqus User Element Subroutine was developed to describe these coupled equations [4]. Such realistic moisture calculations allow in a next step to also conduct stress calculations. In combination with a multi-surface failure criterion for wood [5,6], it is then possible to evaluate the exposure of wooden structures to realistic climate conditions, taking into account the long-term material behavior as for example described in [7].

Within the category of structures that show excellent seismic resistance performance, Cross Laminate Timber (CLT) is becoming more and more popular, also for its environmental compatibility qualities. The general tendency of this construction technology is to approach strategic and high-rise structures; these two tendencies are accompanied by the consideration of design methods for these structures that take into account the concept of resilience and performance-based design. The aim of this study is to contribute to the definition of methods and procedures for the advanced dynamic evaluation of these structures, with particular reference to the forces induced by the wind, which is currently a dimensioning element, above all to ensure sufficient comfort for the users of the structures.A novel modelling approach of CLT structures is proposed here that considers each single connector and the complex system of frictional contacts established in the various panel-to-panel joints , of the entire building. The simulation integrates the following modelling choices:

1. Structural panels are represented individually as shell elements with topological references of the intersections with the panels they are in contact with.
2. Panel-to-panel contact behavior is defined with a continuous frictional contact formulation
3. Connectors such as hold-downs and angle brackets are modelled as discrete elements
4. Distributed connections such as screws between vertical walls are represented by suitably calibrated shells
5. Calibrated Shell elements represent the behavior perpendicular to the grain of floor panels between two walls.

The validation of this method is carried out starting from the experimental test data of a full-scale 3-storey CLT structure, a campaign that was part of the CNR-IVALSA- SOFIE Project. In this case, the low-amplitude seismic tests are considered, in order to exclude plasticization of the connectors, and to directly compare the time-histories of inter-storey drift and base shear with the computational results. A support structure representing the wind-loaded envelope is then defined and the pressure field on it is calculated using Computational Fluid Dynamics (CFD) analysis. The development of a parser for these fields allows their subsequent use within a structural fem solver and their integration in a non-linear dynamic transient analysis.The software used are opensource allowing complete transparency of the methods used, the verifiability and improvability of the routines and the possibility for anyone to implement the methods discussed here.

Numerical simulations provide a highly efficient way to estimate the bending strength of glued laminated timber (GLT) beams. A reliable estimation of the strength requires the consideration of adequate material behavior and relevant failure mechanisms.

Therefore, the approach uses section-wise constant material properties, i.e., longitudinal stiffness and tensile strength, which were derived along entire timber boards based on the procedure proposed by [1]. [2] proposed the use of discrete cracks without predefined positions within the framework of the extended finite element method (XFEM). Additionally, the formation of progressive crack networks is enabled by implementing cohesive surfaces between adjacent lamellas. For the validation, four-point bending tests of GLT beams were simulated to estimate the bending strength of specific beams from an experimental study with well-known knot morphology, which was presented by [3].

Finally, the height effect on the bending strength was studied by simulating GLT beam sections loaded with a constant bending moment. The beam heights ranged from 135 mm to 3000 mm, and the boards were randomly arranged within the GLT beams. As a result, we obtained fitted probability distributions of the bending strength for different global failure criteria and beam heights.

Multi-Physical Modeling and Numerical Simulation of Thermo-Hygro-Mechanical Treatment of Wood for Use in Timber Structures

Robert Fleischhauer[1*] and Michael Kaliske[2]

[1] Institute for Structural Analysis, Technische Universität Dresden, 01062 Dresden, Germany, robert.fleischhauer@tu-dresden.de

Key Words: *Multi-Physical Constitutive Modelling, Thermo-Hygro-Mechanical Wood Treatment, Structural Investigations at Moulded Wooden Tubes*

The contribution at hand introduces computational modelling and realistic simulation concepts for a comprehensive description of the manufacturing and application of densified wood as well as densified and moulded wooden structures.

Wood, as a natural material, is characterized by a very good mechanical load-bearing capacity related to its density. Nevertheless, the ratio between its mechanical properties and its density can be optimized by densification technology for an improved use of wood in structural engineering. The wood densification process is not only a mechanical process with large and irreversible deformations, it is also characterized by temperature and moisture-dependent treatment of the wooden specimens.

Thus, the introduced approaches to predict the material and structural characteristics of compressed and moulded wood, consist of an inelastic and multi-physical constitutive modelling of wood at finite deformations, based on [1]. Furthermore, a computational approach to compute effective structural properties of wood after the thermo-hygro-mechanical densification process is introduced and presented, based on [2].

A successful implementation of the modelling concepts into the Finite-Element-Method (FEM) is presented, which is verified by numerical investigations. A validation of the numerical results is carried out by use of experimental data at beech wood (Fagus Sylvatica, L.). First, thermo-hygro-mechanical densification processes are modelled, see [3]. Second, the computed effective properties of densified beech wood are validated at experimental data. Finally, the structural investigations of densified and moulded wooden tubes with respect to their load deflection behaviour are presented. Therefore, digital image correlation based deformation patterns are compared to FEM based simulated deformation patterns for tubes under compressive loads.

web page: https://www.imws.tuwien.ac.at

Key Words: *Wood, Phase field, Fracture*

Wood, as a naturally grown material, exhibits an inhomogeneous material structure as well as a quite complex material behavior. For these reasons, the mechanical modelling of fracture processes in wood is a challenging task and requires a careful selection of numerical methods. Promising approaches like limit analysis [1] or the extended finite element method (XFEM) in combination with microstructure materials models [2] deliver good but not yet satisfying results. Particularly the latter approach, including XFEM, has severe difficulties with crack paths in regions with complex morphology, mainly around knots. Therefore, in this work, focus is laid on the recently emerging and very popular phase field method [3]. Especially geometric compatibility issues that limit the use of XFEM can be avoided, as the crack is not discretely modeled but smeared over multiple elements. This allows the formation of complex crack patterns, defined by the underlying differential equations and boundary conditions but not restricted by the mesh geometry.

The present implementation contains a stress-based split [4] which allows proper decomposition of the strain energy density for orthotropic materials. Furthermore, the geometric influence of the wood microstructure on crack propagation is taken into account by a structural tensor scaling the length scale parameter of the phase field [5]. For solving the system of differential equations, a staggered approach is used where the phase field equation and deformation problem are solved separately. The staggered approach is enhanced with an additional Newton-Raphson loop that ensures convergence.

The developed algorithm was tested on various problems. Compared to XFEM more computation time was needed as the phase field method requires a finer discretization. However, crack patterns, including branching and merging, could be modeled very stable and accurately, even in the vicinity of knots where the material structure of wood is particularly complex and interface zones exist.

Key Words: *numerical simulation, transient thermal analysis, Ansys, experimental validation, CLT, glued butt-joint*

With the Timber Structures 3.0 technology, timber components are bonded together in a statically load-bearing manner by a 4 mm thick butt joint on the face side of cross-laminated timber (CLT) plates filled with a casting resin. In particular, this offers the possibility of creating biaxial load-bearing ceiling panels made of CLT in any geometry.

However, the processing temperature of at least 17 °C [1] specified by the casting resin manufacturer still poses a challenge for the construction site application. Therefore, the possibility of locally tempering the 4 mm thick casting resin joint during the curing process is being investigated. For this purpose, a groove is milled into the surface to be cast, into which a heating wire is inserted. This heating wire is intended to heat the casting resin joint to above 17 °C during curing by low ambient temperatures.

In order to investigate whether this measure causes a sufficient temperature in the joint, a numerical simulation is carried out in Ansys. For the timber, the material parameters (thermal conductivity and heat storage capacity) are known as a function of the respective fibre direction, but for the casting resin, the values known for the cured state are used first. Although these differ from those in the fluid respectively curing state, they represent a good first approximation. Likewise, a justified assumption is made for the exotherm. With these input values and clearly defined boundary conditions of geometry, ambient temperature and heat transport, the temperature distribution in the joint is calculated over time and over the cross-section. Subsequently, an experiment with the same boundary conditions is carried out and the results are compared. In the following, the material parameters of the casting resin in the simulation are adjusted so that the simulation and experiment match. With the values determined, the application is planned and carried out on the construction site.

To verify the input values, the site application is monitored with temperature sensors and compared with the previous simulation. This comparison shows that the simulation represents reality sufficiently accurately. Therefore, the simulation can be extended to different boundary conditions, such as panel thicknesses and ambient temperatures, and used in the future to determine the number and amperage of heating wires for construction projects at below 17 °C.

Key Words: *Molecular Simulation, Cell Wall, Interface, Wood-Water Relation, Hygromechanics*

Wood cell wall, especially the thickest S2 layer, dominates the hygro-mechanical performance of wood. The exploitation of the full potential of wood calls for a thorough understanding of its mechanics and hierarchical structure, especially of the nanoscale wood-water relation.

The exact material configuration of cell wall is still under debate because the nanoscopic polymer interactions are beyond the detection limits of contemporary experimental techniques. In contrast, computational studies, especially molecular modelling methods, are capable of agilely experimenting various material configurations and probing the working water-wood mechanisms on the molecular scale.

We employ molecular dynamics (MD) simulations to understand the structural, physical, and mechanical impact of hydration on wood cell wall. Individual polymeric components, their composites and interfaces, and a state-of-the-art S2 cell wall layer model are proposed and characterized systematically. The yielded unprecedented micromechanical dataset reveals the working mechanism of cell wall that is otherwise unobtainable.

It is demonstrated that the interphases between different polymeric components exhibit densities or mechanical properties distinct from bulk material. Although the matrix itself is soft and isotropic in bulk, its interphase is stiff and anisotropic owing to the influence of cellulose fiber. Hydration induces the weakening of wood cell wall by causing mechanical degradation of matrix and fiber-matrix interface while leaving the cellulose fiber mostly intact. Hemicellulose glues lignin and cellulose fiber together, and water severely disturbs the hemicellulose-related hydrogen-bonds. In contrast, lignin is rather hydration independent and serves mainly as a space filler. The fibril-fibril and fibril-matrix interfaces are probed by MD pulling tests. The stick-slip behavior is explained by the strong correlation between the number of hydrogen bonds and the interfacial shear stress, suggesting the force rendered by a single hydrogen bond to be ∼140 pN.

Key Words: *expansive clay mineral, electro-chemo-mechanical phenomena, cementation, tunnel, finite element method*

In bedrock including expansive clay minerals, the pore fluid composition affects the mechanical behavior of the bedrock such as swelling. It is necessary to elucidate the mechanism of the behavior and evaluate the deformation caused by the swelling quantitively because the swelling behavior of expansive bedrock causes problems when tunnel excavation and earth cutting. To simulate the issues regarding swelling behavior, a constitutive model that considers the electro-chemo-mechanical phenomena on the surface of expansive clay mineral crystal, stiffness of bedrock, and the degradation of the internal structure is required.

This research proposes a new model targeting expansive bedrock by means of combining an elastoplastic model considering electro-chemo-mechanical phenomena with the Cam-clay model introducing cementation and its degradation due to plastic deformation. The proposed model describes the process of degradation of cementation due to the swelling caused by the electro-chemo-mechanical interlaminar action occurring between crystal layers, which can lead to the transition of a rigid rock mass to soft soil.

Tunnel excavation and swelling analyses are demonstrated by incorporating the proposed model into a finite element analysis code. The simulation results indicate that the proposed model is applicable to the geotechnical problems occurring in expansive bedrock.

Key Words: *FEM; effective stress analysis; penetration; model test; cavity expansion*

Although the penetration resistance is not a physical parameter inherent to the soil material but is a value reflecting the response from the ground, there are many estimations that directly associate penetration resistance with various ground physical properties. Penetration resistance is subject to both the influence of the properties of the ground material such as strength parameters or dilatancy of the soil, and the influence of the boundary condition such as layer boundary and drainage condition around the target ground. Therefore, in order to improve the accuracy of the CPT, it is im-portant to analyze the behavior of the soil by considering cone penetration as a complicated boundary value problem and clarify the influence of boundary conditions and soil characteristics on penetration resistance.

As preparation for a future numerical investigation focused on the details of the combined effects of soil properties and various boundary conditions, a series of numerical analyses was conducted using a FEM code named GEOASIA (All Soils All States All Round Geo-analysis Integration) developed by Asaoka et al. in [1] and sophisticated by Noda et al. in [2], in which the Super/subloading Yield Surface Cam-clay model, in short, the SYS Cam-clay model in [3,4] was used as the constitutive equation of the soil skeleton.

The influence of mesh size on the tip resistance is confirmed at first. Then, as a part of preparations for future experimental validations through numerical simulations of a series of calibration chamber tests, a series of numerical parametric simulations evaluating the influence of lateral boundary conditions and confining pressure on cone tip resistances are conducted. Further, the analytical results are roughly compared with a series of trial experimental results. Since those experimental results contained some ununiformity problem of stress distributions in the model ground, it remained that a similar qualitative tendency was observed between the simulation results and the experimental results.

Key Words: Slope stability analysis, Hovland's method, Three-dimensional simplified Bishop's method

Hovland's method[1] is well known as one of the three-dimensional limit equilibrium methods for slope stability analysis. The method has been widely employed even in practical situations because of its simple calculation algorithm, while a lot of researchers have pointed out that the method cannot accurately evaluate the risk of slope failure. On the other hand, more sophisticated methods, such as simplified Bishop's method[2], simplified Janbu method[2], and Spencer's method[2], are also recognized as methods based on the limit equilibrium theory. Although calculation algorithm of these methods are much complex than that of Hovland's method, the importance of using those methods has been mentioned in a lot of literatures. However, the potential of the methods has been discussed only under limited conditions and the capability of each method for risk analysis of wide-area disasters has not been well studied.
This study aims to explore the accuracies of Hovland's method and simplified Bishop's method by applying them to wide-area slope stability analysis under the condition of a real heavy rainfall event. In order to consider realistic slip surface, both methods are extended to satisfy the moment balance under the assumption of the ellipsoidal slip surface. However, since Hovland's method is generally formulated under the assumption of circular slip surface, the original Hovland's method is also used for comparison. Slope stability analysis are then performed using these three methods to reproduce the slope failures caused by an actual heavy rainfall event. Distribution maps of the factor of safety are compared with the actual slope failure distribution and the consistency is quantitatively compared using the ROC curve. The obtained results indicates that the result obtained by simplified Bishop's method is the most consistent with actual slope failures.

Key Words: *Peridynamics, DEM, Geotechnical engineering, Fracture mechanics*

Peridynamics is characterized as a continuum-based, mesh-free, and non-local numerical analysis method. Many studies have shown that the peridynamics is one of the effective tools for crack propagation and fracture phenomena in brittle and quasi-brittle materials. In the field of civil engineering, the peridynamics has been successfully applied to the problems of the fracture of rocks and concrete structures. Compared to these types of materials, there are a few applications to the problem of the fracture of soils, such as mudstone and compacted clay [1]. The soils are quite different from the rocks and the concrete in that they need to be observed after cracking and failure. For the soils, it is necessary to deal with both the fracture and the post-fracture, while for the rocks and the concrete, it is sufficient to deal only with the fracture.

The study proposed a 3-D combined model of the peridynamics and the DEM (Discrete Element Method) to continuously handle the process of the failure of the compacted clay [2]. The bond-based model of the peridynamics is employed to reproduce the behavior from the initiation of cracks to the fracture. At the same time, the DEM is also introduced so that the interaction forces between the fragmented pieces after the fracture can be calculated including the friction force. In addition, a bilinear bond softening model was introduced to obtain a nonlinear stress-strain relationship which is often seen in the compacted clay. The proposed model was validated by comparing the experimental results and the numerical results of the uniaxial compression test and the diametral compression test of the soil specimens with a single initial crack.

Key Words: *Rigid-plastic finite element method, Soil reinforcement, Anisotropic strength, Soil-reinforcement interaction, Duality*

The authors developed a hybrid type rigid-plastic finite element method (RPFEM) [1] for a stability problem of the ground. This method is based on the Lagrangian function of lower bound analysis with spatial discretization of the finite elements. Due the the duality of limit theorems, both stress and velocity fields can be solved simultanesouly by the interior point method of Second cone optimzation programming. In this study, a simple model of the interactions of reinforcement members and the surrounding ground is proposed and implemented into RPFEM to evaluate a stability of a reinforced ground.

A bearing capacity mechanism of a ground reinforcement method is a confining effect of soils by the reinforcement members, i.e., confining forces or pressures by the reinforcement members enhance the resistance against failure. In order to deal with a reinforced ground problem in the framework of RPFEM, Asaoka et al. [2] added velocity constraints between two nodes, such as no change in lengths or angles to the upper bound limit analysis . From the point of the duality of limit thoerems, these velocity constraints stand for unlimited strengths of the reinforcements.

In the formulation of hybrid type RPFEM, both velocities and stresses are unknow variables. Considering the duality, velocity constraints are always accompanies by Lagrangian multipliers, which can be interpreted as confining forces. So, we can simply introduce inequality constraint conditions on these confining forces to express limited strengths of reinforcement members. This is a direct extension of the previous study [2], but this extention can be only achieved by the hybrid type formulation of RPFEM.

Velocity constraint conditions are imposed on the nodes of a finite element of a ground. Only a mesh of a ground is required. No special finite elements are required for reinforcement members. In addition, slipage between reinforcement members and the surrounding ground can be modeled by introducing inequality constraints of two adjacent member forces. This model is similar to an interaction between piles and soils, i.e., a change of axial forces of piles at two sections due to skin frictions.

This newly proposed method can predict various failure modes including member-failure and pull-out failure as solutions without any assumption of failure modes. Some numerical examples are presented to demonstrate the features of the proposed method.

Key Words: *Unsaturated Soil, Ceramic Disc, Microporous Membrane Filter, FEM Simulation*

Ceramic discs, which have high air entry values, are commonly used for matric suction control in the axis-translation technique for element tests on unsaturated soils. The main limitation of this method is the long duration time of unsaturated element tests due to the low permeability of a ceramic disc. As an alternative, microporous membrane (MM) filters have been introduced to shorten the necessary time for establishing suction equilibrium. Nevertheless, some researchers pointed out that there are some discrepancies in test results when using ceramic discs and MM filters.

In this study, to investigate the differences between using ceramic discs and MM filters, triaxial tests on unsaturated completely decomposed granite, or called Masado in Japan, were firstly conducted using the two matric suction control methods. Then, soil-water-air coupled finite element analyses were conducted to simulate the consolidation process in triaxial tests as initial/boundary problems. In the numerical calculations, a saturated/unsaturated soil constitutive model and a water retention curve (WRC) model [1] were employed to describe the hydro-mechanical behaviors of unsaturated Masado. Meanwhile, the WRC and permeability-saturation relations of a ceramic disc and an MM filter, as porous materials, were properly taken into consideration.

Both the experimental and numerical results showed that the changes in degree of saturation and suction within the ceramic disc are no longer interpreted as element behaviors. In the numerical calculation, after applying suction to the specimen, though the ceramic disc remained highly saturated, the suction within it significantly increased, which resulted in the greater drainage discharge of the specimen. Therefore, the axis-translation technique in triaxial tests for unsaturated soil with ceramic discs should be reassessed as an initial/boundary problem.

Key Words: *complete formulation, relative acceleration, unsaturated soil, centrifuge test*

Dynamic coupled analyses considering pore air of unsaturated soil have been performed. Pore air plays an important role in the dynamic response of unsaturated soil and hence the pore air pressure should be explicitly considered in the formulation of dynamic problems. However relative acceleration of pore water and air to soil skeleton has been usually ignored in simplified formulations such as *u-p* formulation [1]. Complete formulations such as *u-U* formulation considering the relative acceleration of pore fluid [2] have been already presented; however, the effect of relative acceleration of pore fluid on seismic response of unsaturated soil has not been clarified. In dynamic centrifuge tests with saturated soil viscous water has been used as a pore fluid to reduce the permeability. However pure water has been used in some cases with unsaturated soil; therefore, the effect of relative acceleration can be significant.

In this study the effect of relative acceleration of pore fluid on seismic behaviour of unsaturated soil is discussed through numerical simulations with complete and simplified three-phase coupled formulations. First both formulations governing the dynamic behaviour of unsaturated soil, u-v-p and u-p formulations, were briefly shown based on porous media theory and constitutive models. Next both formulations were used for the simulations of dynamic centrifuge experiments with unsaturated embankment dam [3] and slope [4]. The effect of relative acceleration of pore fluid on seismic behaviour of unsaturated soil was discussed through simulations of centrifuge experiments.

Key Words: *Slope failure, Intermittent rainfall, Unsaturated soil,*

Rainfall induced landslides are a quite common phenomena that happen all over the world consequential to climate change. Safety margins of these slopes possess high during the period of dry weather conditions with the help of unsaturated soil mass above the groundwater table. As a result of prolong rainfall conditions, destruction of matric suction causes triggering of slope failures. Many published data revealed that slopes experience mostly an intermittent rainfall conditions rather a steady rainfall before the failure took place. To investigate the slopes subjected to intermittent rainfall conditions, this study carries out a series of centrifuge tests. The generation of excess porewater pressure and deformation of slopes are recorded using pore-pressure transducers and image recording system respectively.

The aim of this paper is to compare and validate the physical modelling test results by numerical simulation. The unsaturated soil behaviour is simulated using the three-phase (soil-water-air) coupled hydro-mechanical model which is based on the governing equations derived by [1]. A conventional elastoplastic model and soil-water characteristic curve (SWCC) model are incorporated in these simulations. It is expected to demonstrates the ability of this model to evaluate the temporal variation of pore-pressure and the deformation process of slopes subjected to intermittent rainfall conditions.

[3] Civil and Environmental Engineering, Tohoku University, Aoba 6-6-06, Sendai, 980-8579, Japan

Key Words: Surface Flow, Infiltration, Slope Stability, Shallow Landslide, Flood Inundation

Landslide and flooding are two of the most common hazards associated with intense and heavy rainfall. While the relationship and coexistence between the two hazards have been observed and documented, limited studies have been published assessing both hazards, with most studies focusing exclusively on either landslide or flooding. Therefore, this study presents a regional-scale multihazard approach characterizing the nature of both phenomena through a combination of hydrologic and geotechnical principles. This is done by incorporating surface flow, infiltration, and slope stability analyses to visualize the spatio-temporal response of both landslide and flooding with respect to intense or heavy rainfall.

To reduce computational costs, a hybird approach using local- and zero-inertia models [1] of the two dimensional shallow water equations is utilized to approximate the surface flow curbing restrictive time-step conditions common in hydrologic models. Moreover, rainfall infiltration is approximated using the one-dimensional Green-Ampt model [2], and slope stability is obtained using a limit equilibrium method defined for an infinite slope whose failure mechanism is generated from the forces arising from the effects of surface flow and the downward propagation of the wetting front [3]. The model is then applied in Marumori, Japan which suffered numerous landslide and flooding disasters during Typhoon Hagibis in 2019. Validation indicate that the proposed model successfully simulates the hydrologic and geotechnical response of slopes showing the distribution of both unstable slopes and inundated areas indicative of landslide and flooding hazards.

Large Deformation Simulation for Geotechnical Engineering Based on Cosserat Continuum Theory and Isogeometric Analysis

Hongxiang Tang[1]*, Feng Zhu[1]

[1] State Key Laboratory of Coastal and Offshore Engineering, Dalian University of Technology, 116023 Dalian, China, tanghx@dlut.edu.cn

Key words: *Isogeometric Analysis, Finite Element Analysis, Strain Localization, Elastoplastic, Cosserat Continua, Saturated Porous Media, Biot Consolidation Theory, Shear Band*

Combined with the Cosserat continuum theory, the isogeometric analysis is extended to simulate the strain localization problems of geomaterials due to strain softening, that leading to the so-called Cos-IGA method. The numerical results demonstrate that the numerical solution based on Cos-IGA is convergent and mesh-independent and that the Cos-IGA has the ability to capture the initiation and propagation of shear band as strain localization problem involved. Also, it illustrates that the Cos-IGA effectively avoids the shortcomings of mesh distortion and overstiffness in Cos-FEA, and improves the path-bifurcation phenomenon and makes the transition of force-displacement curve smoother in softening stage due to the non-interpolation and variation diminishing properties of NURBS basis functions.

Also, the Biot-Cosserat continuum theory is combined with isogeometric analysis (Biot-CIGA) to simulate dynamic strain localization in saturated soils. The results demonstrate that Biot-CIGA can solve the ill-posed problem of saturated soils caused by strain-softening properties and non-associated flow rules, thereby obtaining a convergent, mesh-independent numerical solution. Compared with the finite element analysis of Biot-Cosserat continuum, the high-order continuity of Biot-CIGA provides a smooth pore pressure gradient field and thus ensures the local mass balance of pore fluids. Additionally, the Biot-CIGA describes the inflow and outflow of pore fluids in the element, which means it is able to accurately simulate the volumetric strain of the element. Simulation results also show that the Biot-CIGA method can also effectively alleviate the mesh distortion in shear bands when materials experience large deformation. Last but not least, because Biot-CIGA adopts NURBS as its shape functions, it can conduct simulations directly on CAD models, which not only maintains the precise geometry, but also avoids an expensive intermediate meshing step.

Key Words: *MICP, electricity-reaction-diffusion system, homogenization method*

Soil improvement techniques have been developed experimentally and empirically from various geotechnical viewpoints based on physical, chemical, and biological findings. According to traditional microbiological perspectives, microbially induced soil cementation techniques have been attracted as an environmental-friendly soil improvement technique. Microbially induced carbonate precipitation called as MICP, especially, has been known that microbial metabolism can induce a precipitation of calcium carbonate in the pores and on the surface of sand particles. Eventually, the ground is stabilized physically since discrete sand particles can be bound by calcium carbonate.

The precipitation and growth of calcium carbonate on the sand surface and its pores can be simulated using the recently proposed numerical simulation techniques. However, these proposed techniques have not incorporated parameters such as electrical properties and adsorption. Therefore, the precipitation process on the sand surface and the bridging pattern between sand particles remain ambiguous.

In the current study, the authors proposed a novel multi-physical model that considers the behavior of microorganisms and ions in a weak electrostatic field around the sand particles. To validate the proposed model, lab-based MICP experiments were conducted, and the experimental and simulation results were compared. Furthermore, the changes in mechanical parameters due to calcium carbonate precipitation were investigated by integrating the homogenization method into the proposed model.

Mathematical and numerical modelling of photoautotrophic calcification on rock surface

Hitoshi Matsubara[1*] and Ibuki Nishimura[2]

[1] School of Civil Engineering, University of the Ryukyus, 1 Senbaru, Nishihara-cho, Nakagami-gun, Okinawa, 903-0213 Japan, matsbara@tec.u-ryukyu.ac.jp
[2] Graduate school of Engineering and Science, University of the Ryukyus, 1 Senbaru, Nishihara, Nakagami, Okinawa, 903-0213 Japan, k208486@eve.u-ryukyu.ac.jp

Key Words: *Reaction-diffusion system, photoautotrophic microbes, calcification*

Traditional stabilization of weathered rock surfaces has relied on physical approaches such as anchoring and retaining walls. Naturally, these techniques require ongoing maintenance and restoration, as their effects are not permanent. Thus, the development of novel techniques of rock-surface stabilization with self-organizing and environmentally friendly restoration functions has been required.

On the other hand, microbially induced rock surface improvement techniques have attracted a great deal of attention in recent years. This technique enhances the mechanical properties of rock surfaces by precipitating calcium carbonate microbially. It is interesting to note that microbial protection techniques based on photoautotrophic microbes like green algae and diatoms would be helpful in protecting aging rock surfaces. Photoautotrophic calcification may achieve self-organizing restoration of aging rock surfaces since the microbes can grow and induce calcium carbonate precipitation under sunlight continuously. However, in most of traditional research, this novel technology has been studied by laboratory and field investigations, and has not been examined by mathematical and numerical approaches. This is because mathematical models for the analysis of the coupled behavior between microbes and calcification have not yet been proposed.

In this study, the authors propose a novel multi-physical model based on the reaction-diffusion system that considers the behavior of photoautotrophic microbes and the precipitation of calcium carbonate on rock surfaces. As a result of numerical simulations, it was clarified that the self-organizingly precipitation of calcium carbonate on rock surfaces can be expressed by the proposed model.

Modelling landslide debris flow with entrainment: development and validation

***I. Li[1], E.K.L. Wong[1] and E.H.Y. Sze[1]**

[1] Geotechnical Engineering Office, Civil Engineering and Development Department,
The Government of Hong Kong Special Administrative Region, Hong Kong SAR, China
Corresponding author: I. Li (ivanli@cedd.gov.hk)

Key Words: *Landslide, debris flow, debris mobility modelling, entrainment*

The volume and mobility of a debris flow could increase with distance travelled as it has the potential to entrain a substantial amount of channel-bed material along its travel path. This entrainment effect renders the debris flow more devastating to downslope populations and facilities. In modern landslide risk management, being able to predict the characteristics of debris flows is essential for the design of mitigation measures against landslide hazards. Such need has led to the development of a variety of debris mobility models around the world in recent times. There is a need for modelling methods which are capable of simulating entrainment effects in a rational but practical manner.

Over the past two decades, the Geotechnical Engineering Office (GEO) of Hong Kong has expended considerable effort to develop debris mobility modelling tools for use in routine engineering practice for forward prediction purposes. Recently, GEO has completed a study to enhance an in-house debris mobility code. Physical parameters which can be estimated from the field by engineers or geologists are incorporated in the code to predict entrainment effects in a simple and rational manner. This allows the modelling of varying entrainment potential along a debris flow path. The code has been checked against simplified analytical solutions and validated against field observations in a major historical landslide event involving high-mobility debris flows in Hong Kong. The numerical modelling results indicated that simulated entrainment volume and mobility characteristics are broadly consistent with geological field mapping records.

Numerical elucidation of the graben crack damage that formed in the Aso caldera due to the 2016 Kumamoto earthquake

Kentaro Nakai[1*], Toshihiro Noda[2] and Akira Asaoka[3]

[1] Nagoya University, 464-8603, nakai@civil.nagoya-u.ac.jp
[2] Nagoya University, 464-8603, noda@civil.nagoya-u.ac.jp
[3] Association for the Development of Earthquake Prediction, 101-0064, asaoka@adep.jp

Key Words: *Stratum irregularity, Soft clay, Consecutive earthquake, Seismic response analysis*

In the 2016 Kumamoto earthquake, graben crack damage occurred in the northwest part of Aso Caldera. It was thought that the Futagawa fault zone did not reach to the Aso Caldera, and no causal relationship has been identified between the graben damage and the fault zone. Therefore, various causes have been considered, such as collapse of underground cavities, surface seismic faults, liquefaction-induced horizontal movement in deeper ground, etc. However, the definite cause of graben cracks have not been identified yet. Yasuda et al. [1] revealed that most of the grabens appeared at the location above the old lake which existed about 9,000 years ago. In addition, they have confirmed that the lake sediments have the property that the shear rigidity decreased sharply with strong repeated shear stress from the laboratory testing.

The aim of this study is to elucidate the mechanism of graben cracks formed in the Aso Caldera in terms of "stratum irregularity" formed by the old lake basin in the Aso Caldera, the "presence of soft clayey soil" of the old lake deposit and the "two consecutive earthquakes" that characterize the Kumamoto earthquakes. Therefore, 2-dimensional seismic response analysis was conducted to elucidate these effects on the subsurface damage. The analysis code was the soil-water coupled finite deformation analysis [2], which incorporates an elasto-plastic constitutive model that allows description of mechanical behavior of soils ranging from sand through intermediate soils to clay within the same theoretical framework [3]. The following conclusions were obtained.

(1) By considering the effect of stratum irregularity, (a) the focal phenomena of the body waves, (b) the excitation of the surface waves and (c) these amplification interference ("edge effect") were numerically reproduced. Therefore, the wave propagation became intricated and the oscillation became larger at a specific point near the ground surface.
(2) The clayey lake deposit was in a soft condition. Therefore, the effective stress was easily decreased by seismic motions, which causes further increase in natural period of the ground.
(3) As mentioned in (2), natural period of the ground was increased by foreshock. The continuous occurrence of main shocks significantly amplified long-period oscillations. This long-period and large shaking caused graben damage at the surface.

Key Words: *construction process analysis, particle-element coupled method, large deformation*

In the soil-structure interaction analysis, substructures installed in the ground are modelled where they are planned to be, ignoring their construction process. This type of numerical modelling is called *wish in place method*, which does not occur in actual construction sites. However, this type of numerical simulation is very popular in the practical engineering because it is quite simple to model the target system. The method has disadvantages, for example, that in case of simulating a driven pile penetration into geomaterials the method cannot consider the volume convection of geomaterials. The reason why the conventional numerical methods, e.g., FEM, have not considered for or they have not been applied limitedly to the construction process with the volume convection is because the discretized elements are not suitable for the large deformation, and because they need the intensive computational cost in re-meshing of the target system.

Particle-based method is one of the numerical methods of continua, giving a solution for simulating the construction process analysis. Particle-based method is capable of considering the volume convection of geomaterials and simulating the intensive large deformation. In this study, the authors have performed the numerical simulation of a pile penetration into geomaterials using the particle-element coupled method (PEM) [1], which is the combination of particle- and element-based method enabling the reduction of computational costs. According to the numerical results, PEM can simulate both the ground resistance and deformation with good agreements, and it also realized that the ground resistance and deformation are dependent on geomaterial dilatancy characteristics.

Key Words: *Rockfall, Distribution Characteristics, Rocky-DEM, Shape Effect, Sphericity*

This study aims to quantify the contributions of rock shape on the characteristics of rockfall run-out. A series of rockfall simulations is performed using the Discrete Element Method (DEM) to analyse the relationships between rock shapes and rockfall movements. A software Rocky-DEM, which is capable of handling polygonal elements, is employed[1] to conduct this numerical experiment.

In order to define rock models with different shapes, we vary the geometrical parameters that are aspect ratio, oblateness, and cut ratio. A total of 200 simulations are carried out for each of 36 different models characterized by these three parameters. Although the three parameters are used to control the shape properties, the parameters partially represent characteristics of rock shape, and there is some overlap in the physical meaning of these parameters. To overcome the problems, the sphericity, which is a measure of how close the object is to a sphere, is newly employed for analysing the contributions of rock shape. There have been however a lot of definitions of sphericity, we employ some of them to investigate the effectiveness of each sphericity. In terms of rockfall run-out, the mean and the coefficient of variation obtained from the distribution maps of the final run-out position are quantified to characterize the distribution characteristics. Based on the results of all calculation cases, the correlation between the statistical values of rockfall run-out and the sphericity is examined.

The obtained results show that two of the sphericities have a strong contribution on the distribution characteristics. According to a result of the principal component analysis, it was also found that the two sphericities have a mutually influence on the rockfall run-out. It is therefore concluded that it is possible to represent characteristics of rockfall run-out by the two sphericities.

Key Words: *Cam-clay model, Elastoplastic analysis, Multiplicative decomposition of deformation gradient, zeta stress, Eshelby-zeta stress*

In the framework of finite deformation elastoplasticity, several researchers (e.g., Borja and Tamagnini, 1998; Yamakawa et al., 2010) have formulated the Cam-clay model that was based on the multiplicative decomposition of the deformation gradient and employed a hyperelastic body. However, these pioneering works do not fully consider the volume change in the intermediate configuration. This shortcoming makes the previous models unable to guarantee the existence of the state boundary surface, which plays an important role in the derivation of the Cam-clay model.

Therefore, this study reconstructs the isotropic Cam-clay model that can explain the existence of the state boundary surface using zeta stress and Eshelby-zeta stress derived by considering the non-negativeness of plastic dissipation by focusing on the unit volume in the intermediate configuration with referring to Bennett et al. (2016). In the proposed formulation, the hyperelastic body proposed by Houlsby et al. (2006) is applied to the elastic part. This study also constructs an implicit stress update algorithm for the model and derives the tangent modulus consistent with the algorithm. Moreover, to verify the reconstructed model and the stress update algorithm, numerical analysis is performed using finite element analysis code that implements the model.

By simulating triaxial compression tests to verify the model and algorithm, this study presents that the developed code can reproduce the basic mechanical behaviors of reconstituted and normally consolidation clay. In addition, the simulation also demonstrates that the derived implicit stress update algorithm and the consistent tangent bring the quadratic convergence to the global Newton-Raphson procedure for finding equilibrium of force.

Key Words: *Seismic response, Dam, Space-Time finite element method, Elasto-plastic constitutive model*

The safety of earthen structures, such as dams, tunnels and embankments, draws growing attention in Japan, which is one of the most earthquake-prone countries in the world. In order to assess the safety of the structures during earthquakes, the dynamic response analysis is numerically conducted commonly by the finite element method. In finite element framework, several methods have been proposed to achieve accurate results, and one of them is the velocity-based space-time finite element method, abbreviated by v-ST/FEM, which is based on time discontinuous Galerkin method.

The conventional method for the assessment of seismic performance of dams investigates the seismic response assuming the elastic behaviour of the structure, and predicts the permanent deformation caused by a slip surface having the lowest factor of safety according to the above seismic response analysis. However, this method results in the inaccurate prediction of both the seismic response and the permanent deformation especially when the structure is subjected to seismic loading induced by big earthquakes, called level-2 earthquakes. Then, the seismic response analysis in which appropriate elasto-plastic constitutive models are installed is required in order to predict the permanent or residual plastic deformation accurately.

Velocity-based space-time finite element method (v-ST/FEM) for the seismic response analysis of earth-fill or rock-fill dams, which undergo the permanent deformation during strong-motion earthquakes, is developed herein, assuming the infinitesimal deformation. Since the space-time FEM realizes the higher accuracy of time integration, the performance of v-ST/FEM is compared with that by Newmark-β through a one-dimensional problem, i.e., the propagation of a shock-wave. Then, two-dimensional seismic response analysis of existing rock-fill dams are carried out, in which an elasto-plastic constitutive model based on Mohr-Coulomb criterion is implemented in v-ST/FEM, and the permanent deformation of rock-fill dams are computed as well as the dynamic ground motion.

Key Words: *Soil-Water-Air Coupled Elastoplastic Finite Deformation Analysis, Unsaturated Soil, Inertia Force, Rainfall*

In recent years, there have been many collapses of slopes due to heavy rain. In most cases, to predict the collapses of slopes in heavy rainfall, seepage flow analysis and stability analysis are used together. However, it is insufficient to perform a stability analysis that judges whether a safety factor exceeds 1 or not, using the stress state determined from a seepage flow analysis. It is necessary to analyze slope behavior from deformation to failure caused by seepage. In addition, the failure phenomena are accompanied by acceleration motions even if the external force is rainfall. Therefore, it is necessary to take into consideration the inertial force. Furthermore, to simulate large deformation that leads to failure, it is essential to consider change in the geometry based on finite deformation theory.

With the above background in mind, a rainfall model test [1] was simulated using a soil-water-air coupled finite deformation analysis code considering inertia force [2] to elucidate the failure mechanism of unsaturated slope. The constitutive model for the soil skeleton is an elastoplastic constitutive model employing the unsaturated effect in the Super/subloading Yield Surface Cam-clay model (SYS Cam-clay model) [3,4].

As a result, we succeeded in simulating the rainfall-induced deformation behavior leading to failure accompanied by acceleration. The failure mechanism is explained as follows: 1) The entire unsaturated slope became a normally consolidated state caused by an increase in saturation degree (a decrease in suction), in addition to a rise in pore pressure and an increase of self-weight. 2) The stress state became located above the critical state line in mean skeleton stress p'–deviator stress q space especially near the slope toe where pore water gathered. Therefore, the soil element showed softening behavior with plastic volume expansion, which is a characteristic of the Cam-clay model. 3) A slip failure started to occur near the slope toe, and suddenly expanded to the upper part of slope with a significant acceleration.

Key Words: *Thrust, Compression, Imbrication, Décollement, Elasto-plasticity, FEM*

Lateral compression of ground generates a wide variety of fault topography such as thrusts and décollements with a single displacement discontinuity. As for typical structures with multiple slip surfaces, there exist a "pop-up" with conjugate slip surfaces, and an "imbrication" with parallel slip surfaces. To simulate their irreversible and multi-step formation process, (1) the elasto-plastic constitutive model for describing material nonlinearity and (2) finite deformation scheme for tracing changes in shape and state of the ground are necessary. In this presentation, we introduce the results of the formation analysis of these structures based on our analysis code ***GEOASIA*** [1] that can consider (1), (2), the presence of pore water, and dynamics.

First, an single-phase elasto-plastic deformation analysis was performed using three plane-strain finite element meshes with different boundary conditions. SYS Cam-clay model was incorporated as an elasto-plastic constitutive model of soil skeleton. The parameters for overconsolidation exhibiting remarkable softening after the peak strength were set. The shear strain distributions indicate that the analysis without fixation of the bottom displacement exhibited pop-up, whereas the analysis with the prescription of the linear bottom displacement distribution obtained imbrication. Furthermore, the separation of the imbrication and the thrust sequence, i.e., piggyback and overstep, were affected by the presence of the end friction. We successfully simulated characteristic structures with the irreversible and multi-step strain localization in the compressed ground based on the elasto-plastic finite deformation analysis and confirmed the effect of boundary condition.

Next, the soil-water coupled analysis for the saturated semi-consolidated ground was conducted. The final shear strain distribution exhibited the formation of horizontal décollements and the accretion of the lower region to the upper region. The occurrence of the positive excess pore water pressure and the generation of a seismic wave due to brittle deformation were also solved.

Key Words: *tsunami, coastal landslide, simulation, centrifuge*

Landslide events are often secondary phenomena that are triggered by other disasters such as meteorological disasters, earthquakes, and volcanic eruptions. Earthquakes can cause landslides in both onshore and offshore areas. Submarine landslides can cause tsunamis which have a catastrophic impact on coastal areas. Studying submarine mass movements and their consequences have been started in 1952 with the work of Heezen and Ewing on the Grand Banks slide and tsunami (Locat and Lee, 2009). As of today, many catastrophic submarine landslide events that generate tsunami have been reported including the dramatic landslide-generated Papua New Guinea tsunami in 1998, which devastated three villages with the loss of over 2200 lives (Tappin et al. 2008), 2018 Sulawesi earthquake with a magnitude of Mw 7.5 and tsunami hit property and life with more than 2000 fatalities. 30% of the World's population of lives within 60 km of the coast, and the understanding and hazard assessment of tsunamigenic landslides becomes very important (Yasuhiro et al., 20012).
The research applies the integrated numerical model including landslide and tsunami for simulating the complicated process of earthquake induced landslide causing tsunami. The centrifuge results will be used to validate the landslide generation tsunami model.

Avalanching of variously shaped DEM particles in a rotating drum

Dominik Krengel[1*], Hans-Georg Matuttis[2], Ryota Shiyake[1] and Mamoru Kikumoto[1]

[1] Yokohama National University, Tokiwadai 79-5, Hodogaya, Yokohama, Kanagawa 240-8501, Japan, krengel-dominik-ds@ynu.ac.jp
[2] The University of Electro-Communications, 1 Chome-5-1, Chofugaoka, Chofu, Tokyo 182-8585, Japan, hg@mce.uec.ac.jp

Key Words: DEM, avalanche, rotating drum, shape effects, non-convex particles

In the majority of particle simulation methods, round particles still dominate, while in actual granular materials, the particles are angular or even non-convex. Attempts to enforce "realistic behavior" with unrealistically high coefficients of rolling friction (e.g. [1]) do not necessarily result in a realistic dynamics for moving particles.

In this research, we compare how assemblies of "round", irregular convex and non-convex particles behave with respect to avalanching in a two-dimensional rotating drum using a polygonal discrete-element method based on [2]. Round particles are modelled as regular convex polygons with a high number of corners, but the differences to the ideal round shape are negligible. Solid friction is implemented via the "numerically exact" Differential-Algebraic-Equation formulation [3].

All things being equal, we find that aggregates of round particles are clearly distinguishable from aggregates of non-round particles – whether convex or non-convex – in a parameter space describing the whole of the aggregate, as well as in the behavior of avalanches, due to the differences in particle mobility and strength of solid friction. On the other hand, the deviations in the behavior between aggregates of irregular convex and non-convex particles are less marked. We find differences in the angle of marginal stability, as avalanching starts at a higher slope angle for non-convex particle aggregates compared to aggregates of convex particles, but both mixtures revert to the same steady-state angle after an avalanche. We see further differences between convex and non-convex particles in the distribution of the phasespace trajectories of the bulk center-of-mass, where the translational and the rotational energy as functions of the center-of-mass height form more compact cycles for convex than for non-convex particles, while for round particles the cycles are compact with little dependence on the drum rotation.

Key Words: Multi-scale modeling, Surface coupling, Volume coupling, granular media, Coarse-graining

Surface and volume coupling methods are reformulated for concurrent multi-scale modeling of granular materials. Based on a micro-macro transition technique called "coarse-graining" [1], we derive homogenization operators in more generalized forms than those reported in the literature. For surface coupling [2], coarse graining allows distributing the coupling forces beyond the finite elements that the particles are locally coupled with, namely, from contact points to their neighboring integration points. For volume coupling [3], coarse-graining is applied to enrich the homogenization/localization operations on particle-scale quantities, thereby offering a non-local coupling approach. The generalized coupling terms contain one user-defined parameter, namely, the coarse-graining width, setting a length scale for the "coarse-grained" fields. The benefits of coarse-graining in surface and volume coupling are exemplified by modeling particle-cantilever interaction and wave propagation between discrete particles and continuum bodies. We show that the CG-enriched new formulation removes high-frequency/short-wavelength numerical oscillations and gives more physical predictions in the example of particle-cantilever interaction, compared with the conventional formulation using finite element basis functions. In the wave propagation example, the numerical dissipation, which is a known artifact of the volume coupling method, is reduced with an optimal coarse-graining width. In particular, the benefit of coarse-graining appears to be significant when the waveforms become increasingly complex and contain high frequency contents.

Key Words: *DEM, Aluminium Bar, Belled Pile, Pull-out Resistance*

The upward external forces applied on a pile head due to earthquakes, wind loads, etc. cause large piles pulled up in the base graound. Considering the frequency of natural disasters in recent years, it is quite important to understand the ground behavior in pile uplifting, and it is also importran to investigate numerical methods that is applicable to simulation involving ground large deformations.

In this study, the authros performed the model experiments of uplifting belled pile, forcusing on the large deformation behavior. In the experiments, both the ground behavior in belled pile uplifting and the mechanism of exerting the pull-out resistance were investigated. To understand the ground behavior further, Discrete Element Method (DEM) is adopted for the numerical analysis method, because it is expected to trace the ground behavior involving large deformations. DEM is applied to uplifting belled pile simulation, compared to the experimental results.

Model experiments of uplifting belled pile were performed with a model pile set in the circular aluminium bar laminated ground. The pull-out load and the pile head displacement were measured. Also, the spatial displacement and strain of the ground were obtained by image analysis using Particle Image Velocimetry (PIV).

2D DEM simulation was performed to investigate the stress propagation inside the ground and how the ground resists the pull-out force, because it is difficult to know the stress propagation in the experiment. The pull-out load, particle displacement and strain were simulated and compared with the experiments, resulting in that the numerical results and the deformed regions give good agreement to those of the experiments. The mean normal stress of particles and the contact force network were visualized for further consideration, and it enabled us to observe how the pull-out resistance of the ground was exerted from the viewpoint of stress propagation.

Kinematics of Granular Materials Considering Realistic and Pseudo-Realistic Particle Morphology

NSSP Kalyan[1*], Ramesh Kannan Kandasami[2]

[1] Indian Institute of Technology Madras, Chennai, India, ce19s020@smail.iitm.ac.in
[2] Indian Institute of Technology Madras, Chennai, India, rameshkk@iitm.ac.in

Key Words: *Discrete Element Method, Non-Convex Polygons, Node-to-Segment contact, Hopper flow*

Granular materials are a collection of discrete solids exhibiting complex behavioral responses under different physical and boundary conditions. Particle morphology is a critical component that needs to be incorporated in discrete simulations to model the micro mechanics accurately. Although there have been extensive numerical studies [1] understanding the effect of particle morphology on the overall material behavior, the complex shapes are generally modeled using multi-sphere/disc clumping methods (pseudo-realistic shapes). The primary objective of this study is to investigate whether pseudo-realistic particle morphology is capable of mimicking the kinematics of exact shapes accurately. Thus, 2D DEM simulations of conical hopper flow are carried out using realistic and pseudo-realistic particles.

Scanning Electron Microscopy images of natural sand are obtained, and particles are segmented using the modified Watershed technique, and the exact boundary pixels of each particle are extracted. The electronic noise is eliminated by smoothing spline regression combined with the cross-validation technique. For contact modeling of these non-convex irregular polygons, the node-to-segment method is employed in which the noise-free grain contours are represented locally by smoothing spline [2]. The Pseudo-realistic shapes are formed by filling the smooth outlines of grains with multiple discs. Conical hopper simulations incorporating both shapes are conducted. Linear elastic contact law is adopted with identical numerical parameters and initial void ratios. During the gravity deposition, the velocity fluctuations (linear & rotational), coordination number evolution are monitored. The velocity magnitudes towards the hopper opening are higher in the pseudo-realistic particles. The arching patterns are significantly different for both cases. Under deposition, the realistic morphologies show higher interlocking between particles. Even though the particle shape descriptors such as sphericity for both cases are same, the behavior shows considerable variations ($>$10%). Thus, it indicates that modeling a clumped system is not ideal for mimicking realistic behavior. Further, the changes in the velocity fields, coordination number, force networks (spatial & temporal) are studied as a function of roundness and sphericity of grains.

Key Words: *aluminum bar, discrete-element-method , pile-penetration*

The pile-ground interaction is one of the engineering interests that involves the ground movement. Driving precast pile and steel pipe pile drive the soil material away without boring any holes when they are installed in the ground. The ground movement in pile installations induces the increase of ground density and stress. The advantages and disadvantages of the ground change in pile penetration are discussed quantitatively but qualitatively so far. When the numerical methods are applied to pile penetration into granular materials such as soil, it is quite difficult for the methods based on the continua theory because the subdivided elements go under intensive large deformation that induces the mesh-tangling. Therefore, Discrete Element Method (DEM) is one of the engineers options used for pile penetration simulation. In this study, in order to understand the ground behavior in pile penetration, DEM is applied , and the numerical simulations are compared with experimental results of vertical penetration of piles into aluminum bar laminated ground. In the experiment, a model ground was constructed using aluminum bars, simulating the granular materials, and a steel solid pile was set above the model ground. While the piles were installed on the model ground, the penetration resistances and the photographs of the model ground were obtained. The experimental results were analyzed by Particle Image Velocimetry (PIV) to obtain the ground displacement , and the maximum shear strain were calculated. In the numerical analysis, the experimental results were simulated, and the particle displacements and maximum shear strains were obtained and compared with the experimental results. The results of the numerical analysis using the discrete element method shows that the penetration resistances, displacements, and deformation regions give close agreement to the experimental results. Physical quantities that could not be obtained experimentally, such as angular velocity of the particles and mean stress, were also calculated in the simulation. The distribution region of the maximum shear strain in experiments coincided with the angular velocity distribution region of the particles. Therefore, the rotational motion of the particles is related to the formation of the shear zone.

Modern problems [1] that use finite elements require substantial computing resources. One of the most efficient solutions in terms of the SIMD approach is the use of matrix-free methods on GPU [2]. This paper discusses the usage of the Element-by-element (EbE) method [3] for some 3D Solid Mechanics problems. The main idea of the EbE method is the absence of global stiffness matrix assembly. This results in high memory efficiency. The purpose of this work is to prove the possibility of a cross-platform implementation of the Finite Element Method using parallelism on high-performance hybrid architectures [4]. This is conducted by a comparative analysis of the performance of CUDA and oneApi technologies realizations. Obtained results make it possible to perform calculations faster than many adapted computational modern systems.

Key Words: *finite strains, poroplasticity, coupling, numerical modeling, spectral element method, CUDA, GPU*

The presentation outlines an approach to solving coupled non-stationary problems of modelling hydro-geomechanical processes taking into account both physical (poroelastoplasticity) and geometrical (finite strains) nonlinearities. The considered poroelastoplastic model generalizes classical Biot's model for a two-phase liquid-saturated poroelastic medium. A distinctive feature of this model is the two-way coupling between mechanical processes occurring in a porous elastoplastic matrix and a saturating viscous fluid, which makes it possible to take into account both the effect of a change in the pore pressure of a fluid on the stress-strain state of a porous matrix and vice versa – an effect of a change in the shape of the pore space (due to the accumulated elastoplastic finite strains) on the pore pressure in a fluid. and, as a consequence of Darcy's law, on the rate of fluid flow inside the porous medium taking into account dynamic variations of both porosity and permeability.

To simulate the accumulation of elastoplastic deformations, the plastic flow theory with a non-associated plasticity law is used according to the Drucker-Prager model, which takes into account volumetric plastic deformation. In addition, within the framework of the considered poroelastoplasticity model, the nonlinear dependence of the model parameters (elastic moduli, Biot's modulus, permeability, etc.) on porosity, which, in turn, depends on the volumetric deformation of the skeleton, is taken into account. Non-recoverable plastic part of porosity variation is considered also in the suggested mathematical model.

For the numerical solution of the problem Galerkin's method and the isoparametric spectral element method are used to discretize the geometric model and equations in space on curvilinear unstructured meshes of high order (orders up to the 15th were used for solving model problems). The software implementation of the developed algorithm is performed using the CUDA technology. The spectral element mesh is naturally mapped onto the GPU's Grid, and accordingly, each spectral element is mapped onto a streaming block, within which individual SEM nodes are processed by the corresponding threads. This approach makes it possible to efficiently use the capabilities of shared memory for caching data inside a spectral element, which significantly increases the throughput of the parallel version of the algorithm.

Results of a numerical solution of several model problems are presented: a problem of the development of zones of localization of elastoplastic deformation near a well drilled in a porous rock saturated with fluid, a problem of a pure shear loading under finite strains of a model with a circular stress concentrator in its centre. The change in porosity and permeability because of the accumulation of finite plastic strains is analysed.

The research was performed in Lomonosov Moscow State University and was financially supported by the Ministry of Education and Science of the Russian Federation as part of the program of the Moscow Center for Fundamental and Applied Mathematics under the agreement №075-15-2019-1621 and by the grant of the President of the Russian Federation for young scientists - doctors of sciences MD-208.2021.1.1.

Key Words: Sea Ice Formation, Phase-field Method

Sea ice is an important component of the global climate system, which forms naturally as seawater freezes. In polar regions, the ice forms an interface between the ocean and atmosphere, consequently influencing the exchange of heat, moisture and moment between these components. As a material, sea ice is complex as it consists of solid ice, brine inclusions, solid salts, and gas bubbles. The porosity of sea ice results from the incompatibility of salt and ice crystals, leading to brine inclusions with a high salt concentration, which changes the freezing point of seawater. The variability of the porous structure of sea ice is connected with that of temperature and salinity and profoundly influences the properties of sea ice. Other formation phenomena include the precipitation of salt ions and the liquid brine motion driven by pore pressure gradients and gravity drainage. Despite the importance of sea ice, the realistic prediction of a three-dimensional sea ice growth has not yet been achieved. It is against this backdrop that this paper models the temporal evolution and spatial distribution of the pore structure, focusing on the seawater-ice phase transition and salt-ice phase separation using the phase-field method in three dimensions.

A Viscoplasticity Model for Creep-Induced Failure of Clay

Babak Shahbodagh[1*], Ngoc Mac[2], Golnaz Esgandani[3], and Nasser Khalili[4]

[4] Professor, the University of New South Wales, Sydney, NSW 2052, Australia, n.khalili@unsw.edu.au

Keywords: *Viscoplasticity, Creep Failure, Clay, Bounding Surface*

Creep-induced instability in clayey slopes generally occurs at stress levels less than the peak strength, but above the critical state line. It develops as a result of the accumulation of plastic volumetric dilation with time, leading to gradual softening and reduction of the peak strength, and ultimately failure of the soil (Tavenas et al., 1978 and 1981; Lefebvre, 1981; Hunter & Khalili, 2000). In this study, a viscoplastic model is presented for the creep-induced failure of clayey soils. The constitutive model is developed within the context of the bounding surface plasticity using the critical state theory and the consistency viscoplastic framework (Wang et al., 1997). The model enables capturing the accumulation of viscoplastic strains upon loading and unloading as well as creep rupture observed in over-consolidated clay under drained condition. In the model, the size of the bounding surface is defined as a function of viscoplastic volumetric strain and strain rate. Unlike the overstress models, the model proposed meets the consistency condition and allows for a smooth transition from rate-dependent viscoplasticity to rate-independent plasticity. Numerical results are presented and compared with the experimental data to demonstrate the performance of the model.

Key Words: Pore Pressure Parameters, Effective Stress, Hydraulic Hysteresis, Unsaturated Soils

In this study, an analytical framework developed based on the effective stress principle is presented for the determination of the pore pressure parameters in unsaturated soils under undrained condition. The concept of conservation of mass for the water phase and Boyle's law for the air phase are employed for the derivation of the pore air and water pressure parameters. The effect of hydraulic hysteresis on the effective stress parameter and the soil water characteristic curve is also considered in this study [1,2]. The proposed analytical solution is successfully validated against the experimental data presented by Campbell [3]. The results illustrate that with the increase in the saturation level of the soil, the pore air and pore water pressure parameters increase and approach unity. The outcomes indicate that the pore pressure parameters are significantly dependent on the compressibility of the soil skeleton. Moreover, the effects of hydraulic hysteresis and the initial hydraulic state, which are extensively overlooked in other studies on the pore pressure response of unsaturated soils, are investigated. The results reveal that hydraulic hysteresis can have a substantial effect on the pore water pressure parameter. However, the pore air pressure parameter is slightly affected by the hydraulic hysteresis since it is mostly influenced by the compressibility of the air phase. The results show that an increase in the degree of saturation of the soil leads to a reduction in the instantaneous settlement, and that the hydraulic hysteresis can have a significant impact on instantaneous settlement.

Key Words: Deep Learning, Approximation with Deep Neural Network, Convolutional Neural Networks, Eigenvalue, Helmholtz' Equation

Recently, there has been a surge of interest in utilizing Deep Neural Networks (DNNs) for a wide variety of tasks in the real world. In particular, Convolutional Neural Networks (CNNs) is regarded as a powerful tool for various fields such as image and voice recognition. The application of CNNs has been spread to computational mechanics (e.g. [1] and the references therein).

This study proposes a method to estimate eigenvalues from a given shape of the domain Ω in terms of (interior) eigenvalue problems for the 2D Helmholtz equation, following a previous attempt to estimate the solution of boundary value problems for the same equation [2]. We basically exploit an existing CNN, that is, VGG-19, and modify it so that multiple eigenvalues can be output at the same time. To obtain supervised data, we first generate a closed curve, which corresponds to the boundary of Ω, on a plane and then transform it into a 2D binary picture, where each data consists of N-by-N pixels. Finally, we solve the eigenvalue problem in Ω to calculate the lowest M eigenvalues. We considered 30,000 datasets in the following test.

In the case of $N = 224$ and $M = 1$, we measured the accuracy of our CNN with the mean absolute percentage error (MAPE). The error was 3.32% for 24000 training data and 8.63% for 6000 validation data. In our setting, both the errors saturated when the epoch was about 100, where an epoch size is defined as around 200. It seems that we cannot improve the accuracy even if the number of dataset becomes larger. On the other hand, increasing the number N of pixels much more could lead to a higher accuracy, but our computing resource prohibited us from increasing N.

In our talk, we will show the above-mentioned methodology and numerical result as well as the other results for different settings.

Key Words: *Scaffold, Deep learning, 3D printing, Bone growth, Bayesian optimization.*

Treating large bone defects remains a significant clinical challenge using existing bone tissue scaffolds [1,2]. The successful regeneration of functional bone tissues in large bone defects requires scaffolds capable of restoring the patient-specific biomechanical functions of the target bone tissues. While additive manufacturing (AM) techniques have shown great potential to fabrication of tissue scaffolds with tailored biomechanical properties, their true capability has not yet been fully exploited due to lack of effective patient-specific design methods [3]. This study proposes a subject-specific framework by combining 3D printing techniques with a novel deep learning-based design approach to fabricate functionally graded scaffolds based on Triply Periodic Minimal Surfaces (TPMS), aiming to fulfil the anticipated biomechanical requirements of target bone defects. The proposed deep learning-based design strategy coupled a Bayesian optimization algorithm [4] with finite element analyses to enable dynamic mechano-biological optimization of the scaffolds at a fairly low computational cost. A Lithography-based Ceramic Manufacturing (LCM) technique was then employed to fabricate the optimized scaffolds with functionally graded TPMS. In a representative example relating to bone scaffolding in a segmental defect in sheep tibia, the simulated bone formation results showed that the optimized scaffolds with functionally graded TPMS led to significantly enhanced bone formation outcome compared with scaffolds composed of uniform TPMS, thereby demonstrating the efficacy of the proposed design strategy. This study is expected to provide an effective tool for design and fabrication of tissue scaffolds for personalized treatment of bone defects.

A machine learning model to forecast of a cable-stayed bridge deformation by using weather forecast data

Youqin Huang[1*] and Shaofan Li[2]

[1] Guangzhou University, Guangzhou, China, yqhuang@gzhu.edu.cn
[2] University of California, Berkeley, USA, shaofan@berkeley.edu

Key Words: *Strain Prediction, Cable-stayed Bridge, Temperature Data, Weather Forecast, Long-term and short-term memory (LSTM) network*

Strain is an important type of structural response used for structural performance evaluation and a key monitored parameter in Structural Health Monitoring (SHM) [1]. In SHM, various types of sensors are installed in the structure to measure essential structural loading and responses [2]. In this study, the time histories of stain at 10 various locations of 3 cross-sections of a real cable-stayed bridge with main span of 648m, Hedong Bridge in Guangzhou, China, is predicted according to the temperature data from local weather forecast based on the long-term and short-term memory (LSTM) network.

The strain prediction from forecasted temperature is realized by two-nested networks. Firstly, the temperature at the location of each strain sensor is predicted from temperature of weather forecast, in which the dataset of forecasted temperature and measured bridge temperature is used to train the LSTM network for temperature prediction. Then, the stain at the location of each strain sensor is predicted by the predicted temperature, in which the dataset of measured strain data and predicted temperature is used to train the other LSTM network for strain prediction.

The characteristics and correlations of forecasted and measured temperatures, or measured temperature and strain, are analysed carefully before strain prediction. It is found that the time histories of measured temperatures are generally close to forecast temperature, and the temperatures measured at different locations have similar time variations, though they may have different amplitudes. This conclusion is also basically applicable for strain. Moreover, according to the coefficients of distance correlation, the time histories of measured temperature and strain do not always have strong correlations at different sensor locations, which directly influences the prediction accuracy of strain.

According to the results of two-nested LSTM procedure, about 50% predicted bridge temperatures deviate from their measured values below 0.5℃, with about 80% under 1℃. The predicted and measured strains have consistent time variation, and the relative error is within 5% at most moments. Consequently, the proposed method successfully predicts the strains at various locations of a real cable-stayed bridge for car traffic from forecasted weather data. In the further study, the presented method will be used to predict other types of responses in the bridge, such as displacements and accelerations, based on the weather forecast information.

Abstract

Clustered tensegrity structures integrated with continuous cables are lightweight, foldable, and deployable. Thus, they can be used as flexible manipulators or soft robots. The actuation process of such soft structure has high probabilistic sensitivity. It is essential to quantify the uncertainty of actuated responses of the tensegrity structures and to modulate their deformation accurately. In this work, we propose a comprehensive data-driven computational framework to study the uncertainty quantification (UQ) and probability propagation in clustered tensegrity structures, and we have developed a surrogate optimization model to control of the flexible structure deformation. An example of clustered tensegrity beam subjected to a clustered actuation is presented to demonstrate the validity of the approach and its potential application. The three main novelties of the data-driven framework are: (1) the proposed model is able to avoid the difficulty of convergence in nonlinear Finite Element Analysis (FEA), by two machine learning methods, the Gauss Process Regression (GPR) and Neutral Network (NN). (2) A fast real-time prediction on

uncertainty propagation can be achieved by the surrogate model, and (3) Optimization of the actuated deformation is carried out by using both Sequence Quadratic Programming (SQP) and Bayesian optimization methods. The results have shown that the proposed data-driven computational framework is powerful and can be extended to other UQ models or alternative optimization objectives.

Key Words: *Model order reduction, ANN, Surrogate Model, Large-scale problem, Transferability, Topology optimization*

Large-scale simulation is often encountered in many fields of science and engineering. In many cases, problems must be solved over a range of different settings. For example, during the structure design process using the topology optimization, structure evolves at each design iteration and its function/performance must be repetitively evaluated. Tackling this type of problems using conventional methods, for instance, the Finite Element Method (FEM) would entail large computational costs. In recent years, Deep learning-based models with fast online prediction such as artificial neural network (ANN) models have been developed to overcome this issue either by acting as surrogate models for function evaluation [1,2], or directly outputting design solutions [3,4]. These methods have yet to make a major impact because of the poor transferability and scalability of current machine learning models. As a result, a large set of training data is required which is infeasible for large-scale analysis and design. In this talk, we will present some recent work on the development of an efficient ANN-based model-order-reduction method suitable for large-scale problems. In particular, we will show that by using domain decomposition and coarse-to-fine mapping ANNs, surrogate models constructed using training data of one problem can be applied to a range of problems with different domain shape and size, boundary conditions and loading conditions without any re-training. As such, the transferability of the model is greatly improved.

Key Words: Deep learning neural network, Artificial Intelligence, Hull deformation, Ship hull design, Total resistance

The hull design is a complicated process since a minor local change to the hull structure may significantly change the hydrodynamic performance. In order to find the hull model with the best hydrodynamic performance under the design requirements, scholars developed Computer-Aided Design (CAD) by combining computational fluid dynamics (CFD) and geometric modeling. However, the calculation workload of the computer-aided design is considerable, and in most cases, it is only applicable in the design stage with a small design space. Meanwhile, because the computer-aided design needs to perform a performance evaluation after the new ship model is obtained, it will encounter some obstacles in practical applications.

In order to assist the ship design, we applied the deep learning neural network technique, which aims to predict the total resistance of the hull model in real-time through geometric deformation parameters. However, due to the different influences of different types of geometric deformation parameters on the hull structure, its influence on the hydrodynamic performance of the hull will also be different. When processing input parameters with different influencing capabilities, traditional machine learning methods can easily become too sensitive to input parameters with high influencing capabilities. In the hull design, different sensitivity must be avoided to ensure that the designer can obtain the optimal hull according to the changing trend of the hydrodynamic and geometric modification parameters of the hull.

In this work, we simplified the geometry modification process by using two types of geometry modification parameters. The final MINN model was constructed, tuned, and trained based on the virtual reality dataset we created. The final forecast accuracy verification and sensitivity similarity verification show that the architecture of the MINN model can predict the total resistance of a hull model in real-time while maintaining the consistency of accuracy when facing different types of geometric deformation parameters. Moreover, we also proposed an example of MINN model-assisted hull design to approve the effectiveness of artificial intelligence-assisted design (AIAD). We believe our work can provide a fast and reliable assistance solution for the hull design and promote the development of AIAD in ship engineering.

Artificial neural network methods based on boundary integral equations

Key Words: *Artificial neural network, boundary integral equation, Laplace equation*

In Anitescu et al. (2019) [1], the artificial neural network method to solve boundary value problems (BVP) for partial differential equations (PDEs) of the second order was proposed. The method is based on approximating the solution with a deep neural network and minimizing the combined error in the PDE at a set of collocation points inside the domain and the error in the boundary conditions. Such an approach presents an alternative to commonly used finite element methods. In many practical applications, BVPs can be transferred to a boundary integral equation (BIE), which is then solved by the boundary element method (BEM). BEM has a number of attractive advantages over domain-type methods, such as reduction in the dimensionality of the problem and avoidance of domain truncation error in exterior domains.

In this work, we propose an approach to approximate the solution of the boundary integral equation with an artificial neural network. Loss function represents the error in the BIE at a set of collocation points which is minimized by the appropriate weights and biases. The approach inherits the main advantages of the boundary-type methods and allows to reduce the computational cost by using collocation points on the boundary only.

Application of the method to some benchmark problems for the Laplace equation is demonstrated. A detailed parametric study is presented to evaluate the performance of the method.

Key Words: *Silicon, Silicon carbide, Machine learning, Molecular dynamics, Density functional theory, Interatomic potential, Mechanical properties, Genetic algorithm*

In recent years, machine learning (ML) methodology has come to be utilized in various fields. In computational engineering, ML is effectively used for the development of interatomic potential. Such ML potentials are usually constructed on a general functional form and a large number of parameters, and many results of DFT calculations are needed for the learning.

The SNAP, or as its advanced type qSNAP, is one of the ML potentials. In this research, we actually construct SNAP and qSNAP for silicon (Si) and 3C-silicon carbide (SiC) crystal systems and confirm their reproducibility in MD simulations by comparing with an empirical potential such as Tersoff potential. Using a genetic algorithm, optimization calculations are performed so that the errors of the lattice constants and elastic moduli are sufficiently minimized.

We found that the SNAP is capable of reproducing lattice constant and elastic moduli for 3C-SiC, and the lattice constant, elastic moduli, and melting point for Si. Besides, the experimentally observed dimer structure in the free surface of Si {100}, which has not been predicted by empirical potentials, is successfully obtained by qSNAP.

Unfortunately, at this stage, the dislocation behaviour has not yet sufficiently been reproduced in either Si or 3C-SiC crystal. For Si crystal, dislocation cores are generated successfully. But, while pure shear strain is being applied to the crystal, some wrong partial dislocations occur, and the dislocation cores lose their stable shape in sliding. In cases above, we recognize that the reproducibility in the elastic region are sufficiently good, but the behaviour in the plastic region is by no means satisfactory for further MD analyses. So that, some improvement of the SNAP and qSNAP potential is expected by adding extra data on stacking defects to the learning process.

Designing Auxetic Metamaterials using Deep Learning

Xiaoyang Zheng[1,2,*] and Ikumu Watanabe[1,2]

[1] Graduate School of Pure and Applied Sciences, University of Tsukuba, 1-1-1 Tennodai, Tsukuba 305-8573, Japan

[2] Research Center for Structural Materials, National Institute for Materials Science, 1-2-1 Sengen, Tsukuba 305-0047, Japan (ZHENG.Xiaoyang@nims.go.jp; WATANABE.Ikumu@nims.go.jp)

Key Words: *Negative Poisson's Ratio; Metamaterial; Generative Adversarial Network; Additive Manufacturing; Voronoi Tessellation*

As typical mechanical metamaterials with negative Poisson's ratios, auxetic metamaterials exhibit counterintuitive auxetic behaviours that are highly dependent on their geometric arrangements. Forward design is the mainstream method for designing auxetic metamaterials and includes approaches such as bioinspired methods, mathematical control, topology optimization, and Boolean and lofting operations of simple geometries. The forward design approach follows a general process: first, a structure is created, and its mechanical properties are then investigated by finite element method (FEM) simulations or mechanical testing. The mechanical properties of the designed materials are known only after time-consuming simulations or experiments. In addition, because the properties of auxetic metamaterials are determined by the geometry and assembly of periodic unit cells, the traditional methods are highly dependent on the prior knowledge of experienced designers, resulting in a limited number of design spaces.

Recent advances in deep learning have facilitated the inverse design of new materials using various artificial neural networks. This report proposes an inverse design method for auxetic metamaterials using deep learning, in which a batch of auxetic metamaterials with a user-defined Poisson's ratio and Young's modulus can be generated by a conditional generative adversarial network without prior knowledge. The network was trained based on supervised learning using a large number of geometrical patterns generated by Voronoi tessellation. The performance of the network was demonstrated by verifying the mechanical properties of the generated patterns using finite element method simulations and uniaxial compression tests. The successful realization of user-desired properties can potentially accelerate the inverse design and development of mechanical metamaterials.

Key Words: Cell Migration, Variational System Identification, Inverse Reinforcement Learning

The study of cell migration is at the heart of medicinal biology, where a cell culture is observed in the presence or absence of specific drugs. Experiments suggest that migration dynamics are closely linked to certain protein levels within cells, leading to the development of kinase-pathways models for migration. However, these models are inept in predicting the tissue-scale behavior of cells. Advances in cell imaging techniques have allowed simultaneously tracking individual cells over large length scales, providing data that is amenable to continuum scale models using Partial Differential Equations (PDEs). Cells and relevant proteins can be described as a concentration field at sufficient density. In this work, we propose an Advection-Diffusion-Reaction (ADR) system for cell density, where each component of the system represents a continuum-scale homogenization of specific cell behavior. Specifically, the cell proliferation/death is modeled using reactive mechanisms while cells' directed and random motion is captured in the advective and diffusive parts of PDE, respectively.

Individual cells, however, show a much more heterogeneous behavior in terms of their affinity for random walks, directed motion, and proliferation. Therefore, the cells can be clustered into subpopulations with similar migratory features, extending the continuum scale ADR system to a multiphase one. Building upon the available kinase-pathways models, the parameters of the multiphase ADR system are proposed to be functions of homogenized fields. The data-driven Variational System Identification (VSI) approach is opted for developing a parsimonious closed system of differential equations [1]. Treating the behavior of individual cells as a Markov Decision Process (MDP) [2] and guided by the equivalence of transition probabilities in positions of cells to the homogenized behavior of Advection-Diffusion system, an Inverse Reinforcement Learning-based approach is used to study the uncertainty in the proposed ADR system.

Graph theory-based structural analysis on density anomaly of silica glass

Shingo Urata[1*], Aik Rui Tan[2] and Rafael Gómez-Bombarelli[3]

[1] AGC Inc., 1-1 Suehiro-cho, Tsurumi-ku, Yokohama, Kanagawa, Japan. shingo.urata@agc.com

Key Words: *Machine learning, Graph theory, Silica glass*

Silica glass is an ubiquitous but essential material for a vareity of industorial applications, such as optical fibers, optical lens, and substrates in semiconductor fablication. The microstructure of silica glas is composed of the tetrahedral SiO_4 units, which build up silica network by shearing their edges or corners each other. Despite the simple morphology, silica glass exhibits abnormal behaviors. For instance, as in the case of materials composed of tetrahedral units, like water, silica density becomes a minimum at temperature higher than the melting point, then increases with an increase of temperature, that is called as density anomaly. Additionally, mechanical anomaly and fragile-to-strong transition of diffusion behavior are known as typical nonlinear behaviors of silica glass.

These silica anomalies have been studied using molecular dynamics (MD) simulations. Recently, we have devloped a couple of force-fields to reproduce the energy and force calculated by the density functional theory calculations (DFT) using Bayesian optimization [1, 2]. Even though the parameter sets of the two force-fields were optimized based on the similar DFT dataset, one exhibits density anomaly of silica glass, while the other one does not. In this work, we threfore try to identify the origin of the density anomaly by comparing the glass structures obatined via MD simulations with the two force-fields.

For this purpose, the graph-based analysis method, D-measure [3], which evaluates dissimilarity (D-value) between two graphs, was employed. To find characteristics of the amorphous structure by the D-measure metric, the silica glass network was represented by a graph composed of nodes located at all silicon atom positions. The graph nodes were considred to be connected if an oxygen atom bridges two silicon atoms nearby. Then, we analyzed two types of networks: one is the global graph repreenting entire silica glass structure with considering periodic boundary conditions, and the other one is the local graph, which represents local structure extracted with a cutoff distance. The local structures were compared with template structures obtained from a variety of silica crystal phases.

Temperature dependence of the D-value when comparing with the cooled glass structure does not relate to the density anomaly. Contrarily, coesite-like intermediate-range structures, which are more dense and disordered, were identified only in the glass models exhibiting the density anomaly. The success in identifying the origin of density anomaly of silica glass confirms that the graph-based metric combined with theoretical simulations is useful as a new structural descriptor for MI of glassy materials.

Key Words: *Multi-fidelity surrogate, Transfer learning, Deep learning, Regression model*

Recently, multi-fidelity surrogate (MFS) modeling technology that efficiently constructs surrogate model using low-fidelity (LF) and high-fidelity (HF) data has been studied to improve the predictive capability of engineering performances. In addition, various neural network (NN) structures for MFS modeling have been presented by combining with the latest developments in deep learning research. Although the existing multi-fidelity NNs have been developed with identical sets of input variables of LF and HF data, they are often different in practical engineering systems. Therefore, this study proposes a new structure of composite NN for multi-fidelity data with different input variables. The proposed network structure incorporates an input mapping network that connects input variables of LF and HF data. Even if physical relation between those variables is unknown, the input mapping network can be trained together in the process of learning the entire network model. The overall process of the proposed method is divided into two simple steps based on the concept of transfer learning. First, LFNN is trained using LF data, and it is transferred to the specific part of the proposed network. Second, while freezing parameters of the transferred NN, the remaining parameters including parameters of the input mapping network are optimized using HF data. To verify the effectiveness of the proposed method compared to a NN model with single-fidelity data, it is applied to mathematical problems with some assumptions regarding the practical engineering issue and real-world engineering problems of various tire performances.

Nonintrusive neural optimization of topology

Miguel A. Bessa[1], Gaweł Kuś[1*] and Shushu Qin[1]

[1] TU Delft, Mekelweg 5 2628CD Delft, The Netherlands ,
* M.A.Bessa@tudelft.nl

Key Words: *Topology Optimization, Artificial neural networks*

Rational design of materials with high-throughput computing and machine learning has made outstanding progress in the last two decades. Yet, machine learning remains ineffective when dealing with inverse design scenarios. We propose a simple pathway where deep learning enhances topology optimization (TO) without intrusive modifications to the physics solver (e.g. finite element analyses). We aim at finding optimum topologies for nonlinear and irreversible properties when solving non-differentiable and strongly non-convex objective functions.

Physics-informed Neural Network Enhanced Reproducing Kernel Particle Method for Modeling Grain Refinement

Key Words: *Artificial Neural Network, Reproducing Kernel Particle method, Strain Localization, Phase Field, Grain Boundary Migration*

The microscopic behaviors of materials under large deformation often entail complicated localized phenomena, such as plastic slip, grain boundary evolution/migration, micro-shearband, and micro-damage. Modeling of such localizations requires highly refined discretization for accurate prediction, which significantly increases the computational cost. While adaptive model refinement can be employed for enhanced effectiveness, it is cumbersome for the traditional mesh-based methods to perform adaptive model refinement. In this work, neural network-enhanced reproducing kernel particle method (NN-RKPM) is proposed, where the location, orientation, and the shape of the solution transition is automatically captured by the NN approximation by the minimization of total potential energy. The standard RK approximation is then utilized to approximate the smooth part of the solution to permit a much coarser discretization than the high-resolution discretization needed to capture sharp solution transition with the conventional methods. The proposed neural network approximation is regularized by introducing a length scale related to the objective dissipation energy. The proposed NN-RKPM is first verified by solving the standard damage evolution problems. The proposed computational framework is then applied to modeling grain refinement mechanisms by coupling the proposed NN-RKPM with phase field and Cosserat crystal plasticity [1], including the migration of grain boundaries at a triple junction and sub-grain formation of a material with activated slip systems, for validating the effectiveness of the proposed methods.

Key Words: *Machine learning, Molecular dynamics, Metallic glass, Stress analysis*

Metallic glass (MG) with no crystalline structure is one of the promising structural materials due to its high strength, workability, and corrosion resistance. In order to expand its applicability, the mechanism of its ductility should be unveiled. Molecular dynamics simulation is a valuable tool to investigate what kind of atomic motion causes plastic behavior in amorphous materials. However, the interatomic potentials previously proposed and frequently employed, such as EAM potential, may be insufficient to capture more realistic deformaiton behaviors [1].

This study developed a machine learning-based (ML-based) potentials [2] with a particular focus on representing shear stress vs. shear strain curve with high accuracy under shear deformaiton. We have included training sets containing isotropically expanded and compressed structures, and sheared structures, obtained from density functional theory (DFT) calculation, to built the ML-based potentials. We compared the results obtained by DFT calculation, ML-based and EAM potentials: Figs. 1 and 2 show the energy curves for isotropically expanded volume and stress-strain curves averaged over six different structures, respectively. Including data under deformation allows us to reproduce the stress-strain curve obtained by the DFT calculations (Fig.2).

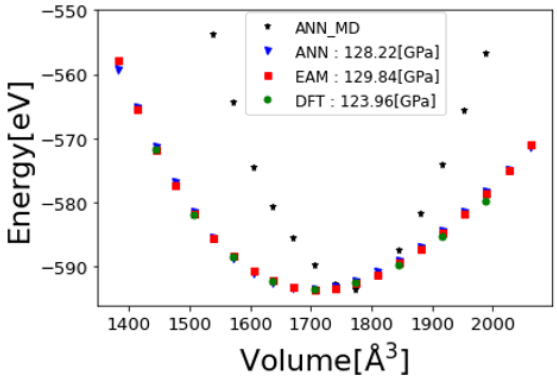

Fig. 1: Comparison of energy curve and bulk modulus for iso-expanded volume.

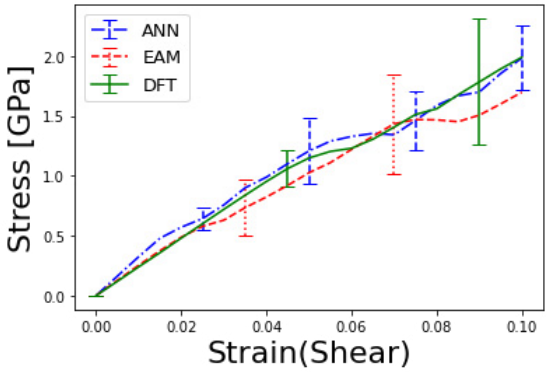

Fig. 2: Shear stress-shear strain curve for six structures.

Combining a Long Short-Term Memory Network with 3D Simulations of Fetal and Maternal Ventricular Excitation for Fetal ECG Extraction

Julie J. Uv[1*], Lena Myklebust[1] and Hermenegild Arevalo[1]

[1] Simula Research Laboratory, Kristian Augusts gate 23, 0164 Oslo, Norway, julie@simula.no

Key Words: Cardiac Electrophysiology, Machine Learning, ECG, Fetal ECG

Congenital heart disease (CHD) is one of the leading causes of infant death. ECG recorded on the maternal abdomen can be used as a non-invasive diagnostics tool for CHD. However, extracting the fetal cardiac signal from the maternal abdominal ECG signal has been challenging prominently due to the low signal to noise ratio and limited access to data of the direct fetal signal which is currently measured through a scalp electrode during delivery. The goal of this study is to develop an electrophysiological model of a maternal torso with a 24-week fetus that can be used to generate realistic ECG data which will be used to train a ML network that can automatically detect fetal QRS signal.

The computational model of a pregnant torso at 24 weeks gestation is based on [1, 3, 2] and [4], which incorporates maternal and fetal biventricular cardiac geometries and additional tissue with assigned conductivities to replicate realistic electrophysiological propagation. Sinus rhythm with different rates for the maternal and fetal heart were simulated using the pseudo-bidomain formulation. Abdominal ECG recordings at locations similar to those recorded in the clinic were extracted. In this study, we measure the obtained performance metrics for fetal QRS detection from maternal ab- dominal ECG recordings using a long short-term memory (LSTM) network combined with a QRS detection algorithm trained on a combination of clinical and generated ECG recordings.

The generated maternal torso model successfully generated realistic maternal and fetal ECG signals. However, preliminary results only show an increase in fetal QRS detection accuracy to 24.62 % for a network trained on both clinical and simulated ECG recordings. To improve the accuracy, we plan to do further augmentations of the generated ECG measurements and experiment with other network architectures. However, the current results demonstrates that computer simulated ECG measurements can be used to improve machine learning models in fetal ECG extraction.

Data Creation for Arrhythmic Risk Assessment in Post-Infarction Patients

Mary M Maleckar[1]
[1] Simula Research Laboratory, Kristian Augusts gate 23, 0164, Oslo, Norway
mmaleck@simula.no, https://www.simula.no/

Key Words: *Computational cardiac electrophysiology, machine learning, data augmentation, data creation*

Background. Assessing risk for arrhythmia can be thought of, from a statistical perspective, as a classification supervised learning task[1]. However, training machine learning classifiers that perform well, whether via classical algorithms or via DLNN, requires sufficient data, the amount of which is often difficult to assess a priori and varies with the task at hand[2]. In contrast, in the health domain, clinical studies often only reflect data from relatively small numbers of patients or samples. New work into data augmentation and data creation[3] can help to increase the effective amount of data for the training of ML algorithms.

Biophysical multiscale modeling for clinical translation, now a mature stand-alone field, can offer additional insights and information about patients from first principles. These models offer mechanistic insight and, recently, also improve performance of ML and DLNN models via data augmentation and creation[4,5]. Anatomically realistic and biophysically detailed multiscale computer models of the heart are playing a significant role in advancing our understanding of integrated cardiac function in health and disease. Retrospective and prospective studies, including our own work, have previously demonstrated that computational simulations using personalized virtual heart models can be used to predict arrhythmic risk e.g., in patients with ischemic scar tissue[6] with greater accuracy than current clinical metrics.

Remodeling due to myocardial infarction (MI) significantly increases patient arrhythmic risk. Simulations using patient-specific models have shown promise in predicting personalised risk for arrhythmia. However, these are computationally- and time- intensive, hindering translation to clinical practice. Classical machine learning (ML) algorithms (such as K-nearest neighbors, Gaussian support vector machines, and decision trees) as well as neural network techniques, shown to increase prediction accuracy, can be used to predict occurrence of arrhythmia as predicted by simulations based solely on infarct and ventricular geometry.

Objective. We and others have earlier presented[5] an initial, combined image-based patient-specific *in silico* and machine learning methodology to assess risk for dangerous arrhythmia in post-infarct patients and demonstrated that simulation-supported data augmentation improves prediction models, combining patient data, computational simulation, and advanced statistical modeling, improving overall accuracy for arrhythmia risk assessment. Here, we aim to extend that work to demonstrate that advanced statistical and shape modeling techniques can critically augment sparse clinical data cohorts to improve risk assessment for dangerous arrhythmias in post-infarction patients.

Methods. MRI-based computational models were constructed from 30 patients 5 days post-MI (the "baseline" population). To assess the utility biophysical model-supported data augmentation for improving arrhythmia prediction, we augmented the virtual baseline patient population. Newly employing shape modeling techniques, patient ventricular and scar geometry in the baseline population was used to create a subfamily of geometric models, resulting in an expanded set of patient models (the "augmented" population). Arrhythmia induction was attempted via programmed stimulation at 17 sites for each virtual patient corresponding to AHA LV segments and simulation outcome, ``arrhythmia" or ``no-arrhythmia", were used as ground truth for subsequent statistical prediction (machine learning, ML) models. For each patient geometric model, we measured and used choice data features, including the myocardial volume and scar volume, as well as the segment-specific myocardial volume and scar percentage, as input to ML algorithms. For classical ML techniques (ML), we trained k-nearest neighbors, support vector machine, logistic regression, xgboost, and decision tree models to predict the simulation outcome from these geometric features alone. To explore neural network ML techniques, we trained both a three - and a four-hidden layer multilayer perceptron feed forward neural networks (NN), again predicting simulation outcomes from these geometric features alone. ML and NN models were trained on 70% of randomly selected segments and the remaining 30% was used for validation for both baseline and augmented populations.

Results and Conclusion. Stimulation in the baseline population (30 patient models) resulted in reentry in 21.4% of sites tested; in the augmented population (129 total patient models) reentry occurred in 12.9% of sites tested. ML and NN models ranged in mean accuracy from ~0.83-0.86 for the baseline population, improving to ~0.91-0.96 in all cases. We conclude that advanced statistical and shape modeling techniques can critically augment sparse clinical data cohorts to improve ML-driven risk assessment of dangerous arrhythmias in post-infarction patients.

Efficient AI-Surrogates for Clinical Translation: Parameter Estimation and Biomechanics Assessment of the Heart

Gonzalo Maso Talou[1*], Thiranja Prasad Babarenda Gamage[1] and Martyn P. Nash[1]

[1] University of Auckland, New Zealand, g.masotalou@auckland.ac.nz, tp.babarendagamage@auckland.ac.nz, martyn.nash@auckland.ac.nz

Key Words: *Deep learning, Surrogate model, Cardiac modelling*

Great strides have been made in the understanding of the mechanical modelling of the heart over the last decades, generating a new dimension of potential tools to aid cardiologists in diagnosing heart disease. However, computational cost, infrastructure and time required by the more accurate models impede the translation of many applications to the clinic.

To tackle these limitations, we have developed AI-surrogate models, which combine dimensionality reduction, model simplification, parallel processing and deep learning techniques. AI-surrogates learn to mimic outputs of computationally intensive simulations using a simplified structure, reducing the computational demand while maintaining prediction accuracy. Additionally, AI-surrogates present the opportunity of calibrating patient-specific models and estimating tissue properties with unprecedented performance [1].

To test this approach, we created an AI-surrogate of the cardiac left ventricle (LV) to simulate its deformation through the passive filling stage of the heart cycle [2]. The AI-surrogate reproduced the ventricular displacements with an absolute error of 0.05 +/- 0.04 mm compared to the finite element method (FEM) counterpart, while reducing the computational time 10-fold. Our experiments showed that the AI-surrogate is able to characterise: the mechanical properties of the LV wall in less than 6.6 seconds; or the intraventricular pressure in less than 1.3 seconds. In comparison, a single LV deformation prediction using traditional techniques may require minutes to hours of computational time, and parameter estimation may require hundreds of such simulations. Our AI-surrogate approach could be applied to help with distinguishing specific mechanisms of dysfunction for early diagnosis of heart failure [3]. Translation to clinical practice would enable near real-time diagnosis of heart disease and potentially improve outcomes for patients.

Key Words: Cardiac Electromechanics, Machine Learning, Reduced Order Modeling, Global Sensitivity Analysis, Bayesian Parameter Estimation

Numerical simulations of cardiac electromechanics play a crucial role in computational cardiology and precision medicine. Therefore, it is of paramount importance to develop reduced-order models (ROMs) that enable real-time numerical simulations of the cardiac function. With this aim, we propose a non-intrusive method, based on Artificial Neural Networks (ANNs), to build ROMs of cardiac electromechanics that surrogate biophysically detailed and anatomically accurate full-order models (FOMs).
The ANN-based ROM is trained from a collection of pressure-volume transients obtained through the FOM while accounting for the dependence on a set of parameters. Once trained, this surrogate model can be coupled with virtually any hemodynamic model for the blood circulation external to the heart, in the same manner as the original electromechanical model, but at a dramatically lower computational cost. Our results show that the ANN-based ROM is accurate with respect to the FOM, while requiring very small training datasets.
We demonstrate the effectiveness of our Machine Learning method in two relevant contexts for cardiac modeling. First, we employ the ANN-based ROM to perform a global sensitivity analysis on both the electromechanical and hemodynamic models. Second, we perform Bayesian parameter estimation starting from noisy measurements of relevant quantities of interest. In both these cases, by replacing the FOM of cardiac electromechanics with the ANN-based ROM, we perform in a few hours of computational time the numerical simulations that would be unaffordable if carried out with the FOM, because of their overwhelming computational cost. As a matter of fact, our ANN-based ROM is able to speedup the numerical simulations by more than three orders of magnitude.

Multi-Fidelity Simulations of Cardiac Electrophysiology with Applications to Atrial Fibrillation

Lia Gander[1*], Simone Pezzuto[1], Rolf Krause[1], Paris Perdikaris[2] and Francisco Sahli-Costabal[3]

[1] Università della Svizzera italiana, Lugano, Switzerland
[2] University of Pennsylvania, Philadelphia, USA
[3] Pontificia Universidad Católica de Chile, Santiago, Chile

Key Words: Cardiac Electrophysiology, Multi-fidelity, Atrial Fibrillation, Eikonal Model

Accurate simulations of the cardiac electrophysiological activity are computationally demanding due to the complexity of the equations involved. Multi-fidelity approaches can be used to reduce the computational cost. The idea is to speed up the computations by combining accurate high-fidelity models and fast low-fidelity models. These low-fidelity models are less accurate, but they are typically constructed from the high-fidelity model, therefore sufficient correlation in the quantity of interest can be expected. One clinically relevant application of the multi-fidelity approaches is atrial fibrillation. During episodes of this arrhythmia, the electrical activity of the atria is chaotic and characterized by re-entrant wavelets that self-propagate in the tissue. An appropriate high-fidelity model for this application is based on the solution of the monodomain equation for the propagation of the electric potential on the atrial surface. The eikonal equation is an approximation of the monodomain equation, based on simplified physics, that allows a fast computation of the activation times. Therefore the eikonal model can be employed as a low-fidelity model. Alternatively, one could also employ the multi-level approach, in which the low-fidelity model is based on a coarser discretization. In this work, we adapt the eikonal model to account for the re-excitability of the tissue, in order to allow the fast simulation of re-entries with this simplified model. Then, we employ the adapted eikonal model in multi-fidelity approaches for the simulation of atrial fibrillation. The multi-fidelity approaches with the eikonal model could also be applied to uncertainty quantification.

The reconstruction of the epicardial potential field from measurements of body surface potentials is a challenging inverse problem. Classical data-driven deep learning (DL) approaches are hardly applicable in this context because they require large datasets based on invasive catheter measurements.

We present a novel DL approach based on physics-based mathematical models, balancing the lack of data with parameterized numerical simulations. Specifically, we develop auto-encoder neural networks whose architecture exploits dimensionality reduction techniques to project the epicardial potential onto a reduced subspace and approximates the forward model with a tensorial reduced basis solver. Finally, we provide the network with body surface potentials organized as time series or low-frequency discrete Fourier transform coefficients.

Numerical results on synthetic data show that the physics-aware auto-encoder neural networks are accurate and efficient tools for reconstructing the epicardiac potential from body surface potentials measurements. This approach mitigates the problem of data availability and also enables the use of low-complexity architectures characterized by a limited amount of hyper-parameters.

This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (Grant agreement No. 740132).

Key Words: Cardiac Modelling, Neural networks, Physics Informed Neural Networks, Inverse Problems

Alongside new developments in the field of biomedical imaging, computational biophysical modeling is raising a growing interest in the research community, due to the great predictive potential of physics-based mathematical models and their ability to have access to crucial clinical biomarkers non-invasively [1]. In the context of cardiovascular modelling, high-resolution and accurate multi-physics mathematical models are computationally demanding and their personalisation entails fine tuning of a large number of parameters, thus potentially limiting the translation of such models to clinical context. In this talk a novel methodology is proposed, based on emerging machine learning techniques, for the efficient and robust reconstruction of displacement fields and the local estimation of heterogeneous passive mechanical properties in cardiac biomechanical models. In more detail, physics-informed neural networks methodologies [2] are extended, adapted and combined with biophysically detailed three-dimensional cardiac biomechanical models, to generate robust and effective surrogate reduced-order models that are able to uniquely identify patient-specific physical properties. The proposed learning algorithm encodes information both from displacement data, that can be routinely acquired in the clinical setting, and from the physics of the problem, represented by a mathematical model based on partial differential equations, that acts as a regularising term. The accuracy and robustness of the proposed method are demonstrated in several benchmarks. This methodology potentially paves the way for the robust and effective identification of patient-specific physical properties.

Key Words: *cardiac strain, machine learning, physics-informed neural networks*

Heart disease is one of the leading causes of death in the world. Disturbances in the mechanical performance of the heart can lead to many, sometimes catastrophic, conditions. Traditionally, cardiac function is assessed with simple metrics, such as the left ventricular ejection fraction. This quantity only reflects the global function of the heart, leaving out important information. For example, it is well documented that patients with ejection fraction in normal ranges can still experience what is called heart failure with preserved ejection fraction. For this reason, more sophisticated metrics that give regional information have appeared, such as cardiac strain. Here, the deformation of cardiac tissue is characterized locally, resulting in much richer information. However, determining cardiac strain from medical images is a challenging and open problem. In this work, we focus on the computation of cardiac strain from cine magnetic resonance images, which contain a sequence of snapshots of the heart motion. These images are ubiquitous and considered the gold standard to assess cardiac function with metrics such as ejection fraction. Nevertheless, cardiac strain cannot be derived directly from these images, as they do not contain motion information. For this reason, we use physics-informed neural networks to solve an image registration problem and estimate cardiac strain from cine magnetic resonance images. Physics-informed neural networks [1] are a promising new tool to solve inverse problems, such as this one, that will allow us to infer the displacement field that transforms images between different stages of the cardiac cycle. This method allows to include the knowledge about cardiac mechanics into the learned displacement field. Here, we enforce the near cardiac tissue incompressibility to improve the accuracy of cardiac strains. We also use a space-time continuous neural network, to reflect the different motion states of the cardiac cycle. We demonstrate the feasibility of this method in a synthetic example, and we show that our method performs favorably to other registration techniques using a cardiac strain benchmark [2]. We expect that our methodology will improve the accuracy and robustness of cardiac strain measures from cine magnetic resonance images. This will pave the way to more sophisticated diagnostic tools for a range of cardiac diseases.

Key Words: Cardiac Fibers, Physics-Informed Neural Networks, Cardiac Electrophysiology, Anisotropic conduction velocity, Eikonal Equation

We propose a method to estimate *in vivo* the cardiac fiber architecture of the human atria from multiple catheter recordings of the electrical activation. Cardiac fibers play a central role in the electromechanical function of the heart, yet they are difficult to determine *in vivo* and hence rarely truly patient-specific in existing cardiac models.

In this work, the fibers arrangement is obtained by solving an inverse problem through the physics-informed neural network formulation. The inverse problem amounts of identifying the conduction velocity tensor of a cardiac propagation model from a set of sparse activation maps. The use of multiple maps enables the simultaneous identification of all the components of the conduction velocity tensor, including the fiber angle.

We extensively test the method on synthetic 2-D and 3-D examples, also with realistic atrial geometry. We show that 3 maps are sufficient to accurately capture the fibers also in the presence of noise. With fewer maps, the role of regularization becomes prominent. Moreover, we show that the fitted model can robustly reproduce unseen activation maps. Finally, we apply the methodology to a publicly available atrial atlas and to clinical data obtained at our center, with very convincing results.

The free energy plays a fundamental role in theories of phase transformations and microstructure evolution. It encodes the thermodynamic coupling between mechanics and chemistry within continuum descriptions of non-equilibrium materials phenomena. In mechano- chemically interacting materials systems, consideration of compositions, order parameters and strains results in a high-dimensional free energy function. Scale bridging between the electronic structure of a solid and continuum descriptions of its non-equilibrium behavior can be realized with integrable deep neural networks (IDNN) that are trained to free energy derivative data generated by first-principles statistical mechanics simulations and then analytically integrating to recover a free energy density function. Here we combine the IDNN with an active learning workflow [1,2] for well-distributed sampling of the free energy derivative data in high-dimensional input spaces, thereby enabling true scale bridging between first-principles statistical mechanics and continuum phase field models. As a prototypical material systems we focus on applications in Ni-Al alloys and in the battery cathode material: Li_x CoO_2 . Phase field simulations using the resulting IDNN representation for the free energy density of Ni-Al demonstrate that the appropriate physics of the material have been learned. This work [3] advances the treatment of scale bridging, starting with electronic structure calculations and proceeding through statistical mechanics to continuum physics. Its coupling of Cahn-Hilliard and Allen-Cahn phase field descriptions with nonlinear elasticity through the free energy density ensures a rigorous treatment of phase transformation phenomena.

Key Words: Deep Neural Network, Computational Science, Wave Equation

The solution of the wave equation is required in a wide variety of fields, such as seismology, electromagnetism, and acoustics. In the last few years, a number of deep learning methods have been developed for the solution of PDE-based problems, in the hopes of producing techniques that are more flexible and faster than the traditional FEM, FD, FV approaches. Deep operator networks (DeepONet) [1] attempt to solve PDEs by learning the inverse of the differential operator for a wide class of initial data, rather than learn a single solution. However, this approach is especially expensive for problems containing high frequencies, such as those with the linear wave equation.

For the approximation of the homogeneous wave equation, we present a neural network architecture that is based on the integral representation formula of the wave equation. This architecture yields a faster learning and a better generalization error when compared to the classical DeepONet architecture. Moreover, with the proposed architecture, a trained network can be retrained for solutions with higher frequencies which results in an efficient learning strategy for high frequency functions. Numerical results in 1D and 2D will be presented to analyze frequency dependent convergence of the proposed approach.

Conditionally Parameterized, Discretization-Aware Graph Neural Networks for Scientific Computing on Unstructured Meshes

*Karthik Duraisamy**, *Jiayang Xu* , *Elnaz Rezaian*

University of Michigan, 1320 Beal Ave, Ann Arbor, MI 48109, USA.

Key Words: Graph Neural Networks, Conditional Parametrization, Surrogate Modeling

While neural networks are extensively used in surrogate and reduced order modeling of PDE solutions, they often ignore interactions or hierarchical relations between input features, and process them as concatenated mixtures. We generalize the idea of conditional parameterization [1] (CP) – using trainable functions of input parameters to generate the weights of a neural network, and extend them in a flexible way to encode critical information in unstructured meshes. Inspired by discretized numerical methods, choices of the parameters include physical quantities and mesh topology features. The functional relation between the modeled features and the parameters is built into the network architecture. Although a direct CP modification will cause a linear increase in the number of parameters with respect to the chosen parameter, such an increase can be compensated by reducing the size of the latent vectors. The method is implemented on different networks and applied to the discovery of unmodeled physics, and the simulation of unsteady flows with chemical reactions. We demonstrate that a drop-in CP modification can bring significant improvements for various existing models on several tasks essential to the modeling of physical systems. We introduce a conditionally parameterized graph neural network (CP-GNet)[2], for the approximation of complex physics on unstructured meshes, with the ability to naturally incorporate different types of boundary conditions. The CP-GNet is shown to be more efficient than the non-CP variant with only a fraction of the training data or with a more shallow architecture. Extensive numerical tests are conducted to demonstrate state-of-the-art performances on problems of different complexities.

Key Words: Deep Learning, Neural Networks, Partition of Unity, Expectation Maximization, Quantum Approximate Optimization Algorithm

Using deep learning methods to approximate continuous functions and operators is a critical problem in both machine learning theory and high-fidelity real-time engineering simulation applications. Recent discoveries in neural network approximation theory motivate novel strategies that combine deep neural networks (DNNs) with basis functions from classical approximation theory, such as polynomials. Moreover, although uncertainty quantification is required in many applications, it may not be naturally produced by the approximation scheme itself [1]. Instead, this work aims at exploring a general framework based on combining DNNs with polynomial approximation schemes that provides confidence regions in addition to point estimations.

We explore the probabilistic partition of unity networks (PPOU-Nets) model of [1, 2] in the context of regression. With the PPOU-Nets, the target function at any given location is approximated by a Gaussian mixture model, where each cluster is associated with a fixed-degree polynomial. The weights of the clusters are determined by a DNN which defines a partition of unity. The target function is approximated by the weighted average of the polynomials. We propose a novel training strategy that leverages automatic differentiation and the expectation maximization (EM) algorithm. We formulate the loss function as the negative likelihood of the Gaussian mixture model. During the training, we (i) apply minibatch gradient descent to update the DNN coefficients; (ii) update the polynomial coefficients using weighted least-squares solves; and (iii) compute the variance of each cluster according to a closed-form formula derived from the EM algorithm. The EM PPOU-Nets outperform the baseline fully-connected neural networks of comparable sizes in numerical experiments of various input dimensions. We also explore the proposed model in applications of quantum computing, where the PPOU-Nets act as surrogate models to accelerate optimization over cost landscapes associated with variational quantum circuits.

Key Words: operator regression, error-in-variables, machine learning, reduced order modeling

Operator regression has emerged as a potential tool for reduced order modeling and PDE model discovery. Most operator regression methods learn the mapping between independent and dependent *functional* variables assuming noise only in the dependent variables. However, experimental and numerical data is often noisy in the independent variables as well. In standard regression, failure to account for noisy independent variables can lead to biased parameter estimates. With noisy independent variables, linear models fitted via ordinary least squares will show attenuation bias, wherein the coefficient will be underestimated. In this talk, we demonstrate a variation of attenuation bias for linear operator regression on functional data with white noise in both the independent and dependent variables. We also propose error-in-variables models for two operator regression methods, MOR-Physics [1, 2] and DeepONet [3], and demonstrate computationally that these new models can reduce bias in the presence of noisy independent variables for a variety of PDE learning problems, including learning the Burgers operator, the heat equation, and the Kuramoto-Sivashinsky equation.

Hyper-Differential Sensitivity Analysis for Operator Inference

*Bart van Bloemen Waanders *, Joseph Hart (Sandia National Laboratories)*

Shane McQuarrie, Karen Willcox (University of Texas at Austin)

Harnessing the full power of physics-based models for decision making is challenging but critical in many engineering analyses. Accordingly, surrogate models with reduced computational complexity are necessary to combat the prohibitive costs of high-fidelity simulations. Operator inference has recently emerged as a data-driven paradigm to non-intrusively construct physics-based reduced-order models. In this work, we use operator inference as a cost-effective approach to encapsulate dynamical constraints in an optimization setting. However, approximation errors need to be accounted for and mitigated. To that end we leverage post-optimality sensitivities as feedback mechanism to iteratively improve the training process. We demonstrate our approach on the optimization of a thermal battery that requires the modeling of multi physics phenomena.

Key Words: *Machine Learning, Graph Neural Network, Equivariance*

Machine learning is a promising technology to improve computation time, accuracy, and stability of physical simulations. However, it is still an open problem to obtain more general and reliable machine learning models because of the data-driven nature of the scheme. In particular, machine learning on mesh-structured data is inevitable to realize accurate prediction because the mesh is a common data structure used in various physical simulations such as the finite element method. For machine learning models that learn mesh-based physical simulations, we put three requirements:

1. Ability to deal with mesh-structured data as an input and an output.
2. Fulfillment of constraints coming from physical laws.
3. Lightweight model to make the computation faster.

In this study, we propose a graph neural network that can reflect physical symmetry and perform prediction efficiently. Graph neural networks can deal with arbitrary meshes without any modifications in the models. Physical symmetries, such as translation and rotation, are considered through the concept of equivariance. Furthermore, we implemented differential operators in the model, which are critical to expressing spatial relationships in physical simulations. Since most physical laws are described using differential equations, it is possible to construct an efficient machine learning model corresponding to a given governing equation, which reduces computation time. We demonstrate that the proposed model learns mesh-based physical simulations with high accuracy. Besides, it can predict simulation results faster than a conventional finite element analysis software and scale up to a mesh with 1M nodes, which is not possible using existing equivariant models. We expect our model to be key to realizing more general and reliable machine learning models for physical simulations.

Key Words: *Physics-informed Neural Network, Moisture Concentration, Low dimensional inputs, Food drying*

Bulk level variations of plant foods during drying are mainly governed by microscale characteristic variations [1]. Investigating such microscale variations have been challenging with physics-based models due to heterogeneity of microstructures, largely unknown property data, and limitations of numerical simulations [2]. On the other hand, the development of data-driven machine learning (ML) models for predicting microscale variations has not yet been succeeded due to the inability of having a sufficient dataset for extracting an interpretable solution.

Therefore, in this work, the Physics-Informed Neural Network (PINN) capabilities are explored to improve the prediction accuracy of moisture concentration variations of a single plant cell during drying with low dimensional input data. In particular, additional information using relevant physics conditions is provided into the feedforward neural network by altering the loss function. The performance of PINN is investigated and compared against pure data-driven ML model predictions for benchmark cases. It can be highlighted that PINN with additional physics information is significantly improved the prediction accuracy even if the training data is very low, indicating the possibilities of integrating PINN for accurately investigating microscale characteristic variations of plant foods during drying.

Key Words: *deep learning, multiscale, composites*

Riding the wave of artificial intelligence (AI), machine learning (ML) and deep learning (DL) methods have been widely used in many domains, including materials science and engineering. Here presents a novel hierarchical multiscale modeling enhanced via deep learning, which plays an important role in this multiscale framework to pass the information from the nanoscale to the microscale and then to the macroscale.

This multiscale method provides a new approach to study the mechanics of metal-ceramic spatially tailored materials, a unique type of composites, in which the volume fractions vary in space at the macroscale. Data sets, collected from molecular dynamics simulations, are used to train artificial neural networks to predict material properties at the macroscale. Then, peridynamics and finite element methods are employed to investigate the mechanical behavior of composites at the microscale, considering microstructure uncertainties. The collected data is utilized to train machine learning regression and classification models. Those predictive models are finally implemented in the macroscale simulations to study dynamical responses of composite structures under various loading conditions.

As a difference from other reported works, microstructure uncertainties are considered in this research so that an artificial neural network is trained as the machine learning classification model to predict the failure probability at the macroscale, which depends on the volume fraction and the deformation (i.e., the strain). In addition to deep learning, extreme learning is utilized for fast learning.

Key Words: *Neural networks, turbulence, computational fluid dynamics*

Turbulence is a phenomena which is studied extensively both experimentally and numerically. In order to resolve all the length scales of a turbulent flow, expensive computational resources are required. To do this experimentally, it also involves significant resources. Recently, there has been quite lot of methods based on machine learning and deep learning which are used to enhance the retrieval of high resolution turbulent data sets. Recent work by Raissi et al[1], on physics informed neural networks (PINN) has used neural networks to find solutions to partial differential equations.

In this work, we use a hybrid PINN model to solve for two-dimensional turbulence. The aim of the work is to capture the statistical properties of turbulence. We find that the standard PINN model does not capture the two-dimensional turbulence while a modified method which uses some data from the interior of the flow domain performs well. We call this method PINN-1. In order to capture the small scales of turbulence we introduce a modified PINN denoted as PINN-2 where we train the small scales separately. We apply these two methods, PINN-1 and PINN-2 to the problem of two-dimensional turbulence in a periodic box and compare it with Direct numerical simulations. We observe the PINN-2 model outperforms PINN-1 in retrieval of solutions as close to DNS results. The turbulent energy spectra is found to match upto eight to nine decades, with only 0.1 % of training data.

We believe that such technologies can in principle be used for storage and retrieval of high resolution and high *Re* simulations where we one requires solutions at very fine time intervals and that the traditional DNS or experiments are costly.

Key Words: *Turbulence Modeling, Liutex, Machine Learning, Adjoint Method*

Existing Reynolds-averaged Navier-Stokes (RANS) models suffer from substantial discrepancies for separated flows, due to the Boussinesq approximation which is regarded as the limitation for modeling turbulence in complex geometries. Recently, the advance of data-augmented model with machine learning technology has shown the potential to significantly improve the accuracy of prediction for separated flows. On the other hand, a new concept of Liutex (previously named Rortex) has proposed to present the local fluid rotation, including a systematic framework of scalar, vector, and tensor forms, which provides several advantages over the traditional vortex identification criteria.

In this paper, a direct integrated field inversion and machine learning framework is presented to correct the momentum equations with the Spalart-Allmaras (SA) model. The main idea is that the feature set is constructed from the local Liutex and shear vectors, which are obtained from the Liutex-based R-S decomposition of the velocity gradient tensor. The weights of the neural network are chosen as the design variables of the framework and the training step is directly integrated within field inversion using discrete adjoint method of the CFD solver and the automatic differentiation embedded in the machine learning library. The gradient-based optimization algorithm is used to solve the field inversion problem. The proposed approach is applied to several challenging separated flows. The results demonstrate that the proposed framework can provide much improved prediction.

Neural network supported surrogate models for particle-laden flow

This project focuses on coupling a data-driven model in conjunction with CFD (Computational Fluid Dynamics) to predict the behavior of biomass particles in a fixed bed. This problem (particle-fluid problem) can be solved by two-way coupling CFD and XDEM. Since this methodology is often computationally expensive, two solutions are proposed. Firstly, the neural network (using TensorFlow) is used as a surrogate model to replace XDEM. Afterward, this surrogate model is coupled with the CFD method to solve the particle-fluid problem employing preCICE (Precise Code Interaction Coupling Environment). An alternative approach assumes the behavior of dense particles in the biomass bed similar to that of fluid (of unknown material parameters). The neural network is used to identify the properties of the fluid. Having the properties of the fluid, the CFD method is used solely to solve the mentioned biomass problem.

Key Words: Neural networks, Fluid-Structure Interaction, Co-Simulation, Computational Mechanics

Traditional computational methods face significant challenges with ever-increasing complexity in the problems of engineering interest. One set of problems that suffer from this phenomenon is those where Fluid-Structure Interaction (FSI) is present. FSI simulations are traditionally time-consuming and computationally extremely expensive. Potential alternatives rely on using a surrogate model to substitute one or more systems involved. A promising approach employs artificial neural networks as the basis for such a surrogate model combined with strong physics simulations based on finite element methods (FEM).

This approach requires the seamless integration of AI algorithms and packages into the simulation workflow. Such an example is the NeuralNetworkApplication developed in Kratos [1]. This application allows the integration of every step needed to implement and integrate the aforementioned surrogate models in the simulation workflow; namely data generation, model set-up, training, testing, and coupling. The routines related to the neural networks are executed through an interface with the API Keras [3].

Mok's [2] benchmark is chosen as the study case to test the capacity of the previous method applied to FSI problems. In a first instance, the structural model in the example is substituted by a neural network-based surrogate model trained on known data while retaining the original fluid model. Additionally, a second case where a surrogate substitutes the fluid model, keeping the structural one untouched, is evaluated. In both cases, the neural network predicts the total response of the system it substitutes. Strong and weak coupling scenarios are considered. The results present improvements in simulation time without sacrificing accuracy, especially when compared with the original benchmark. This contribution discusses the influence of the original data and network architecture in the outcome of the simulation and different considerations for generating surrogate models for FSI.

Building Better Databases to Learn From - Interatomic Potentials for Material Science and Beyond

Mitchell Wood[1*] **and Aidan Thompson**[1]

[1] Center for Computing Research, Sandia National Labs, Albuquerque, NM
[*]mitwood@sandia.gov

Key Words: Molecular Dynamics, Machine Learning, Magnetic Materials

The promise of all machine learning (ML) methods is that model accuracy can in principle be improved indefinitely so long as new training data is provided. This keeps model predictions as interpolations within the trained space rather than relying on uncertain predictions arising from extrapolations. For machine learned interatomic potentials used in molecular dynamics, there is no way to know *a priori* all the states of the material that will be observed in a large-scale production simulation. Automated training data curation either in real-time or diversity maximizing techniques are sought after to alleviate these concerns, though assembled training sets now scale with the size of the computing resources used. However, one must be aware of the limitations regarding the ML model form with respect to the complexity of the training set. This talk will overview our efforts to generate robust training sets and the computationally scalable ML models that enable a new frontier of MD simulations. Examples will be given of quantum-accurate MD predictions for magnetic materials, high-entropy alloys, as well as ML enabled predictions of matter in extreme conditions that challenge what is traditionally tractable in MD. Additionally, this talk will overview advances made in machine learned Spectral Neighborhood Analysis Potential(SNAP) for both their physical accuracy and computational performance on leadership computing platforms.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Key Words: *Materials design, High entropy alloys, pyiron*

High entropy alloys consisting of five or more principle chemical elements offer a much richer design space than conventional single principle element materials. However, the structural and thermodynamic complexity of this new generation of structural materials presents a challenge to their design since experimental trial-and-error approaches, as successfully used in the past, are often no longer feasible. Ab initio approaches provide perfect tools to new design routes but face serious challenges when having to systematically sample high-dimensional chemical and structural configuration spaces. Combining advanced sampling approaches with our python based framework pyiron allows us in a highly automated way to combine first principles calculations with big data analytics and decision making. It will be shown that this combination provides a powerful path to obtain key materials design descriptors such as local order, stacking fault energies or lattice distortions, which require thermodynamic sampling over huge local configuration spaces. The flexibility and the power of these approaches will be demonstrated for a few examples: The design of high entropy alloys with superior mechanical properties or ones using magnetic configurations as additional degrees of freedom.

Fitting and using machine learned interatomic potentials for plasticity

Markus Stricker[1]*

[1] Interdisciplinary Centre for Advanced Materials Simulations, Ruhr-University Bochum, IC 02-503
Universitätsstraße 150, 44801 Bochum, Germany, markus.stricker@rub.de

Key Words: Interatomic potentials, plasticity, dislocations, cross-slip

Studying fundamental mechanisms of deformation and failure in metals an alloys necessitates dependable and accurate interatomic potentials because technologically relevant defects are orders of magnitudes above first-principles' scales. We present a Behler-Parrinello neural network based interatomic potential [1] for pure hcp Magnesium, discuss the training and validation strategy, and apply it to prismatic slip using the nudged elastic band (NEB) method. We find that a very limited training data set focused on atomic structures related to plasticity, similar to a dataset used for fitting an interatomic potential based on the modified embedded atom method (MEAM), yields very good agreement with DFT-computed dislocation structures and fracture behavior. We are able to show very good agreement with in-situ experimental observations of prismatic cross-slip [3] regarding the geometry while seeing some notable disagreement with respect to the double-kink nucleation energy.

Optimal Ressource Allocation in Parallel Trajectory Splicing

Andrew Garmon[1]*, Vinay Ramakrishnaiah[2] and Danny Perez[1]

[1] Theoretical Division, Los Alamos National Laboratory, Los Alamos, New Mexico 87545, USA
[2] Computer, Computational, and Statistical Sciences Division, Los Alamos National Laboratory, Los Alamos, New Mexico 87545, USA

Key Words: task-based programming, speculation, resource allocation, accelerated molecular dynamics

Widely considered a workhorse in materials simulation, MD has struggled to maintain strong-scalability as it only weak-scales with traditional parallelization methods. One method aimed towards improving the strong-scalability of MD is Parallel Trajectory Splicing (ParSplice); a specialized MD method designed to accelerate the dynamics of rare-event systems without compromising the accuracy of MD [1]. It works by generating a large number of independently-generated trajectory "segments" in such a way that they can later be assembled into a single statistically-correct state-to-state trajectory. Due to the impossibility of deterministically forecasting the future evolution of the trajectory (which would be required to perfectly assign the execution of segments), ParSplice relies on stochastic speculation as it assigns segments via a KMC-like model that is parameterized on-the-fly. In this talk we present a method for extracting an estimate of the likelihood that any given segment will be used as part of the simulation. Then, using these probabilities, we derive an optimization framework for dynamically allocating resources among the set of possible tasks (i.e, potential segments). We detail the improvements in performance resulting from our optimized framework as compared to more naive allocation schemes including the maximum-task-throughput and minimum-time allocations. Performance results are illustrated through the use of several models of varying complexity, lending to fully interpretable results. These models enable an understanding as to when and why other allocation schemes fail, thus further highlighting the versatility/importance of our optimized allocation method. We observe that this new strategy can improve throughput up to 20x, thus greatly improving the scalability of a traditionally scale-limited application.

Key Words: *Seismic imaging, Machine learning, Uncertainty quantification*

Seismic imaging faces challenges due to the presence of several uncertainty sources. Uncertainties exist in data measurements, source positioning, and subsurface geophysical properties. Reverse time migration (RTM) is a high-resolution depth migration approach useful in extracting information such as reservoir localization and boundaries. RTM, however, is time-consuming and data-intensive as it requires computing twice the wave equation to generate and store an imaging condition. When embedded in an uncertainty quantification algorithm (like the Monte Carlo method), RTM shows a many-fold increase in its computational complexity due to the high input-output dimensionality. This work discusses an extension of the seismic imaging workflow presented in [1]. The workflow is modified to accommodate machine-learning techniques in all stages. Within a general Bayesian framework, the workflow first stage uses physics-informed neural networks for a simplified inversion, followed in the second stage by an encoder-decoder deep learning surrogate model [2] for generating the seismic images, and, in the last stage, GANs for posterior identification of seismic horizons.

Coupling Optimal Experimental Design and Optimal Control

Rebekah White[1*] **and Bart van Bloemen Waanders**[2]

[1] Sandia National Labs, Albuquerque, New Mexico, rebwhit@sandia.gov
[2] Sandia National Labs, Albuquerque, New Mexico, bartv@sandia.gov

Key Words: Optimal control/design, Optimal experimental design, Bayesian OED

Optimal experimental design (OED) can allow us to accurately represent engineering systems in scenarios where data is limited or significantly reduce the cost associated with performing experiments to calibrate relevant mathematical models. Furthermore, optimal control/design (OC) is a foundational aspect of operating complex systems that meet certain targets or operational requirements. Both optimization problems are challenging to solve in their own right and are often seen as independent problems related to large-scale engineering systems. However, there exists an underlying connection between these ideas as knowledge of the system, provided by the experimental data, is what is used to develop the control or design policies. Rather than focus experimental design on the intermediate step of model calibration, our work considers a more direct approach that focuses on the control policy itself. This requires a coupling of the two optimization problems, the solution of which is an optimal control policy and experimental design that are informed by one another. We develop a framework for solving an OED problem that maximizes information regarding the control objectives at the optimal control. We illustrate our approach on systems modeled using diffusive transport equations.

Data Imputation and Bayesian Inverse using Quantum-Inspired Hamiltonian Monte Carlo

Didem Kochan*[1], Zheng Zhang[2] Youzuo Lin[3] and Xiu Yang[1]

[1] Lehigh University
[2] University of California, Santa Barbara
[3] Los Alamos National Laboratory

Key Words: Bayesian inference, quantum-inspired, Hamiltonian Monte Carlo

We propose a hybrid technique combining Bayesian inference and quantum-inspired Hamiltonian Monte Carlo (QHMC) method for data intensive inverse problems. QHMC is an efficient way to sample from a broad class of distributions. Unlike the standard Hamiltonian Monte Carlo algorithm in which a particle has a fixed mass, QHMC allows a particle to have a random mass matrix with a probability distribution. Our method uses stochastic gradient optimization in QHMC to avoid calculating the full gradient on the entire dataset when evolving the Hamiltonian system. We combine the stochastic gradient QHMC and first order Langevin dynamics to obtain samples whose distribution converges to the posterior one. In many practical problems, the number of observations is large, and it is computationally challenging to apply classical inverse modeling techniques based on conventional Bayesian inference. Hence, our approach is more efficient for these tasks as it accelerates the sampling process while maintaining the accuracy. We will demonstrate the performance of the proposed approach for data imputation problems. Moreover, we combine the proposed approach with a randomized projection method for large scale inverse problems, and we will demonstrate its performance in several scientific computing problems.

Estimation for Time-Enhancement Curves of Regions-of-Interest from Series of X-ray Projection Data Obtained from Intra-oparation

Tomoya HASEGAWA[1], **Kenji AMAYA**[1], **Katsuyuki TAGUCHI**[2]

[1] Tokyo Institute of Technology, amaya@sc.e.titech.ac.jp
[2] Johns Hopkins University

Key Words: Time-Enhancing Curves, Intraoperative X-ray Projection, Singular Value Decomposition, Maximum Likelyhood Estimation, Regions-of-Interest

Estimating real-time time-enhancing curves (TECs) of regions-of-interest (ROI) from intraoperative X-ray projection is a big challenge in clinical practice. Traditionally, the spacial distribution of linear attenuation coefficient of each ROI was obtained from preoperative contrast-enhanced CT and combined with intraoperative X- ray projection to estimate the TECs. However, in actual surgery, there are many cases where preoperative contrast-enhanced CT cannot be obtained or there is uncertainty in the boundary of ROI due to the patient's respiratory movements. To address the problem, we developed a method for estimating TEC of each ROI when there is uncertainty in the boundary of ROI using statistical information available in advance. In the proposed method, firstly, singular value decomposition is applied on the series of intraoperative X-ray projection data, and it is decomposed into the basis of spatial distribution and the basis of time. based on this decomposition the distribution of linear attenuation coefficient and TEC of each ROI can be simply represented by linear combinations of the basis of the spatial distribution and the basis in the time direction with small number of parameters, respectively. In this framework, maximum liklyhood estimation problem under nonlinear constraints with small number of parameters can be formed. In order to verify the effectiveness of this aproach, TECs were estimated for the numerically generated fractal blood vessel model.

Fatigue Crack Growth Prediction under Incomplete Information using Kalman Filter

Rinya HATANAKA[1], Kenji AMAYA[1], Norihiko HANA[2],Masaki UMEDA[2]

[1] Tokyo Institute of Technology, amaya@sc.e.titech.ac.jp
[2] Mitsubishi Electric Corporation

Key Words: Fatigue Crack, Prediction ensamble Kalman Filter, Incomplete Information

Predicting the growth of fatigue cracks in structures is an important issue, and many methods for predicting the growth of fatigue cracks have been researched and developed so far. On the other hand, in actual field application, the information necessary for prediction is often incomplete. For example, information such as the shape and dimensions of the target structure, the current crack length, and the magnitude of the repeated load is often accompanied by uncertainty. In this study, we developed a method for predicting fatigue crack growth under incomplete information using an ensemble Kalman filter. First, a mathematical model of the evolution of the crack length of the prediction is described based on the Paris law, and this model is used as a system model. Since the system model contains the various information mentioned above as parameters, the information with uncertainty is treated as the state quantity to be estimated together with the crack length. Based on the above framework, the nonlinear state estimation problem is set and the estimation is performed by the ensemble Kalman filter. The effectiveness of this method was verified by performing a numerical simulation for the fatigue crack growth problem of the compact tension specimen as an example.

Projected Variational Methods for High-dimensional Bayesian Inference

Peng Chen[1*]

[1] Oden Institute for Computational Engineering & Sciences, The University of Texas at Austin,
201 E 24th St, Austin, TX 78712, USA, peng@oden.utexas.edu

Key Words: Bayesian inference, variational inference, transport map, curse of dimensionality, covid-19

Bayesian inference provides an optimal framework to learn models from data with quantified uncertainty. The dimension of the model parameters is often very high or infinite in many practical applications with models represented by, e.g., differential equations or deep neural networks. It is a longstanding challenge to accurately and efficiently solve high-dimensional Bayesian inference problems due to the curse of dimensionality—the computational complexity grows rapidly (often exponentially) with respect to the parameter dimension. In this talk, I will present a class of transport-based projected variational methods to tackle the curse of dimensionality. We project the high-dimensional parameters to intrinsically low-dimensional data-informed subspaces and employ transport-based variational methods to push samples drawn from the prior to a projected posterior. I will present error bounds for the projected posterior distribution measured in Kullback–Leibler divergence. Numerical experiments, including inference of covid-19, will be presented to demonstrate the properties of our methods, including improved accuracy, fast convergence with complexity independent of the parameter dimension and the number of samples, strong parallel scalability in processor cores, and weak data scalability in data dimension.

This talk covers the following joint work:

Key Words: Crack Identification, Numerical Simulation, Inverse Problems, Candidate Solution

The problem of identifying cracks inside a structure is an important engineering issue. Since the inverse problem of identifying cracks inside a structure is ill-conditioned, it is necessary to apply some regularization method for accurate identification. In this study, we have developed a novel regularization method using crack candidate solutions for the crack identification inverse problem. In this inverse problem, we focus on the changes in strain on the surface of the member that occur before and after the occurrence of cracks, and identify the shape and position of the crack. First, a crack growth simulation is performed to generate candidate solutions for possible cracks. By using the generated candidate solution as prior information, the solution space is limited and the problem is regularized. In order to confirm the usefulness of this method, cracks were identified from the changes in the surface strain of the tensile test piece including cracks.

efebrianto@turing.ac.uk

Key Words: Statistical finite element method, Matérn kernel, fractional stochastic partial differential equations, sparse precision matrices.

The increased availability of observation data from engineering systems in operation poses the question of how to incorporate measurement data into finite element models. The recently proposed statistical finite element construction (statFEM) provides a principled means to synthesise measurement data and finite element models [1]. The uncertainties present in the data, the mathematical model and its finite element discretisation are taken into account using a Bayesian statistical framework. The posterior densities of the finite element solution, model misspecification error and the noise are inferred from the data by updating their respective priors. The corresponding likelihood function depends on the data and the finite element model. In the present work, we assume that all the random fields are Matérn fields and parameterise them using their fractional stochastic partial differential equation (SPDE) representation leading to sparse precision matrices. Consequently, all the precision matrices are sparse, and the precision matrix of the posterior can be obtained using only sparse matrix operations. In addition to improving scalability, the SPDE representation provides a reasonable description of covariance structures on non-Euclidean domains, accounts for smoothness variability in the data and naturally extends to non-stationary random fields. We demonstrate the scalability and efficacy of the proposed approach with several examples from structural mechanics.

The increased usage of computational models for applications ranging from engineering to healthcare has been paired with an increasing need to quantify the numerous uncertainties influencing the input parameters to these models. Data-consistent inversion is a measure-theoretic approach to solving stochastic inverse problems that is especially suited to quantifying aleatoric, or irreducible, uncertainties in such parameters of interest [1]. In the data-consistent approach, initial or prior beliefs about input model parameters are summarized with probability distributions and updated using observed data on output quantities of interest. However, in contrast to Bayesian methods which use the ratio of the joint data-likelihood to a constant evidence term, the data-consistent approach updates the initial probability distribution of parameters using the ratio of the distribution of observed data to a predicted distribution of data. In practice, these predicted and observed probability distributions for the quantity of interest are approximated using kernel density estimates utilizing the push-forward samples from the model and observed data, respectively. This yields a solution to the inverse problem that is consistent in the sense that the push-forward of the updated probability distribution matches the observed distribution of data.

While this approach has been successfully applied in a wide variety of contexts, it has been practically limited to problems where the dimension of the observed quantity of interest is low or reduced by choosing a few components of a principal component analysis [2]. For higher-dimensional quantities of interest, accurately estimating the observed and predicted probability densities becomes a significant challenge, especially if the amount of data is limited or if kernel density estimates, which are well-known to scale poorly with respect to increasing dimension, are utilized. In this work, we employ nonlinear dimension reduction to map the quantity of interest to a lower dimensional space, and then utilize density estimation on the reduced data space. Specifically, we show how nonlinear methods of so-called “manifold learning” are suitable for physical systems where the effective dimension of the quantity of interest is low, even though the natural dimension of the measured quantities is high [3]. By applying such dimension reduction techniques to the quantity of interest, we demonstrate that we can obtain accurate solutions to the stochastic inverse problem using the data-consistent approach in high-dimensional applications.

Electro-deposition is a process widely used in the automotive industry to create a coating film on the vehicle body to protect it from corrosion. This process is particularly challenging to model and optimize due to the uncertainty associated with the physical properties of the coating film during the process and lack of understanding of the physics of the process. The deposition onset of the coating film is associated with threshold parameters leading to discontinuities in the model output, making it difficult to infer such parameters. To efficiently reduce uncertainty, we may design new experiments such that the measurement data provide the greatest value. This is quantified as the mutual information between the parameters and data under different conditions, which is also the expected information gain on the model parameters from data [1]. The overall utility function is estimated through a nested variational inference loop, allowing us to accommodate high-dimensional parameter spaces needed for capturing the effects of missing or inadequate physics [2]. We further employ surrogate models based on random forest or neural network to accelerate the overall computation. The impact of different approximations in the variational inference and surrogate model is carefully assessed.

Neural network-based generative models have been actively investigated as an inverse design method for finding novel materials in a vast design space. However, the applicability of conventional generative models is limited because they cannot access data outside the range of training sets. Advanced generative models that were devised to overcome the limitation also suffer from the weak predictive power on the unseen domain. In this study, we propose a deep neural network-based forward design approach that enables an efficient search for superior materials far beyond the domain of the initial training set. This approach compensates for the weak predictive power of neural networks on an unseen domain through gradual updates of the neural network with active transfer learning and data augmentation methods. We demonstrate the potential of our framework with a grid composite optimization problem that has an astronomical number of possible design configurations. Results show that our proposed framework can provide excellent designs close to the global optima, even with the addition of a very small dataset corresponding to less than 0.5% of the initial training dataset size.

Key Words: *Bioinspired composite, Staggered platelet structure, Gaussian process regression, 3D printing, Bayesian optimization*

The staggered platelet composite structure, one of the most well-known examples of biomimetics, is inspired by the microstructure of nacre where stiff mineral platelets are stacked up with a small fraction of soft polymer in a brick-and-mortar style[1-2]. Significant efforts have been paid to establish a framework to design a staggered platelet pattern that achieves an excellent balance of toughness and stiffness. However, because no analytical formula for accurately predicting its toughness is available due to the complexity of the failure mechanism of realistic composites, existing studies investigated either idealized composites having simplified material properties or realistic composites designed by heuristics. In the present study, we propose a Bayesian optimization framework to design staggered platelet structure that renders high toughness. Gaussian process regression (GPR) is adopted to statistically model the complex relationship between the shape of staggered platelet array and the resultant toughness. Markov Chain Monte Carlo algorithm is used for the determination of optimal kernel hyperparameter set for the GPR. Starting off with 14 initial training data collected with uniaxial tensile tests, GPR based Bayesian optimization that uses expected improvement (EI) acquisition function is carried out. As a result, it was possible to design a staggered platelet pattern that has toughness 12% higher than the best sample in the initial training set, and this improvement is achieved after 5 iterations of our optimization cycle. As this optimization framework does not require any material theories and models, this process can be easily manipulated and applied to various other material optimization problems, based on a limited set of experiments or computational simulations.

Key Words: *Interpenetrating Phase Composite, Generative Design, 3D architecture, Elastic Modulus*

Interpenetrating phase composites (IPC) are a type of architected materials, consisting of multiple phases with topological continuity and microstructural interconnectivity[1]. While the properties of each component in an IPC can be preserved to a large extent, the overall performance of the composite is highly tunable, which makes it advantageous in a wide range of applications[2,3]. However, due to the intrinsic structural and compositional complexity of IPCs, there is still lack of clear principles to guide the optimization of the composites based on a comprehensive description of the structure-performance relationship. In this study, high throughput finite-element-method (FEM) calculations in conjunction with generative machine learning models were adopted, for investigating the correlations among the target mechanical properties, the compositions of the components, and the patterns of material microstructures. The training dataset was constructed by a combination of high-symmetry patterned IPCs and randomly generated configurations followed by topology optimization. Next, extended from the current generative design approach for 2D patterns[4], the 3D structures were transferred to multi-slice images that were then learnt by deep-neural-network based models inspired by those in medical imaging. Finally, new IPCs with promising mechanical properties were proposed, where critical local structural features were identified and analyzed. This FEM-ML framework is expected to provide useful guidelines for 3D materials design, as well as throw light on the mechanistic understandings on IPCs.

Key Words: *Ballistic performance, Composite, Machine learning, Optimization*

High impact performance is one of the essential mechanical properties for designing structures such as armor that may be subjected to high velocity or ballistic loading. Understanding the fundamental mechanisms and behavior of materials when undergoing high velocity loads is critical to building next generation impact resistant materials. Previous works in the field have created composites inspired from natural materials for better impact performance under dynamic loading. However, most of the literature have focused on low-velocity loading conditions or limited design spaces have been explored due to an extremely large design space of the microstructure of composites. In this work, we aim to design novel two-phase composite microstructures with superior impact resistance when undergoing high velocity loads (>500 m/s). Our approach involves a generative machine learning-based optimization approach that incorporates a genetic algorithm and deep neural networks. Thousands of random microstructures pixelated as soft and stiff square elements are generated and their impact performance is calculated using finite element method (FEM) for training data in our machine learning model. Convolutional neural networks (CNNs) are then employed to study the complicated correlation between the high dimensional input (microstructure) and output (residual velocity and displacement). The trained CNNs predict the performance of composites much faster than FEM which requires high computational cost. Leveraging the fast inference and high prediction accuracy of CNNs, we utilize them as surrogate models combined with genetic optimization to accelerate the design process. The genetic algorithm generates new designs which have higher impact performance than that of training datasets based on greedy decisions made by CNN. The new input datasets are then fed back into the model for active learning to improve the prediction accuracy of the CNN. Results show that our final designs have remarkably improved impact performance compared to conventional composite designs and we discuss the strength of machine learning in accelerating the optimization process.

Image-based Structural Composite Design and Mechanical Characterization via Image-to-particle Conversion and GPU-accelerated Lattice Spring Fracture Simulation

To extend and expedite the design of structural composites, a fast and high-fidelity framework to predict the mechanical responses beyond elasticity becomes essential in the design cycle. One of the viable numerical approaches is lattice spring model (LSM), a coarse-grained particle spring network capable of predicting the elastic and fracture behaviors of complex composite geometries. Due to the increasing geometric complexities and configurations for material design, a large number of particles are often needed to reach convergence in LSM simulations, greatly abating the potential as an integral part of data generation pipeline for machine learning aided design. We have recently reported ImageMech—a novel platform that converts image-based geometries into particle models and simulates the mechanical responses under external loading. In our platform, the CUDA-accelerated C++ code for LSM simulation (CuLSM) outperforms the CPU-centered code by a remarkable speedup up to two orders. The platform enables a faster and more flexible mechanical characterization on structural composites and holds the key for faster exploration over the composite design space.

Key Words: *Composites Forming, Finite Element Analysis, Gaussian Process Emulator, Surrogate model*

In the field of composites, infusion techniques are a cheaper manufacturing alternative to autoclave moulding of prepreg. However, the latter is often the favoured manufacturing route in the aerospace sector as it allows for the production of better quality parts (in this industry passenger safety is paramount). One of the challenges with infusion techniques is the high deformability of the dry fibrous precursor material, which makes it susceptibly to defects and part variability. In particular, prior to the infusion phase, the dry fibrous reinforcement, is formed to shape; the quality of the final part is sensitive to both variabilities in materials and the forming process itself. If the material and process (including their variabilities) are not understood or controlled, this can result in design tolerances not being met, reducing composites weight saving advantages through requiring "over design".

In the last two decades, FE-based methods have been developed to help optimise process conditions for the best part quality. However, these require large number of explicit iterations because of significant dynamic and non-linear behaviour, making them very time-consuming especially for complex models. The design space and the number of process parameters that can be optimised can be quite large (e.g. bagging material, boundary conditions etc) making the optimisation process computationally intensive. Therefore, an intelligent strategy must be used to design these simulation tests and conduct optimisation with the computational cost as low as possible.

In the present contribution, FE simulations of a forming process of an industrial inspired geometry are conducted based on forming simulation tools developed at the University of Bristol [1-2] to produce a small dataset required to build an emulator for process optimisation. The simulations consider four tensioning springs attached at the boundaries of the textile material to provide tensile force during forming process (see the figure), of which the positions and stiffnesses are variables. A Gaussian process emulator (surrogate model) is then built [3-5] to model and optimise these variabilities. Gaussian emulators excel in situations where only small datasets are available. They also have the added benefit of uncertainty quantification, thus no manipulations are required for inclusion of variability. This work will present the methodology for building such emulators for optimisation of composite manufacturing simulation, including

the possibility to improve emulator performance through sequential design. The long term ambition of this work, is to build a fully autonomous forming rig with embedded sensors and active controls where the manufacturing conditions are adapted on the fly and defect formation mitigated based on rich, live experimental data feeding into real-time simulation and optimization of the process.

Key Words: *Nano-plastic, Activated carbon, Adsorption mechanism, Molecular dynamics*

In recent years, many plastic materials had been produced and widely used in our daily life. However, there is an increasing concern on the subject of plastic pollution. The fragment of plastic can be easily delivered and accumulated between animals and the environment. Nano-plastic is a fragment of plastic that assemble into small particles. The Nano-plastic particles size range between 1 nm to 1000 nm. Due to its small size, nano-plastic could penetrate into cell membranes and affect protein structures and functions in our body. Activated carbon (AC) is the powder which has high porosity and surface area to adsorb molecules and is widely used for filtration and purification. Because of its excellent property, many wastewater or gas system filters are based on AC.

In this study, we focus on the nano-plastic property in water and investigate the interactions between nano-plastic and AC by using the full atomistic approach. We construct four common types of nano-plastic: polyethylene (PE), polystyrene (PS), Nylon66, and polyethylene terephthalate (PET) with different particle sizes. Through analyzing the diffusion property of particles and their adsorption mechanism on AC, our results provide fundamental insights into the molecular mechanism of nano-plastic, which can further lead to new inspirations for resolving these environmental issues.

Key Words: *Homogenization, Transfer learning, Short fiber-reinforced composite, Machine learning, Deep Neural Network, Adaptive incrementally affine*

We recently proposed the adaptive incrementally affine method as a novel homogenization scheme that enables accurate prediction of the nonlinear mechanical response of particulate-reinforced composites under cyclic or multiaxial loading conditions [1]. However, being a mean-field homogenization method that relies on the solution of Eshelby's inclusion problem, the aforementioned method does not provide an accurate prediction when the shape of the reinforcement has a high aspect ratio or the interaction among reinforcements becomes significant. Herein, we propose a combined theoretical and data-driven approach in which the homogenization method is followed by transfer learning to enhance the prediction of the nonlinear mechanical response of particle/short fiber-reinforced composites [2]. We first trained a deep neural network (DNN) with a massive stress-strain curve dataset of a composite subjected to uniaxial loading and cyclic loading in the elasto-plastic regime based on the adaptive incrementally affine homogenization method; then, we fine-tuned the pre-trained DNN via transfer learning with a relatively small dataset based on time-consuming three-dimensional (3D) finite element analyses (FEA). The transfer learning approach exhibited better predictive performance than the DNN directly trained only with the FEA dataset did, for a wide range of reinforcement volume fractions and shapes. With transfer learning, the DNN exploits the knowledge learned from the homogenization theory to perform a new learning task on a small dataset from 3D FEA. The combined theoretical and data-driven approach proposed herein can be extended to the prediction of various physical properties of composites in regimes where the applicability of the homogenization theory is limited and where direct experiments or numerical simulations require excessive time or cost to generate a large dataset.

Key Words: *Chloride Attack, Airborne Chloride, MSM, Numerical Simulation, SWAN*

Reinforced concrete structures in coastal areas are susceptible to chloride attack caused by airborne chloride. Therefore, quantitative and accurate prediction of the amount of airborne chloride will enable rational construction design and maintenance management against chloride attack and extend the service life of buildings. However, a method with high prediction accuracy has not yet been established because of the complexity of environmental factors involved in airborne chloride. The authors have been predicting the airborne chloride using machine learning, based on data on airborne chloride observed in various regions of Japan and environmental data such as wind and waves available on the Internet [1][2]. As a result, the predicted values generally captured the actual measured values, but the accuracy of the prediction could not be determined accurately because the observation sites of the environmental information used and the observation sites of the airborne chloride far apart. In this study, wind data were obtained using the Japan Meteorological Agency (JMA)'s Grid Point Values (GPV) produced from the Meso Scale Model (MSM) (: MSM-GPV), which is thought to better reproduce the environment of the observation site for airborne chloride. For the wave data, we used the open-source Simulating WAves Nearshore (: SWAN) developed by Delft University of Technology in the Netherlands. For other environmental data, we used data available on the Internet as in previous studies. The training data for machine learning (airborne chloride data) used in this study are those observed at the Benoki exposure site in Kunigami Village, Okinawa Prefecture. The period covered is from January 2008 to December 2021. From these data, we predicted the airborne chloride using PyCaret, which can compare multiple machine learning programs at once. The results showed that the predicted values generally captured the trend of the measured values. In addition, the prediction accuracy of airborne chloride using MSM-GPV and SWAN was high.

Key Words: *superresolution, wavelets, isotropic turbulence, vortex structures*

We examine whether superresolution of small-scale turbulence can well preserve the position and structure of coherent vortices in three-dimensional (3D) turbulence. Convolutional Neural Networks (CNN) are used, because they can well learn characteristic spatial structure. Here we develop a wavelet-based 3D CNN (WCNN3d) for superresolution of coarse-grained data of homogenous isotropic turbulence. Wavelets are well-localized functions in scale and position and yield an efficient orthogonal multi-scale representation of the spatial structure of the vortices using the fast wavelet transform, see e.g. Ref. [1].

Recently, Kim et al.[2] applied Cycle GAN to perform superresolution of turbulent flows and showed that turbulent statistics, such as probability density function (PDF) of vorticity and energy spectra in two dimensions are well preserved. However, the positions of vortices are not well kept.

We performed direct numerical simulation (DNS) of turbulence in a periodic box at 512^3 grid points. The coarse-grained data are then obtained by applying a Gaussian low pass filter. The 512^3 data are divided into 8^3 subcubes with 64^3 grid points each. Then, we apply the discrete wavelet transform to each subcube and subsequently use 3D CNN. To this end PyWavelets,[2] an open source of Python, is used. For the wavelets we choose 'coif2' (called Coiflet 12 in Ref. [1]) having four vanishing moments and impose 'symmetric' boundary conditions in the wavelet transform of the subcube data.

We assess the performance of our WCNN3d in terms of 3D visualization of vorticity, PDF of vorticity, enstrophy spectra, etc. We find that WCNN3d well reproduces the vorticity statistics and the positions of the vortices from coarse-grained vorticity fields. Moreover, we also show that without wavelets, 3D CNN does neither well reproduce the vorticity statistics nor the vortical structures. We will discuss the influence of choice of low-pass filters on WCNN3d and the influence of the Reynolds number.

Key Words: *Convolutional, Neural network, Super resolution. Floating point, Precision*

A real time prediction of micro meteorology is expected to provide a valuable information such as temperature distribution to prevent heatstroke. However, the calculation cost of high resolution micro meteorology simulation is extensive. In recent years, the convolutional neural network (CNN) have achieved the significant improvement in graphic image. We had presented the Image-SR which predicts a high resolution temperature from a low resolution micro meteorology simulation using the super-resolution technique based on the CNN. The CNN requires more GPU memory in training of supervised machine learning as number of training data increases. To reduce the amount of GPU memory usage as well as calculation time, we examined the effect of changing floating point precision and other factors. The results indicated that the mixed floating point precision would be sufficient for the inference accuracy. In addition, the modification of hyperparameter and network architecture enables good performance especially in half precision.

Analyses of Odor Gas Advection around the Miura Peninsula Using High-Resolution Meteorological Simulation

Keigo Matsuda[1*] and Toru Sugiyama[1]

[1] Japan Agency for Marine-Earth Science and Technology, 3173-25 Showa-machi, Kanazawa-ku, Yokohama 236-001 Japan, k.matsuda@jamstec.go.jp, tsugi@jamstec.go.jp

Key Words: *Mesoscale Atmospheric simulation, Gas Advection, Lagrangian Particle Tracking, Environmental Flows*

Since June 2020, complaints about a strange smell of unknown origin have been repeated around the Miura Peninsula in Kanagawa Prefecture, which is located to the south of Tokyo. According to the Kanagawa Prefectural government, 22 cases of odor reports occurred during the period from June 2020 to October 2022 [1]. However, the clear source of the odor gas has not been identified yet. Therefore, in order to contribute to the elucidation of the source of odor gas, a high-resolution meteorological simulation is performed using the Multi-Scale Simulator for the Geoenvironment (MSSG) [2, 3, 4] for the first case on June 4, 2020. In this case, the number of odor reports to the fire department exceeded 200, and the reporting areas spread more than 15 km from north to south in the cities of Miura and Yokosuka.

The MSSG is a multiscale atmosphere-ocean coupled model, which can cover the global, meso-, and urban-street scales. Here, a mesoscale atmospheric simulation is performed for the largest domain of 350 km × 422 km with 3 nested domains. The horizontal grid spacing of the innermost domain is 100 m. To analyse the advection of odor gas near the ground surface, the Lagrangian particle tracking method is used. Particles are transported by winds on complex terrain and turbulent random perturbation.

To investigate the reason of widespread odor report locations, particle tracking is conducted backward in time from odor report locations. The results suggest that the odor gas is transported from the south edge or further south of the peninsula. Particle tracking is then conducted forward in time from the southern sea of the peninsula. Temporal change of the obtained particle distribution near the ground surface qualitatively agrees with the actual temporal change of the odor report locations. These results indicates that the odor gas could have been transported from the south edge or further south of the Miura peninsula by weak winds near the ground surface.

Key Words: *Turbulent mixing, Swirl jet, Direct numerical simulation*

A jet issued into a cross-flow, or also called a transverse jet, is a common phenomenon in engineering applications [1]. The transition from a laminar to turbulent jet often occurs and the intricate turbulent motions enhance the mixing of fluid, which also contributes to the transfer of heat, momentum, and energy. The turbulence generated in the transverse jet plays important roles in, for example, the diffusion of chimney plumes and the flow induced by air-cooled heat exchangers used in various types of plants, where the jet flow issued into the atmosphere often has a swirling motion generated by an axial fan. Therefore, swirling jets issued into a cross-flow are important in the industrial application of micro-meteorology prediction.

The present study performs direct numerical simulations (DNSs) of a swirling jet in a cross-flow and a conventional transverse jet without swirling motion, where the jet fluid is slightly heated. Here, the temperature difference between the jet and cross-flow is assumed to be small enough to treat temperature as a passive scalar. The DNS code solves the incompressible Navier-Stokes equations and the transport equation for temperature with the fractional step method, where the second-order central difference and the 3rd-order Runge-Kutta method are used for spatial and temporal discretizations, respectively. The same code has been used in our previous studies [2,3]. The DNS data is analyzed to investigate the turbulent mixing in the swirl jet, where the effects of swirling motion are evaluated by comparing the results with a conventional transverse jet. Flow visualization shows that the swirling motion significantly suppresses the vertical heat transport by the turbulent jet and the high-temperature fluid from the swirling jet tends to stay near the ground. The effects of the swirling motion are further investigated by the statistics related to turbulent mixing.

Key Words: trees, multi-scale, adaptive-mesh, CFD, drag, fractal, l-system, micro-meteorology

Modeling the aerodynamic behavior of trees has remained challenging in great part due to their multiplicity of scales owing to self-similar fractal structure and dynamic response to wind [1]. We investigate the drag coefficient for different complexities of fractal trees in order to produce models of standalone trees found in urban environments. The computational fluid dynamics code WABBIT [2], developed for the study of insect flight [3] is utilized for its ability to resolve multiple scales with an adaptive grid. Various tree like geometries are modeled using an iterative algorithm capable of generating fractal structures [4]. Drag is found to reduce linearly as tree complexity increases, despite a non-linear increase in frontal area. We propose that trees have naturally selected for a fractal arrangement in dense canopies to slow inter-canopy flow and reduce wind loads. The outlook is to find if a geometrically independent quantity, as the fractal dimension, that can be used to model aerodynamically similar trees in urban micro-meteorological simulations.

Acknowledgments

This study was carried out using the TSUBAME3.0 supercomputer at Tokyo Institute of Technology.

Highly Resolved Regional Climate Simulations over Southern Kanto in Japan with Pseudo Global Warming Method

Toru Sugiyama[1*] and Keigo Matsuda[1]

[1] Japan Agency for Marine-Earth Science and Technology, 3173-25 Showa-machi, Kanazawa-ku, Yokohama 236-0001 Japan, tsugi@jamstec.go.jp, k.matsuda@jamstec.go.jp

Key Words: *Pseudo Global Warming Method, Dynamical Downscaling, Mesoscale Atmospheric Simulation, Adaptation Measure*

Mitigation measures for climate change are globally discussed so far, and today adaptation measures are also important issues for local governments. Recently the planning of the adaptation measures gets to be supported in information platforms (e.g. A-PLAT [1]) by national institutes. However, the climate information is not enough for planning adaptation measures because the spatial resolution of the climate information is coarser than municipal area size. Thus, highly resolved climate information is required. Here we have performed regional climate simulations using the Multi-Scale Simulator for the Geoenvironment (MSSG) [2] on Earth Simulator 4. Dynamical downscaling from GPV data of Japan Meteorological Agency has been conducted. The horizontal spatial resolution is 320 meters. We have also considered the climates both 2 K and 4 K warmer than the preindustrial climate using the pseudo-global warming method. The used data base for future climate is DDS5TK (5km-grid Dynamical Downscaling Dataset, SI-CAT DDS5TK [3]).

Here we have estimated the global warming effects between current and future climate on the summer in the past 10 years of 2010 to 2019. In these ten years, both the rainy-cool and hot summers are included. The area is the southern part of Kanto area in Japan.

The highly resolved results show the regional features, e.g., as follows:
The increases of the one-month averaged temperature (Tave) is larger in the coastal area within about 1-km than those in the inland area. This is because the temperature of sea-breeze becomes higher in the future climate.
The increase of "Tave" in the valley bottom area is also larger than the hill top. This is also related with the wind speed. It is also observed that the temperature increase depends on the shape of the valley, those are, depth (~tens of meters), width (~hundreds of meters) and the mouth of the valley. The temperature increase is larger for the valleys with the mouths facing to the coastal side.
These results can contribute to the planning of sustainable future cities by local governments and area managers.

Key Words: *Mircrometeorology simulation, Drone logistics, Long Short-Term Memory*

In future urban cities, various autonomous systems will provide various social services accounting the ever-changing and complex weather and society without people's awareness. The autonomous systems will be connected to the Internet and constantly access integrated information on past, present, and future weather and social networks reproduced in cyberspace. While the autonomous systems providing the services, their real-time sensing data will be assimilated into weather forecasting simulations. That is, the so-called digital twin is achieved through the autonomous systems. The use of the real-time sensing data for weather predictions is the key to realize such future cities. One of the promising future social services is the drone logistics, which is expected to start in urban areas where people and goods are concentrated. Drones rely on the micrometeorology (microscale weather near the surface) rather than the meteorology. Their sensing data would be useful for the micrometeorology predictions. We here aim to confirm the impact of real-time sensing data obtained by drones on the micrometeorology predictions. We performed micrometeorology simulations targeting actual urban streets using a multiscale weather model named MSSG (Multi-Scale Simulator for the Geoenvironment [1,2]). Obtained dataset were considered as the ground truth and virtual observations were created from the dataset. Prediction tests were then performed using the Long Short-Term Memory (LSTM) of Recurrent Neural Network [3]. We have confirmed that the prediction accuracy is improved by considering the additional information at drone flight altitudes compared with the case in which only the observation data near the ground surface are considered. This indicates a promising future cooperative development of drone logistics and urban micrometeorology predictions.

[4] Japan Agency for Marine-Earth Science and Technology, 3173-25 Showa-machi, Kanazawa-ku Yokohama 236-0001 Japan, k.matsuda@jamstec.go.jp

Key Words: *Hot Air Recirculation (HAR), Jet in Cross Flow (JICF), LES, POD*

Air-Cooled Heat Exchangers (ACHEs) are large fans sitting atop of high pipe racks in the Liquefied Natural Gas (LNG) plants and discharge a large amount of hot air into atmosphere. The performance of ACHEs can be significantly reduced as the hot exhaust air recirculates back into the ACHEs intakes under crosswind conditions causing the Hot Air Recirculation (HAR). The flow pattern of the hot air discharged from a single ACHE fan under the crosswind condition is similar to a jet in cross flow (JICF). The understanding of the physics in JICF will therefore help predict HAR phenomena for achieving more efficient operations and production increase of LNG plant.

This study aims to clarify the physics in JICF by means of three different numerical approaches (1) steady flow simulation with the Reynolds-Averaged Navier-Stokes (RANS) model, (2) Large Eddy Simulation (LES) and (3) Direct Numerical Simulation (DNS). The computational conditions in Sherif et al (1989) [1] and Yuan et al (1999) [2] were adopted, but with various grid settings. The same coarse-resolution uniform grid was used for the three different LES models; implicit LES [3], front-flow/red (FFR) [4] and MSSG [5], and RANS models with different schemes. The results were compared with the reference high-resolution DNS results.

The three LES models reproduced the mean and fluctuations of velocity magnitude well, while the RANS models did not reproduce the fluctuations successfully although the mean velocities were reproduced well. The coarse-uniform-grid simulations show similar flow profiles with the DNS although they fail in reproducing the turbulence generation near the jet outlet. In order to clarify which modes of flow were captured and missed in the coarse simulations, the Proper Orthogonal Decomposition (POD) analysis was applied to 2D snapshots of the simulation results. The analysis provides physical insight into the relation between the grid resolution and flow modes in JICF, which will contribute to predicting HAR phenomena.

hu.x.ae@m.titech.ac.jp, onishi.ryo@gsic.titechc.jp

Key Words: *Jet in cross flow, Large eddy simulation, Unsteady Reynolds-averaged Navier-Stokes*

In the liquefied natural gas (LNG) plants, air-cooled heat exchangers (ACHEs) with an array of large fans are utilized to cool hot process fluid, and hence, a large amount of hot air is emitted into atmosphere. The performance of ACHEs can be reduced remarkably if the hot exhaust air recirculates back into the intakes of ACHEs under crosswind condition, which is so called hot air recirculation (HAR). The flow pattern of the hot air discharged from a single ACHE fan under the crosswind condition is analogous to a jet in cross flow (JICF). Therefore, it is considered that the understanding of flow behavior in JICF is helpful for predicting HAR phenomena to improve the operations of LNG plant and increase its production.

The present study aims to investigate the effects of turbulence model and mesh size on CFD simulation results of JICF. The computational conditions used is the same as those in Sherif et al. [1] and Yuan et al. [2]. CFD simulations were conducted using large eddy simulation (LES) and unsteady Reynolds-averaged Navier-Stokes (URANS) model in the modified open-source CFD code FrontFlow/Red (FFR) [3]. The turbulence models for LES and URANS are dynamic Smagorinsky model (DSM) [3] and realizable k-epsilon (RKE) model [4], respectively.

The DSM-based LES analyses predicted the mean and fluctuations of velocity magnitude well for both coarse mesh and fine mesh, compared with the experimental results by Sherif et al. [1] and LES analysis results by Yuan et al. [2]. On the other hand, the RKE-based URANS simulations underpredicted the fluctuations remarkably although the mean velocities were predicted relatively well for both coarse mesh and fine mesh. Also, fine mesh provided better predictions of the mean and fluctuations of velocity magnitude than coarse mesh for both LES and URANS simulations. The difference between LES and URANS simulation results is attributed to the fact that the DSM model for LES can predict the sub-grid scale (SGS) turbulent eddy viscosity better, and however, the RKE model in URANS overpredicted the turbulent eddy viscosity and hence the predicted flow fluctuations are damped by the numerically overestimated turbulent diffusion.

Three-Dimensional Super-Resolution of Passive-Scalar and Velocity Distributions Using Neural Networks for Real-Time Prediction of Urban Micrometeorology

Yuki Yasuda[1*], Ryo Onishi[1] and Keigo Matsuda[2]

[1] Tokyo Institute of Technology, 2-12-1 Ookayama, Meguro-ku, Tokyo 1528550, Japan, yasuda.y.aa@m.titech.ac.jp, onishi.ryo@gsic.titech.ac.jp

Key Words: *Building-Resolving Micrometeorological Simulations, Three-Dimensional Super-Resolution, Neural Networks, Real-Time Prediction*

In future cities, various IoT devices such as drones will constantly access meteorological data and social network information on cloud networks. Each system using IoT devices will provide a variety of services in response to complex changes in weather and society without people being aware of it. Such social services will require real-time predictions for urban micrometeorology.

Our research group has developed a micrometeorological model that can resolve buildings and tree canopies at several meter resolution in urban areas (e.g., [1]). However, the computational cost of such simulations is high, and the real-time prediction is difficult even with a supercomputer. We have recently proposed a "super-resolution simulation method" [2] using deep learning, where high-resolution inferences are obtained with a neural network from the low-resolution results of micrometeorological simulations. Once the neural network is trained, it can make inferences at low computational cost, which would make the real-time prediction possible.

Our previous study [2] demonstrated the feasibility of super-resolution simulations for two-dimensional temperature, whereas the information of three-dimensional wind velocity is essential for flying IoT devices such as drones. Although there have been studies on super-resolution of three-dimensional velocity with neural networks (e.g., [3]), these studies discussed canonical flows such as channel turbulence and the effectiveness of three-dimensional super-resolution for complex real-world flows has not been confirmed. This research proposes a neural network super-resolving both passive-scalar and three-dimensional velocity and applies it to building-resolving micrometeorological simulations in urban cities. We discuss the generalization performance of the neural network and the feasibility of the real-time prediction using it.

Key Words: *Artificial Neural Networks, Dynamic Mode Decomposition, Forecasting*

To ensure the safety of structures, payload, and crew in adverse weather conditions, ships must have good seakeeping and manoeuvrability performance. In this regard, ships must meet International Maritime Organization Guidelines and Regulations and NATO Standardization Agreements. Therefore, the prediction capability of ship performance in waves, along with the understanding of the physics involved, is of utmost importance. Synergic computational and experimental fluid dynamics studies [1] have demonstrated the maturity of computational tools for the prediction of ship performance in waves, including highly nonlinear dynamics in extreme sea conditions. The computational cost associated with the analysis is generally very high, especially if statistical convergence is sought after and complex hydro-structural problems are investigated via high-fidelity solvers. Computations and experiments usually produce a large amount of data, whose investigation via machine learning (ML) methods could shed light onto the underlying physics of the problem. Nevertheless, ML studies for ships in waves are still limited, where ML is usually used as a black box, with limited explanation capabilities.

The objective is to present and discuss the development and application of ML methods to improve knowledge and forecasting of global/local loads, motions, and trajectories for ships operating in waves. Hybridization of ML approaches, such as recurrent neural networks (RNN) [2], with modal-decomposition methods, such as dynamic mode decomposition (DMD) [3], is investigated to (a) predict/forecast global/local loads, motions, and trajectories of ships operating in waves, (b) extract statistical predictive models for relevant dynamics and kinematic quantities of interest, and finally (c) facilitate the interpretation and explanation of ML results.

The proposed hybrid approach is data driven and equation-free, providing also, whenever possible, the uncertainty associated with the prediction. Development, assessment, and optimization of hybrid architectures is discussed for the course keeping of a destroyer-type vessel in stern-quartering irregular waves at sea state 7. Training data are taken from URANS computations in [1]. A first architecture runs in parallel the DMD and RNNs. The final forecast is provided by a Bayesian version of RNNs; DMD is used to gain knowledge of the physics via linear modal representations; finally, the difference between linear (DMD) and nonlinear (RNNs) results is used to assess the importance of the nonlinear dynamics. A second architecture is studied, applying RNNs to the modal coordinates associated to the DMD representation, allowing for equivalent capabilities to the first architecture.

Key Words: Multifidelity methods, active learning, Bayesian optimization, multidisciplinary design optimization

Bayesian optimization is a popular strategy for the optimization of black-box objective functions [1]. In many engineering applications, the objective can be evaluated with multiple representations at different levels of fidelity, to enhance a trade-off between cost and accuracy. Accordingly, multifidelity methods have been proposed in a Bayesian framework to efficiently combine information sources, using low-fidelity models to enable the exploration of design alternatives, and improve the accuracy of the solution through limited high-fidelity evaluations [2]. Most multifidelity methods based on active learning search the optimal design considering only the information extracted from the surrogate model. This can preclude the evaluation of promising design configurations that can be captured only including the knowledge of the particular physical phenomena involved [3]. To address this issue, this presentation discusses original domain-aware multifidelity Bayesian frameworks to accelerate design analysis and optimization performances. In particular, our strategy comes with an active learning scheme to adaptively sample the design space, combining statistical data from the surrogate model with physical information from the specific domain. Our formulation introduces physics-informed utility functions as additional contributions to the acquisition functions. This permits to enhance the active learning with a physics-based insight and to realize a form of domain awareness which is beneficial to the efficiency and accuracy of the optimization task. The presentation will discuss several applications and implementations of the proposed approach for single discipline and multidisciplinary aerospace design optimization problems.

Gaussian process regression for ship dynamics: Between the Scylla of slow Karhunen-Loève convergence and the Charybdis of transient features

Stephen Guth[1*] **and Themistoklis Sapsis**[1]

[1] Massachusetts Institute of Technology, 77 Massachusetts Avenue Cambridge, MA 02139, USA, sapsis@mit.edu (sandlab.mit.edu)

Key Words: Gaussian Process, LAMP, Karhunen-Loève Theorem, Vertical Bending Moment

For a number of stability and fatigue problems in marine structural dynamics, engineers need accurate statistics for kinematic and dynamical quantities, such as pitch angles and bending moments. Unfortunately, the response statistics depend on stochastic processes, such as sea surface elevation, in a relationship with important nonlinearities. These difficulties prevent naval architects and safety engineers from using fast Fourier space methods such as Weiner-Khintchine, and instead force them to perform expensive experiments and time-consuming numerical simulations.

In order to avoid the data requirements in the Monte Carlo regime, we present a machine learning framework to minimize training set requirements. Our framework consists of two parts. First, we use the Karhunen-Loève theorem to represent stochastic sea states over finite intervals with a low dimensional projection that nonetheless captures the features important to hydrodynamics and structural mechanics. However, the choice of interval is caught between the Scylla of slow Karhunen-Loève series convergence for long duration and the Charybdis of transient behavior for small duration. To combat this dilemma, we propose a division into a fixed region, designed for parametric interpolation and machine learning, and a variable region, designed to control transients and initial conditions.

The second part of our framework is a Gaussian Process Regression surrogate model designed to learn the mapping from sea state to structural outputs. The Gaussian Process is able to take advantage of the low dimensional parametric representation of the sea state in order to converge with reasonably-sized training sets (on the order $n \approx 100$). At the same, we use a projection representation in order to directly reconstruct the output time series. The principal advantages of the Gaussian Process surrogate are the blazing speed of evaluation–ten thousand times faster than the Large Amplitude Motions Program we use to generate data [1]–and the built in uncertainty quantification.

Taken together, we can reconstruct the statistics of the responses by sampling sea states via the Karhunen-Loève construction, estimating the corresponding model outputs using the trained Gaussian Process, and estimating statistics of interest through direct Monte Carlo calculation.

Key Words: Ship Hydrodynamics, Maneuvering, Seakeeping, Machine Learning, Neural Networks

Accurate and computationally efficient prediction of ship responses in waves with physics-based numerical hydrodynamic tools is an integral part of the ship design process and in the development of operational guidance for vessels. However, once ships are designed, built, and deployed into the harsh ocean environment, analyses performed for nominal operating and environmental conditions may not reflect the real-time phenomena experienced by the vessel. As autonomy becomes more prominent in deployed vessels, accurate short-term temporal forecasting of ship responses, given the current wave environment and desired ship operation (e.g. speed, heading, maneuver, etc.) can reduce the overall risk on-board both manned and unmanned vessels. Numerical hydrodynamic tools that leverage formulations such as blended-nonlinear potential flow and unsteady Reynolds-averaged Navier-Stokes (URANS) methods, allow for simulations of ship motion in waves with varying levels of fidelity but are too expensive computationally to produce a real-time temporal prediction of ship responses, given the desired operation and the current wave environment. The recent advancements in machine learning and neural networks has led to their consideration for marine dynamics problems, where data produced by higher fidelity numerical tools can be employed to build fast-running surrogates that represent the underlying dynamical process. In particular, long short-term memory (LSTM) neural networks have been utilized for ship motion forecasting and were demonstrated most recently in [1], where a methodology was developed to represent the full six degree-of-freedom (6-DoF) ship response in irregular random waves. Previous methodologies implementing neural networks and ship motions have focused on developing a model based on a single speed, heading, and sea state and have not been shown to be generalizable to other operating and seaway conditions. The current work extends the work developed in [1] into a more generalized framework by using estimates of ship encounter frame and including training data from different sea states. Estimating the encounter frame based on a given nominal speed, heading, and maneuver and considering different sea states will empower the models to be more general in developing a relationship between the instantaneous wave elevation around the hull and the global ship motion response. The present work will detail the improved methodology, demonstrate a case study for a ship in multiple seaway and operating conditions, and explore the convergence of the constructed models with respect to training data quantity.

Multi-fidelity Bayesian experimental design for extreme-event statistics

Yulin Pan[1*], Xianliang Gong[2]

[1] Department of Naval Architecture and Marine Engineering, E-mail address: yulinpan@umich.edu

[2] Department of Naval Architecture and Marine Engineering, E-mail address: xlgong@umich.edu

Key Words: *multi-fidelity model, Bayesian experimental design, extreme events*

In this work, we develop a multi-fidelity Bayesian experimental design framework to efficiently quantify the extreme-event statistics of an input-to-response (ItR) system with given input probability and expensive function evaluations. The key idea here is to leverage low-fidelity samples whose responses can be computed at a certain fraction of that for high-fidelity samples, in an optimized configuration to reduce the total computational cost. To accomplish this goal, we employ a multi-fidelity Gaussian process as the surrogate model of the ItR function, and develop a new acquisition model based on which the optimized next sample can be selected in terms of its location in the sample space and fidelity level. In addition, we develop an inexpensive analytical evaluation of the acquisition model, avoiding numerical integrations that are prohibited for high-dimensional problems. The new method is tested in the context of bi-fidelity models for a series of synthetic problems with varying dimensions, low-fidelity model accuracy and computational costs. Comparing with single-fidelity method and bi-fidelity method with a pre-defined fidelity hierarchy, our method consistently shows best (or among the best) performance for all the test cases. Finally, we demonstrate the superiority of our method in solving an engineering problem of estimating the extreme ship motion statistics in irregular waves, using computational fluid dynamics (CFD) with two different grid resolutions as the high and low fidelity models.

Power Spectrum Estimation Based on the Long and Short-Term Memory Neural Network Subject to Missing Data

Wanxiang Zhao[1], Yuanjin Zhang[2*]

[1]School of Safety Science and Emergency Management, Wuhan University of Technology, Wuhan, China, 303377@whut.edu.cn

[2*]School of Safety Science and Emergency Management, Wuhan University of Technology, Wuhan, China, ylzhyj@whut.edu.cn

Key Words: *Neural network; Stochastic process; Missing data; Power spectrum*

Abstract: This paper develops a power spectrum estimation method based on long short-term memory (LSTM) neural network subject to the missing data[1]-[2]. In actual engineering applications, the accuracy of power spectrum increases with the rise of time history samples.. However, there are some cases where the data is difficult to obtain or some data may be missing, due to the restrictions of the measurements or data corruption. In this regard, LSTM neural network is introduced to deal with the missing data problem. First, missing data can be filled with zeros to obtain samples of the full time history. In order to solve the problem of exploding and vanishing gradients occurring in neural networks, LSTM blocks are used to embed gates into hidden neurons of recurrent neural networks. In this sense, an advantage of the LSTM framework is that key information can be stored or updated by manipulating the gates introduced. Furthermore, LSTM models are able to retain information for a long time without vanishing gradients. In addition, the zero padding samples are used to train the LSTM neural network model. The accuracy of the model can be improved by appropriately selecting an prediction sequence length and building the corresponding neural network structure. Next, the trained LSTM neural network model can be used to predict the remaining missing data and obtain the power spectrum. During the forecasting process, the predicted value is used to replace the zero value, and the sample time series data is continuously updated until all the zero values are replaced by the predicts of the neural network model.The significant advantage of this method is that it can maximize the use of missing data to obtain more time history samples, so that the target power spectrum can be restored more accurately[3]. The comparison between the target power spectrum and the power spectrum estimation based on LSTM neural network demonstrates the accuracy and effectiveness of the proposed method.

Key Words: Prognostics and Health Management, Remaining Useful Life, Multifidelity Modeling, Machine Learning

The fault detection and failure prognosis of complex engineering systems are a major challenge for health management and maintenance planning, as the mutual interactions of heterogeneous subsystems result in behaviours that are difficult to model accurately. A robust real-time estimate of the current system health and Remaining Useful Life (RUL) is a key element to enable the actuation of predictive maintenance tasks and reduce the overall operating costs of the equipment. At the same time, the high computational cost usually associated to such estimates hinders the execution of these tasks on-board [1]. We propose to combine physics-based representations with data driven knowledge of the observed system, to achieve accurate estimations of the current and future health of the monitored equipment, while keeping the computational time of the entire process suitable for a nearly-real-time evaluation [2]. We demonstrate our approach on the failure prognosis of an aircraft electromechanical actuator for secondary flight controls. The results suggest that the algorithm is able to assimilate measured data in real-time, learning from physics to progressively increase the accuracy and robustness of RUL predictions.

Key Words: scientific machine learning, operator learning, non-intrusive model reduction, nonlinear partial differential equations, data-driven modeling

We present a new *scientific machine learning* method that learns from data a computationally inexpensive surrogate model for predicting the evolution of a system governed by a time-dependent nonlinear partial differential equation (PDE), an enabling technology for many computational algorithms used in engineering settings. Our formulation generalizes to the PDE setting the *Operator Inference* method previously developed in [B. Peherstorfer and K. Willcox, *Data-driven operator inference for non-intrusive projection-based model reduction*, Computer Methods in Applied Mechanics and Engineering, 306 (2016)] for systems governed by ordinary differential equations. The method brings together two main elements. First, ideas from projection-based model reduction are used to explicitly parametrize the learned model by low-dimensional polynomial operators which reflect the known form of the governing PDE. Second, supervised machine learning tools are used to infer from data the reduced operators of this physics-informed parametrization. For systems whose governing PDEs contain more general (non-polynomial) nonlinearities, the learned model performance can be improved through the use of *lifting* variable transformations, which expose polynomial structure in the PDE. The proposed method is demonstrated on a three-dimensional combustion simulation with over 18 million degrees of freedom, for which the learned reduced models achieve accurate predictions with a dimension reduction of six orders of magnitude and model runtime reduction of 5-6 orders of magnitude.

Key Words: *Biologically inspired structural composite materials, reinforcement learning, optimization, Q learning, hierarchical design, design system*

Here we propose a new design method using reinforcement learning to solve bioinspired composite materials in a complex system. Biological structural materials are made by a stiff matrix and a compliance glue to exhibit extraordinary mechanical properties which synthetic materials do not possess. The reason for this excellent performance is because a particular order makes them of microstructures. To imitate the exceptional material properties of biomaterials, the idea of bioinspired structural material has been proposed. However, the number of combinations of design space is usually intractable. Therefore, we offer a new design method by using reinforcement learning to solve the problem. Here we developed a hierarchical design paradigm. The hierarchical design process starts from a design space with limited combinations. After obtaining the best design of the current system size, we expanded the design system and searched for the best design with higher resolution. We searched for the best crack resistance by using the hierarchical reinforcement learning from a lower resolution. By comparing the design results in the two design systems, the hierarchical design can effectively increase the convergence rate. We further discussed the results obtained from each hierarchical level. It can be observed that the best structure obtained from a high-resolution design space shows a significant improvement by depressing the stress concentration at the crack tip. The best composition was examined through 3D printing. The experimental results show that there is an excellent agreement with our AI design. The design framework proposed in this research can be used as an alternative method for optimization in a complex design system with various constraints. This research can be potentially applied to bionic structural design, nanoengineering, and material design in the future.

A Neural Network Enhanced Finite Element Method for TPMS based Mechanical Metamaterials Simulation

Yan-Zhen Chen[2*], Tsung-Yeh Hsieh[1], Tsung-Hui Huang[1], Cheng-Che Tung[2], Po-Yu Chen[2]

[1]Department of Power Mechanical Engineering, National Tsing Hua University (NTHU), Hsinchu, Taiwan

[2]Department of Materials Science and Engineering, National Tsing Hua University (NTHU), Hsinchu, Taiwan

Key Words: *Machine Learning, Neural Network, RVE, Finite Element Method, Triply Periodic Minimal Surface*

Mechanical metamaterials are artificial structures where the structure rather than the composition primarily determine their material properties. Triply periodic minimal surface (TPMS) is one of the well-known metamaterials; its volume is occupied with distorted morphology and sophisticated tunnel systems. Such distinctive topology-driven cellular structures can also be discovered in nature, such as butterfly wings and sea urchins [1]. In tradition, the finite element method (FEM) is employed to simulate the metamaterials, but plenty of defects and twist geometry pose difficulty in the model construction. Excessive low-quality mesh is found in the TPMS model, and therefore, the direct numerical simulation (DNS) becomes computationally inefficient and ineffective. In this study, we employ the neural network enhanced finite element method (NN-FEM) to improve the simulation performance. In this framework, a surrogate model can be employed without detailed structural topologies, and the hypothesis constructed by the neural network replaces the traditional analytical constitutive model in the numerical simulation. In order to train the neural network offline, the representative volumetric element (RVE) is defined at a local scale, and its mechanical responses are obtained by imposing various boundary conditions [2] to acquire the datasets. The usage of RVE in the surrogate model results in a homogeneous mesh to model a complicated TPMS structure. Such simple mesh not only saves the unfavorable mesh cost, but also enhances the convergence of the solver, which further saves computational costs. Some comparisons with traditional FEM are performed to validate the superior efficiency of NN-FEM. Dataset tuning methodologies and generalized-TPMS scheme are also proposed to speed up the NN-FEM, which will be presented. TPMS structure will be parameterized, and thus regarded as input of neural network in NN-FEM. Various engineering applications have been examined and the numerical results in both deformation and stress distribution is consistent with DNS results, which verify the robustness and effectiveness of the framework toward TPMS. The scheme provides a new and efficient way to design, model, and optimize complicated engineering metamaterials.

A new Physics-Informed Neural Network based Topology Optimization framework for structural optimization

Hyogu Jeong[1*] YuanTong Gu[1]

[1] Queensland University of Technology, 4000, hyogu.jeong@hdr.qut.edu.au

Keywords: Topology optimization, Evolutionary structural optimization, Physics informed neural network, Machine learning, Solid Mechanics.

This paper presents a novel paradigm for Physics-Informed Neural Network based Topology Optimization (PINNTO). The proposed study replaces conventional FEA with an energy-based PINN to establish an approximation function for the displacement field [1]. Here, a supervised neural network that respects governing energy method described by partial differential equation (PDE) is trained without any labelled data to solve linear elastic solid mechanics problems. Combining with Bi-directional Evolutionary Structural Optimization (BESO) as the generation of solid-void optimal topology, a new PINN based topology optimization is developed in this paper [2]. A number of compliance minimization examples are presented to demonstrate the validity and effectiveness of the proposed PINNTO for achieving convergent optimal designs for structures. Compared with the existing BESO method, PINNTO does not require traditional FEA. Instead, the structures obtained using PINNTO is comparable to the conventional topology optimization methods.

Keywords: Topology optimization, Evolutionary structural optimization, Physics informed neural network, Machine learning, Solid Mechanics.

Key Words: *Molecular dynamics, Coarse-grained model, Glass fiber, Composites, Chloride*

Glass fiber reinforced polymers (GFRPs) have been widely utilized in marine applications due to its inexpensive, versatile and excellent performance. In the past decade, extensive experimental and theoretical studies have been conducted on reinforced polymer composites to facilitate the development of construction materials. Although a number of experimental investigations have been carried out to determine the characteristics of GFRPs under various experiments, the in-depth insight into molecular-scale processes involving interfacial interactions between fiber and matrix cannot be provided. Therefore, molecular dynamics (MD) simulation is needed when analyzing the mechanism of material failure that is originated from molecules. Despite the wide application of MD simulation in the modeling of GFRP, its applicability is limited by the tremendous computational resources and the restricted time and spatial scale compared to experiments. To bridge nanoscale modeling and macroscopic experiment, coarse-grained (CG) models beyond the capacity of atomistic simulations have been put forward. In this work, a CG model of GFRP is developed, the applicability and efficiency of which in predicting GFRP composites under environmental-introduced deterioration are evaluated through verification processes. The developed model consists of defining CG beads for the microscopic system and calculating their spatial distribution. The interactions between beads are then obtained based on the results from full atomistic models. To predict mechanical behaviors of GFRP under marine environment, the degradation of GFRP caused by chloride effect and the mechanism involving bond breaking and formation are explored. The CG model can reproduce macroscopic experimental observations and measurements. Tensile fracture snapshot of CG model is compared with SEM photo of GFRP composite, also the morphologies of the CG models that present the deterioration of GFRP under chloride effects are compared. The application of the method in modeling of large unit cells with randomly distributed glass reinforcements is examined. The changes of internal pore distribution, interfacial morphologies, and the mechanical properties of GFRP show that the degradation of microstructure and mechanical properties under environmental intervention can be well predicted by this novel CG model. The newly proposed modeling framework with basic description of material structure can be further extended to the research on the deterioration of other engineering composite materials, and provide insight towards the development of new nanocomposites.

Key Words: *Artificial neural network, Potential energy and force, Thermoelectric materials, Pb-Te-Ga alloy materials, First-principles calculation*

Lead telluride (PbTe) emerged as a promising thermoelectric material for intermediate-temperature waste-heat-energy harvesting. For the purpose of increasing its ZT value and further reducing its thermal conductivity, it can be achieved by doping Ga[1]. However, since the optimal composition of the complex and diverse ternary material, PbTeGa, has not yet been discovered, numerical calculations can be used to accelerate the exploration. The thermal conductivity coefficient of Ga ternary thermoelectric materials with different compositions can be calculated using well-known numerical methods of Equilibrium and Non-Equilibrium Molecular Dynamics (EMD and NEMD, respectively). Yet, there is no complete and reliable material potential function in the literature to accurately describe the interatomic interactions in ternary thermoelectric materials. Therefore, in this work, we use an artificial neural network (ANN) to fit the potential energy of binary and ternary thermoelectric materials. Firstly, the neural network potential package (n2p2) program[2] was used to fit the potential function of the binary material PbTe with the training dataset of 12,300 PbTe structures generated by first-principles calculations. Then, the function was used to perform molecular dynamics (MD) simulations. As a result, the verified microstructure is stable and the lattice volume energy curve is consistent with the first-principles calculations. Furthermore, in the prediction of material-related properties, taking elastic modulus as an example, the error between the predicted value and theoretical value provided by Material Project is within 6%. This shows that ANNs can successfully and effectively predict the potential energy and force of the binary material through the characteristics of the local atomic environment. Secondly, the research is further extended to the ternary thermoelectric material PbTeGa, the training dataset contains 24,600 PbTeGa structures, and a special step-by-step training strategy is proposed, in which the potential functions of pure element, binary and ternary materials are fitted separately. The advantage of the strategy is that the accuracy of potential energy fitting of ternary materials can be imporved and guided by the fitted parameters of existing pure elements and binary materials. In summary, the potential functions fitted by ANNs are efficient, accurate, and not affected by the scale of the system. The present work results are expected to be helpful for the development of PbTeGa ternary thermoelectric materials.

Key Words: *Instructions, Multiphysics Problems, Industrial Applications, Covid-19*

Natural materials, which have risen from billions of years of evolution, have developed unique characteristics, such as hierarchical structures, multi-functionality, self-assembly at ambient temperature and pressure, capabilities of self-healing and environmental adaptation. Distinct from engineering materials, which are unable to perform both lightweight and high strength; high stiffness and high toughness, biological materials are often composites of hard/brittle minerals and soft/ductile proteins arranged into complex hierarchical structures which possess remarkable mechanical properties, combining lightweight, high strength and high toughness owing to strengthening and toughening mechanisms from nano-, micro-, meso-, and macro-scales.[1] Learning from Nature can lead to revolutionary breakthrough and innovation in materials science and technology. In this talk, selected biological materials, including abalone nacre, dragonfly wings, bamboos and plant seeds will be introduced. [2,3] Inspired from the structural designs of these natural materials, we further applied multi-scale simulation/modelling, genetic algorithm, machine learning, and A.I.-related approaches to optimize the bio-inspired structures and validated by 3D printing and mechanical testing. Novel mechanical metastructures and composites inspired from Nature and optimized by A.I. could lead to wide potential applications in industrial fields, including bicycles, automobiles, aerospace, intelligent robots, biomedical materials and assistive devices.

Key Words: *Multiscale Simulation, Data-Driven Computational Mechanics, Deep Material Network*

Due to many challenges posed by traditional multiscale simulation methods, there has been lately an increasing interest in data-driven multiscale tools. For instance, inspired by DDCM [1], Xu et al. [2] proposed a data-driven FE^2 solver in which online macroscopic analysis is performed by searching over an offline-generated database of stress-strain points. Although the results were promising, this approach has its limitations: it requires a fixed and large dataset, hence making it not suitable to problems with path-dependent mechanical response. It is also computationally expensive, although to a lesser extent than the traditional methods. In this work, we combine DDCM with a deep material network (DMN) [3] to formulate a DMN-DDCM solver to circumvent those difficulties in data-driven multiscale simulation (DDMS). By utilizing a multi-level strain sampling strategy whereby the range of data is adaptively adjusted, we can timely feed DDCM with sparse, dynamic datasets generated through DMN. This strategy greatly enhances efficiency of DDMS. The on-the-fly generation of data is guided by macroscopic stress-strain conditions and DMN which enables the flow of information between scales through homogenization/de-homogenization and can capture complex materials behaviors. The result is a data-driven multiscale solver which can both efficiently and accurately capture the intricate responses of heterogeneous materials. This solver shows the potential to become an excellent and reliable tool in data-driven multiscale simulation.

Key Words: *Deep neural network, LiFePO4/graphite cells, End-of-life, Remaining useful life, Data-driven features*

Rechargeable batteries, such as LiFePO4/graphite cells, have great economic and environmental value. In this work, we proposed deep neural networks with a special convolutional training strategy and taking advantage of recently published battery cycling data. The residual life of a battery can be predicted with a mean absolute percentage error of 6.46%, using only one cycle of testing. The cycle-by-cycle profiles, such as discharge voltage, capacity, and power curves of any given cycle, of used batteries with unknown age can also be accurately predicted. Moreover, our models can extract data-driven features from the data which were much more influential on the predicted properties than human-picked features such as the maximum and minimum temperatures, based on the analysis by using deep tayler decomposition. Finally, a powerful Full RUL DNN which allows the prediction of remaining useful life (RUL) and the current battery age of used batteries is proposed. Our DNNs are suitable to be an important component of modern quality control systems in battery manufacturing and battery management systems. It is expected to provide tremendous economic and environmental benefits since reuse and recycling of batteries can be better planned.

Key Words: *graph neural networks, recurrent neural networks, stress-strain evolution, texture evolution, elasto-viscoplasticity, mechanical properties*

Multiscale simulation is widely used in modeling microstructure-induced inelastic mechanical behavior. However, direct numerical simulation (DNS) and concurrent multiscale simulation suffer from an expensive computational cost that makes the process infeasible. In this work, we aim for developing an efficient surrogate model for constitutive modeling of metallic materials that combine graph neural networks (GNN) [1] and recurrent neural network (RNN) [2, 3] to incorporate geometric representation of polycrystals and memory-dependent behavior. Extended from Vlassis et al. [1], we introduce a graph neural network to extract grain topology and properties in polycrystalline metals as low-dimensional graph embedding to predict the evolution of the properties, e.g., texture. By such graph representation, the nature of the polycrystalline materials topology, i.e., grain connectivity, can be incorporated into the machine learning model, and generalized to predict mechanical response of unseen topologies at the online stage. To further enhance the predictability on nonlinear elasto-viscoplasticitic behavior, RNN is incorporated to establish time correlation of the historical loading path. In this work, the proposed hybrid machine learning model is trained on the dataset generated by a high-fidelity crystal plasticity model to predict stress-strain response and microstructure evolution under uniaxial tension and various loading path. The predictions of the proposed surrogate model show a good agreement with DNS method with a significant improvement in computational efficiency. We also demonstrate the generalizability of the proposed surrogate model by verification on various polycrystalline geometries. This work paves the path for future concurrent multiscale simulations, such as macroscopic formability coupling with microscale texture evolution.

Key Words: *Hierarchical Deep-learning Neural Networks, Proper Generalized Decomposition, Convergence Study and Error Bound*

We propose a novel reduced order deep learning approach for solving a class of PDEs, called HiDeNN-TD [1], which is a tensor decomposition (TD) [2] based reduced-order model of the hierarchical deep-learning neural networks (HiDeNN) [3]. The proposed method keeps advantages of both HiDeNN and TD methods. HiDeNN-TD adopts the concept of separation of variables and considers the solution of PDEs as a summation of the products of multiple one-dimensional functions. But differently, each of these 1D functions is represented by structured deep neural networks (DNNs), i.e., the 1D HiDeNN. In these neural networks, the weights and biases are functions of the nodal positions, which allows the optimization of the nodal coordinates in each dimension. This idea makes the HiDeNN-TD more accurate than the finite element method (FEM) and conventional proper generalized decomposition (PGD) [4] and TD, using a fraction of the FEM degrees of freedom. Here, the accuracy and convergence of the method have been studied theoretically and numerically, with a comparison to different methods, including FEM, PGD, TD, HiDeNN and Deep Neural Networks. Theoretical analysis and numerical examples both show that HiDeNN-TD has a high accuracy with orders of magnitude fewer degrees of freedom than FEM, which shows a high potential to achieve fast computations with a high level of accuracy for large-size engineering and scientific problems. As a trade-off between accuracy and efficiency, we further propose a highly efficient solution strategy called HiDeNN-PGD. Although the solution is less accurate than HiDeNN-TD, HiDeNN-PGD still provides a higher accuracy than PGD/TD and FEM with only a small amount of additional cost to PGD. In addition, we have theoretically shown that the PGD/TD converges to FEM at increasing modes, and the PGD/TD solution error is a summation of the mesh discretization error and the mode reduction error.

Short-fiber-reinforced composites (SFRC) have been widely used as high-performance engineering materials for structural applications in automotive and electronics industries. Typically, SFRC are manufactured by injection molding, which induces heterogeneous microstructures across different length scales, and the resulting nonlinear anisotropic behaviors are challenging to predict by conventional micromechanical methods. In this work, we present a data-driven multiscale modeling framework that integrates the injection molding simulation, material homogenization, and a mechanistic machine learning model referred to as Deep Material Network (DMN) [1]. The physics-embedded DMN learns the microscale material morphologies hidden in Representative Volume Elements (RVE) [2] of composites through offline training, and the trained network is able to predict the nonlinear material behaviors at a computational speed orders-of-magnitude faster than the high-fidelity RVE simulation. Through transfer learning [3] of different material microstructures, a unified DMN database is created to cover a full range of SFRC geometric descriptors. Recently, we have coupled the trained DMN database with macroscale finite element models in the engineering simulation software LS-DYNA to perform concurrent multiscale structural simulations [4]. The proposed multiscale simulation framework achieves extraordinary computational performance, and it is quite promising for the design and analysis of composite structures.

Key Words: *4D printing, Shape morphing, Inverse design, Deep learning, Fully Convolutional Network, Finite element analysis (FEA)*

4D printing is an extension of 3D printing technology. By printing smart materials, 3D-printed objects have the ability to deform again due to certain external stimuli such as heat. Although the shape morphing characteristics makes it possible to create complex 3D surfaces from 2D simple structures[1], it is very difficult to inverse design this process because of the nonlinearity of the morphing mechanism and the entanglement between different parts. In this study, we use deep learning techniques to overcome this difficulty and automate the inverse design process. Specifically, this research studies a 2D grid design space that deforms to 3D gridshell through 4D printing process. The 2D grid is composed of rectangular arranged double-layered segments. Each layer is made of shape memory polymer (SMP55) or PLA, resulting in four combinations for each segment. The size and material combination of each 2D grid is specified to control both global and local curvatures of the deformed gridshell which can achieve a variety of complex structures. Three traditional Japanese “Noh masks” are chosen as the target shapes because Noh masks are an ideal model system as each mask has unique aesthetic features. We use parametric polynomial functions describe face features and generate random mask designs. Combining with the deformed shapes simulated by FEM software, we produced a dataset which contained 60k data. We use fully convolutional network (FCN) [2] which typically used in image segmentation task to inverse design 2D grids based on the depth images of the desire shapes. The trained FCN model can predicted 2D grid designs with over 0.95 pixel accuracy and 0.9 mean IOU. Also by the calculation of structural similarity, the average similarity of 3D gridshells deformed from FCN-output designs and target 3D gridshells is 0.9. Although the model is limited to the distribution of the training dataset and performs poorly on Noh masks, it is still a successful proof of concept that deep learning can be utilized in the inverse design problem of 4D printing 2D grid design.

Key Words: *Atomistic Simulation, Machine Learning, High Entropy Alloy*

The increasing demands for developing novel chemically complex alloys has imposed a significant challenge to the modeling and simulation community. The mechanical properties of these complex alloys are pivotal for their applications; however, the length scale required for studying the plasticity of these alloys is beyond the reach of conventional quantum chemistry calculations. In this study, we harnessed the power of machine learning and trained a potential model for the chemically complex $Ni_{0.25}Co_{0.25}(Hf_{0.33}Ti_{0.33}Zr_{0.33})_{0.5}$ alloy system by combining the spectral neighbor analysis (SNAP) model and the Bayesian optimization based on a large data set of training images labeled with energies and atomic forces computed from the density functional theory (DFT). We demonstrate that the trained potential model can predict the energies and atomic forces of this chemically-complex alloy with high fidelity to the DFT calculations. A series of large-scale (over 10^5 atoms) molecular dynamics simulations were performed to examine the deformation and dislocation dynamics of both nanowires and bulk structures, and the formation of amorphous, shear band-like region following dislocation pinning was observed, which is in excellent agreement with experiments. Furthermore, the large-scale molecular dynamics also revealed the impacts of chemical microenvironment on the dislocation dynamics, which is impossible to be retrieved from current experimental techniques. Hence, the present study demonstrate that the machine-learned SNAP model yields quantum accuracy even for complex alloy comprised of five constituents, allowing for investigating the plasticity deformation of chemically complex alloys with atomistic insights.

Prediction of Wood Surface Characteristics by Using Deep Learning on Tracheid Effect

Chun-Ping Huang[1*], Tzu-Yu Kuo [2] and Wei-Chung Wang [3]

[1]Engineering Building I, National Tsing Hua University, Taiwan 30013, Republic of China
[1] s109033704@m109.nthu.edu.tw, [2] asmit.com@msa.hinet.net, [3] wcwang@pme.nthu.edu.tw

Key Words: *Tracheid Effect, Surface Characteristics, Artificial Intelligence, Deep Learning*

Tracheid effect is a phenomenon that a laser speckle appears on the wood surface where the laser light is illuminated on. Recently, based on the tracheid effect, a three-dimensional fiber orientation scanning system (3D FOSS) was developed at the National Tsing Hua University in Taiwan [1]. In contrast to the elliptical shape of the laser speckle formed when the light is irradiated on the surface of the clear wood, non-elliptical shape scattered image is produced when the light is projected on the surface defect (e.g. knot, crack, edge, etc.). To reduce the influence of wood surface defects on the accuracy of fiber direction measurement based on tracheid effect, artificial intelligence (AI) deep learning method was employed to identify the laser speckle.

In this paper, 26234 laser speckle images of Japanese cedar were collected by the 3D FOSS and a database was established. The images were classified into four categories: clear wood, knot, crack, and edge. The You Only Look Once (YOLO) [2], a single-stage object detection algorithm, was used to perform deep learning on the four categories of laser speckle to form a prediction model. YOLO has the advantage of being able to quickly predict and classify the input data with good accuracy. YOLO has been used to perform prediction behaviours such as vegetable and fruit discrimination at different maturity stages [3], flower species discrimination [4] and animal face expression discrimination [5] with accuracy from 80% ~ 90%.

By using the commercially available software package MATLAB, the predicted results can be visualized for comparison with the original specimens. The preliminary results showed that the surface characteristics of the wood can be successfully predicted.

Key Words: *Plasticity, Surrogate models, Recurrent Neural Networks*

Multiscale approaches are an essential tool of mechanical modeling. From a description of a material's microstructure, and mechanical models of its constituents, the material's effective behavior can be deduced via numerical homogenization. However, leveraging this microstructural knowledge on large-scale components either directly or even using FE^2 approaches can remain computationally prohibitive. A numerically advantageous alternative consists in constructing a surrogate model of the homogenized response, i.e. a faster algorithm that approximates the homogenized response, for example by constructing a Reduced Order Model.

Recently, an alternative approach based on deep-learning algorithms called Recurrent Neural Networks (RNNs) has emerged. A number of studies have established that, given sequences representative of strain histories and the corresponding stress response of various materials, RNN models could be trained to reproduce this behavior.

Unfortunately, the stress response predicted by typical RNN models (based on LSTMs or GRUs) depends on the number of increments used to discretize a given strain-path, leading to poor predictions when long sequences are considered. This shortcoming complicates the application of RNN models to explicit finite element simulations.

The authors have recently proposed an alternative RNN formulation, called Linearized Minimal State Cell or LMSC, that addresses this issue [1]. By updating the RNN's state-variables following exponential decay trajectories, the RNN's response can be made insensitive to the number of increments used to describe a path. As a result, models trained on sequences a thousand long or less can be implemented into explicit finite element frameworks and deliver precise responses for structural simulations involving millions of time-increments.

In this presentation, we will detail applications of LMSCs to elastoplastic models, in particular to homogenized behavior drawn from crystal plasticity simulations. We will discuss the precision of the results and their sensitivity to dataset properties. We will also highlight that directly implementing the RNN-models as finite element material models leads to numerical instabilities, and propose numerical strategies to overcome this shortcoming.

Key Words: *Dental implant, Topological optimization, Genetic algorithm, Finite element analysis, Mechano-regulatory, tissue differentiation, Deep Learning*

The geometries of dental implants have a great influence on osseointegration and bone healing. Thus, topological optimization of dental implants has been widely discussed in clinical researches. However, the finite element analysis process of osseointegration based on mechano-regulation method [1] is time-consuming. In this study, a genetic algorithm combined with a deep learning network [2] is developed for topological optimization. The deep learning network which can be a substitute for finite element analysis is developed. It can rapidly predict the tissue differentiation in different designs of healing chambers during the bone healing process. The results of osseointegration is evaluated by bone area (BA) and bone-implant contact (BIC) around the implant. In genetic algorithm [3] , the candidate of dental implant is represented as chromosomes via the encoding method. The BA and BIC values are regarded as the fitness function of genetic algorithm.

After several iterations in genetic algorithm, the optimized geometry design of dental implant is obtained. Where the optimized geometry has finer thread at the top and wider space between threads at the middle, which is very similar to the design of the commercial dental implant. Thus, by assigning different constraints or requirements, the current framework can rapidly optimize the design of dental implants to result in the best osseointegration around the implants.

National Cheng Kung University, 1 University Road, Tainan City 70101, Taiwan
*Corresponding author: clin@gs.ncku.edu.tw, phone +886-6-2757575 ext. 62139

Abstract:

This talk presents a new micromechanics model, dubbed unified unit-cell model, to modeling the effective mechanical properties of particulate, fibrous, and laminated composite materials. Composite connectivities are limited to 0-3, 1-3 and 2-2 types, and mechanical properties are limited to linear elasticity. Considering a periodic composite, a representative volume element can be identified as a unit cell. It is divided into only four subcells. This innovative architecture of a unit cell achieves a concurrent simulation of 0-3, 1-3 and 2-2 composite materials by employing the minimum number of subcells among existing unit cell-based micromechanics models. Effective mechanical constants are derived via concentration-factor tensor technique that addresses the micromechanical relations based on the continuity conditions among the unit cell and its subcells. The unified unit-cell micromechanics model retains an explicit formulation for the overall mechanical properties. Numerical results for 0-3, 1-3 and 2-2 composite materials are shown in order to demonstrate the comparability of the present model with the Mori-Tanaka micromechanics model. Moreover, the predictions are compared in view of existing experimental data of particulate composite materials.

A Physics-Informed Machine Learning Meshfree Method for Hydrodynamics Modelling

Jinshuai Bai[1*], Emilie Sauret[1] and Yuantong Gu[1]

[1] Queensland University of Technology, 4000, jinshuai.bai@hdr.qut.edu.au

Key Words: *Physics-Informed Machine Learning, Hydrodynamics modelling, Meshfree method*

In recent years, machine learning techniques have brought revolutionary changes for hydrodynamics modelling [1]. Herein, a Physics-Informed Machine Learning (PIML) meshfree method for hydrodynamics modelling has been proposed [2]. In the method, the Feedforward Neural Network (FNN) is applied to predict the field variables within the computational domain. The FNN is trained by physics information in terms of the governing equations and experimental observation data. Both explicit and implicit Runge-Kutta (RK) algorithms are leveraged for accurate temporal integration. The performance of the proposed PIML meshfree method has been investigated through benchmark cases. It has proven that the proposed method can effectively simulate hydrodynamics problems with free surfaces. We also highlight that the issue of treating highly uneven particle distributions, which limits the traditional meshfree methods, is greatly alleviated for the proposed PIML meshfree method [2].

Key Words: Adversarial Neural Networks, Partial Differential Equations, Variational Formulation

Solving Partial Differential Equations (PDEs) has been a long-standing challenge in numerical analysis, engineering, and computation. Traditional numerical methods have been widely developed and studied in the last decades for this purpose. For example, Galerkin methods seek the solution in a trial space and employ multiple test functions. In these methods, we want to minimize the residual operator in the dual norm of the test space, which equivalenty reformulates as a min-max problem, where the minimization takes place over the trial space and the maximization over the test space [1].

However, Neural Networks have demonstrated their great capacity for solving PDEs as well as nonlinear formulations. In particular, [2] and [3] propose to solve a weak formulation setting combining two networks adversarially as described above: one to approximate the trial solution, and another one for approximating the test maximizer. However, they select suboptimal norms for the optimization.

In our work, we revisit the Weak Adversarial Networks [2, 3], study their features and limitations, and derive related and more robust methods employing Neural Networks. In particular, we propose a nested double Ritz Method: the outer-loop approximates the trial solution, while the inner-loop approximates locally the trial-to-test operator that maps every trial function with its corresponding optimal test function. In addition, we extend the weak formulations to strong and ultra-weak formulations. We show several 1D and 2D numerical results comparing and analyzing these methods.

Key Words: *Orthodontics, Artificial Intelligence, Force and Moment Prediction, V-bend Wire*

Evaluation of orthodontic force and moment is essential to establish effective orthodontic treatment. However, the measurement of the force and the moment is difficult under treatment. This study proposes a method to predict the force and the moment from a wire shape using machine learning and the finite element method. The study focuses on the v-bend wire, which is a wire with a v-shaped bend. In order to achieve the above goal, we tried

- Development of a finite element simulation for force and moment evaluation of a V-bend wire
- Generation of training data of AI is generated by the developed finite element method.
- Development of AI for orthodontic force and moment prediction from wire shape.

Application of Self-Organizing Map (SOM) to the Classification of Athletes' Psychological Ability

Key Words: *Self-Organizing Map (SOM), Psychological ability*

In the field of sports, it is important to improve mind, technique, and physical strength. To give full play to athletes' ability in the competition, we should consider the combination of mind, technology, and physical strength. Technique plays a role based on physical strength, which is dominated by mind. The exertion of psychological level is an important factor for winning the competition. Therefore, it is very important to support athletes from the field of psychology as well.
There are individual differences in psychological competitive ability. Especially in the case of group competitions, understanding the psychological characteristics of individual athletes leads to improvement in team performance. In this research, we use the self-organizing map (SOM) [1] to analyze the athlete's psychological characteristics. Athletes were examined using the Diagnostic Inventory of Psychological Competitive Ability for Athletes (DIPCA.3), the Athletic Coping Skills Inventory (ACSI), the Mental Toughness Index (MTI), and the Sukumune-Hiew Resilience Test (S-HRS). Total scores for each questionnaire were used as the SOM's input data. The results showed that the SOM clustered the athletes according to their psychological ability. Similar athletes with psychological ability were mapped near and clustered into the same group. We confirmed that SOM is a very effective analysis method for the field of sports psychology.

masuda.masato@mail.u-tokyo.ac.jp

Key Words: Flow Visualization, Computational Fluid Dynamics, Self-Organizing Map, Machine Learning

The authors had proposed a new visualization method using self-organizing map (SOM) for computed results of fluid flow at the last WCCM conference[1]. Most of existing visualization method gives color depending on a certain physical value, such as pressure, vorticity, etc. However the choice of the physical value is arbitrary and sometimes loses important features. The proposed method firstly classifies all flow properties, i.e. pressure, velocity components and their spatial gradients etc. at each grid point, by giving these properties as high order vectors to SOM. Then color is given to each grid point based on its location on the map so that the flow field be naturally painted including all flow properties. SOM is originally a two-dimensional (2D) map as the main purpose of SOM is to visualize high order vectors, but in the proposed method, the map is not directly viewed and only used to determine color of each grid point. Hence three-dimensional (3D) SOM has been also generated to give three color components based on the map. In the present paper, the proposed method is further investigated to show its capability and validity with various flow fields, such as compressible / incompressible flows. Also the choice of flow properties given to SOM are examined. For instance, only the primitive variables are used, only the spatial gradients are adopted, the second derivatives are included, etc. The results will be included in the extended abstract and be presented at the conference as well.

Key Words: *Machine learning, deep learning, data augmentation, surrogate model*

In the manufacturing industry, it is important to produce better products within a certain period for shortening of product lifecycles. Since a large number of computational simulation cases are required in the initial study stage of development. In order to shorten evaluation period, machine learning technologies and 1D-CAE becomes popular in addition to conventional CAE evaluation[1].

The use of predictive models based on deep learning as a substitute for CAE is one of the evaluation methods. While we have much expectations for high accuracy, the applications to engineering problems are not enough to satisfy the expecations[2]. In the fields of material design and computational fluid dynamics, good results have been reported, because huge amounts of data are eventually generated in those research fields[3]. Therefore, the objective of this study is a construction of framework using machine learning technology to evaluate crash box corruption for a significant reduction of CAE analysis cost.

The structural strength evaluation of crash boxes is predicted by machine learning in this study. The training data was obtained from the dynamic elastic plastic analysis of the crash box. The input physical quantities are barrier angle, box thickness, material properties and mass equivalent to vehicle weight. The output physical quantity is the reaction force. F-S diagram is predicted by deep learning using convolutional neural networks with data augmentation for regression problem. Buckling is occurring in the analysis and different directions of curruptions are one of the most interesting phenomenon from a point of engineering view.

We have several difficulties to construct the surrogate model, because of imbalanced frequency problem and The time series of the reaction force maxima is different depending on the data. W'd like to propose an adaptive method for machine learning in structural evaluation that can be used for a wide range of structural evaluations.

Key Words: *Surrogate model, data augmentation, convolutional neural network, deep learning,*

In these days there is a trend to utilize simulation-based verification more frequently rather than verification through experiments using the product in the field of industrial product design. In this context, a development of an evaluation method instead of CAE is needed for more effective designing of industrial products. Machine learning methodology is one of the most anticipated way to accelerate evaluation process.

An application of a surrogate model in deep learning to engineering problems is still studied. In the our researches [1][2][3] the surrogate model using machine learning can predict physical phenomenon within 7% error compared with CAE prediction. The accuracy of the prediction is improved by augmentation technique, which is called as oversampling to avoid overfitting. The augmentation is conducted using data sets with low prediction accuracy.

The objective of this research is studying effective data augmentation for engineering regression problem. SMOTE is based on classification algorithm, however an engineering interpolation should be computed based on physical meanings and influential parameters.

In the machine learning the pedestrian kinematic response with a front part of a car is predicted and the predictor evaluates pedestrian's damage. The responses which are used as learning data are generated by 1D-CAE system. The prediction of the response can be achieved with less than 7% average error using all of data sets. Numbers of training data sets are varied in order to show the enough number and the predictor is evaluated for its accuracy. We'd like to discuss necessary of total number of training data sets and effectiveness of data augmentation.

Key Words: *Machine Learning, Defect Analysis, Finite Element Method, Infrared Stress Analysis, Carbon-Fiber-Reinforced Plastic*

The degradation of Carbon Fiber Reinforced Plastic (CFRP) occurs due to damages such as delamination, fiber breakage and matrix crack. Therefore, we need to conduct high-precision and efficient Non-destructive testing (NDT). Examples of NDT are ultrasonic examination, X-ray tomography and infrared analysis. In ultrasonic examination, objects are required in the water. In X-ray tomography, we need to set object in an analysing room. Hence it is suitable to analyze large structures by means of infrared analysis. In addition, it is hard to estimate the three-dimensional information of defects by means of most of these NDT methods. To solve these problems, some studies propose machine-learning-aided NDT. In this study, we developed an inverse analysis model that predicts the spatial information of defects from the distribution of sum of the principal stress on the surface (DSPSS). The DSPSS is calculated from the temperature change measured by infrared analysis in both experiments and numerical analysis. This inverse analysis model is proposed as an alternative method to the existing damage analysis. Inverse analysis model is composed of two machine learning models. One is for making experimental DSPSS closer to the results of the Finite Element Method (FEM) and the other is for predicting the spatial information of defects from DSPSS by FEM analysis. The proof of concept has been successfully done for the model which predicts the spatial information of defects from FEM analysis [1]. We use U-net [2] for the first machine learning model and Convolutional Neural Network (CNN) for the second one.

Finite element quantitative analysis and deep learning qualitative estimation in structural engineering

Peng Zhi[1*], Yu-Ching Wu[1]

[1]Tongji University, Shanghai, 200092, PR China
[*]pengzhi@tongji.edu.cn

Key Words: *Finite element, quantitative analysis, deep learning, structural engineering*

Finite element method (FEM) has been widely used to study the mechanics of materials and solids, as well as fluid–structure interactions, and building construction strategies. FEM is popular all over the world with the development of computer technology. It is known for powerful computing ability, surpassing humans in computing. In this context, in addition to teaching engineers to use FEM calculation software, structural engineering education in the past nearly two decades also focuses on cultivating engineers' ability of qualitative analysis. However, the rapid development of deep learning methods in recent years means that human qualitative analysis capabilities based on rules of thumb will also be replaced by artificial intelligence. The main question of this study is: what role will deep learning methods play in the future structural analysis? In this paper, a large number of finite element analyses are carried out for three classic boundary value problems, such as the behaviour of wires under load, the problem of heat conduction, and plane strain. The deep learning model is trained with FEM simulation results. It can quickly and accurately predict the results of related similar problems, and evaluate the accuracy and efficiency. The results show that artificial intelligence can to some extent replace the work of human qualitative analysis based on rules of thumb. Predictions and expectations about the role of deep learning methods in future structural analysis processes are given.

[3] The University of Tokyo, 7-3-1 Hongo, Bunkyo, Tokyo, Japan, yoshi@sys.t.u-tokyo.ac.jp

Key Words: *Mixed traffic flow; multi-agent deep reinforcement learning; cooperative control; spatiotemporal information fusion*

A major challenging issue concerning the mixed traffic flow, composed of connected autonomous vehicles (CAV) and human driving vehicles (HDV), is how to improve overall efficiency and safety by assigning collaborate control strategies to CAVs. Multi-agent deep reinforcement learning (MADRL) is a promising approach to address the challenge [1]. It enables the joint training of multiple CAVs by using CAV sensing information and does not need the compliance of HDVs. However, the design of collaborative sensing is non-trivial, especially when there are dynamic numbers of HDVs surrounding a CAV and dynamic numbers of CAVs in the mixed traffic flow system. Under such conditions, the conventional MADRL with fixed neural network structures is no longer effective [2]. In this regard, this paper designs a hierarchical spatiotemporal information extraction module and uses a multi-agent deep Q network (MADQN) to output safe and collaborative lane change decisions of CAVs. More specifically, within the local perception range of every CAV, a long-short term memory neural network with attention mechanism (A-LSTMNN) is employed to extract the sequential motion information and to anticipate the behavior of surrounding HDVs. Then the anticipated and current motion information collected and extracted by each single CAV is aggregated by a graph convolution network (GCN), to realize a collaborative sensing of multiple CAVs. We then propose a hybrid control framework incorporating the spatiotemporal information extraction module into the MADQN, termed as spatiotemporal deep Q network (STDQN), to generate merging strategies for multiple CAVs. The simulation experiment is conducted in an onramp merging scenario, which is one of the most important and commonly seen scenarios in a highway system. Experiment results prove that by using our proposed control framework, the overall traffic efficiency and safety can be improved as compared to baseline MADRL and rule-based methods. The proposed framework can be deployed into a real traffic environment to realize proactive traffic management.

Key Words: *Machine learning, Supervised learning, Graph embedding, Non-linear buckling load, Truss, Shell*

Latticed shells are structures that represent curved surface shapes using beam or bar elements and are widely adopted to cover large spaces. Considering the cost and environmental performance, latticed shells need to be designed with slenderer members as much as possible, but the risk of buckling and yielding increases at the same time. Therefore, it is important to design structural shapes and member sizes considering this dilemma in a balanced manner.

Linear buckling loads often overestimate the value computed by the buckling analysis considering geometric nonlinearity. For this reason, geometrically nonlinear buckling analysis is more accurate to measure structural stability. Furthermore, stress analysis considering geometric nonlinearity is preferable for thin-shell structures because small deflection induces large variation in the equilibrium state. However, geometrically nonlinear analysis requires computationally expensive analysis to trace the equilibrium path.

If an approximate model that can estimate the ultimate load at a small computational cost can be introduced, it will be possible to consider the geometric nonlinearity from the early stage of structural design without worrying about the computational cost. Zhu et al. [1] introduced artificial neural networks and support vector regression, which are standard machine learning (ML) models, to predict the reduction ratio of the nonlinear buckling load of reticulated shells at a low computational cost.

This study develops a prediction model for the nonlinear buckling load of latticed shells by combining graph embedding (GE) and machine learning (ML). A graph is a data structure consisting of vertices and edges, and the structural information of latticed shells is expressed in the form of graphs. GE is a method of extracting features by considering the connectivity of graphs [2]. By combining this method with supervised learning, which is a class of the ML methods, the ML model is trained to estimate nonlinear buckling loads for various latticed shells.

This method can be used to train models for small-scale latticed shells, and the trained models can be applied to larger-scale ones without training. The computational cost required for training and the prediction accuracy of the trained model are verified through numerical examples and reported in the presentation.

Key Words: *PINN, Deep learning, Neural network, Consolidation settlement*

The long-term consolidation settlement, which is one of significant considerations in the constructions of port facilities, is often evaluated by the numerical analysis. However, it requires high computational resources to construct and calculate the numerical models that are on the physics validities. In this study, the applicability and effectiveness of the Physics-informed Neural Network (PINN) to the calculation of long-term consolidation settlements are verified for the aims of its accurate evaluations with low computational costs. The PINN is one of deep learning models considering the physics law represented by the partial differential equation (PDE) in the loss function, that was proposed by Raissi et al. [1]. It can solve the black-box problem in the use of neural network since the consideration of PDE is clearly assured. A simple model of a single clay layer was considered in this study for the verification of PINN performance. The Mikasa's consolidation equation shown below was adopted as the governing equation to predict the strain due to the consolidation.

$$\frac{\partial \varepsilon_{(z,t)}}{\partial t} = C_v \frac{\partial^2 \varepsilon_{(z,t)}}{\partial z^2} \tag{1}$$

where ε, z, t, Cv, are strain, depth of ground, time from the start of loading, and consolidation coefficient, respectively. The strain values at random times and depths of 10 days after the start of loading, created by solving the PDE and adding 10% noise, were used for the training data. In the constructed PINN model, the predicted strain distribution after 100 days was more accurate than that in the NN, that was constructed without physics knowledge for comparison, even for training data with the noise. Additionally, the constructed PINN was shown to provide the prediction of long-term consolidation settlement at any timing with good agreements to exact data. From these results, the improvement of prediction accuracies and also the effectiveness of PINN to the inverse analysis of soil parameters, such as consolidation coefficient, are expected.

Key Words: Physics-informed Neural Networks, Shell Structures, Finite Element Method, Ill-Posed Problems

Shell structures are ubiquitous structural elements found both in nature and society. As the out-of-plane dimension of such structures is much smaller than the in-plane dimensions, one can employ a reduced two-dimensional formulation to simplify their mechanical description. While such theories are mathematically elegant and have shown to be good approximations for small thicknesses, their numerical implementation by means of the finite element (FE) method is notoriously challenging. This is mainly due to the technical formulation rooted in differential geometry and numerical challenges such as shear and membrane locking arising, e.g., for pure bending deformations in the thin-thickness limit, due to limitations of the chosen function space.

While a variety of techniques have been proposed to bypass such limitations in the FE setting, we investigate the use of Physics-informed Neural Networks (PINNs), which can be understood as highly nonlinear function approximators, to solve the Naghdi shell equations in both their strong and weak form. We present encouraging numerical studies that demonstrate the capability of PINNs to accurately approximate the results obtained via FE for a variety of different shell geometries.

Furthermore, PINNs appear to be able to overcome the classical locking observed in FE, although the convergence to the numerical solution worsens in the thin-thickness limit due to an increasingly ill-posed loss function and stiff gradient flow. We expand this discussion and highlight why current techniques in the literature fail to mitigate such problems.

Key Words: *Deep Learning, Neural Network, Surrogate Model, Fiber Reinforce composite materials*

In the field of numerical simulations, a data-driven approach called surrogate model, in which some or all of numerical calculations are replaced by machine learning, is attracting attention. Models using deep neural networks have the potential to replace complex numerical calculations. It is proposed to be used in a wide range of numerical calculations such as structural analysis[1], fluid analysis[2], process simulations[3] and so on.

However, a large-scale deep neural network that can replace complicated numerical calculations requires a large amount of data for learning because the number of parameters is enormous. On the other hand, many numerical calculations require enormous calculation time and resources, and it is often difficult to generate a large amount of learning data. Therefore, a surrogate model needs to be constructed a highly accurate model with a small amount of data.

In this study, a surrogate model that predicts the physical properties of representative volume elements of fiber-reinforced composites with a knitted structure is constructed. We investigated a method for constructing a prediction model with the same accuracy as when using a large amount of data even with a small amount of data. It was confirmed that it is possible to improve the accuracy by appropriately expanding the data even with a small amount of data. We'd like to discuss how much accurate prediction is achieved and the effectiveness of the model in the design process.

Key Words: *Machine Learning, Deep Learning, Data Augmentation, Regression Prediction*

Lead-free solder has become common as environmental concerns increase. Since the maximum temperature of furnace has been increased by the solder, the temperature conditions has become strict. Defects of solder joint have increased due to circuit board warp. If the displacement of board warp is predicted, the defects will be decreased by modification of product design. In this study, we'd like to employ a convolutional neural network, characterize the data relations as a feature, for the prediction of circuit board warpage. The objective is a prediction of the amount of board warp using very limited results of several experimental measurements.

All of input data which include material properties and so on are standardized between 0 to 1. The output data is standardized warp displacement of 9 points in vertical direction on the surface of circuit board. Since a number of original data is very limited, it is necessary to augment training data sets. However, usual augmentation techniques just interpolate closed data in a parameter space. In short, the improvement of the prediction accuracy is limited. We'd like to propose a method called as factor levels augmentation. The fundamental factor levels augmentation is linear interpolation, however it may not be able to represent actual physical phenomena which usually contains nonlinearity. Nonlinear interpolation according to physical phenomenon produces better training data sets.

Prediction accuracies between no augmentation data and factor levels data augmentation is compared. In the case of no augmentation, the prediction results include 40 errors over 20%. In the case of factor levels augmentation, the highest errors are less than 5%. The significance of the factor levels augmentation is confirmed. It is important to keep the trend and characteristics of the dataset remember when using factor levels augmentation so that points with different trends are not taken. We'd like to discuss more appropriate general data augmentation techniques using a smaller number of original data.

Key Words: Bayesian Inversion, Tsunami Modeling, Inverse Acoustics, Surrogate Operators

To improve tsunami preparedness, early-alert systems and real-time monitoring are essential. We propose a novel approach for predictive tsunami modeling within the Bayesian inversion framework. This effort focuses on informing the immediate response to an occurring tsunami event using near-field data observation. Our forward model is based on a coupled acoustic–gravity model (e.g., [1]). Similar to other tsunami models, our forward model relies on transient boundary data describing the location and magnitude of the seafloor deformation. In a real-time scenario, these parameter fields must be inferred from a variety of measurements, including observations from pressure gauges mounted on the seafloor. One particular difficulty of this inference problem lies in the accurate inversion from sparse pressure data recorded in the near-field where strong hydroacoustic waves propagate in the compressible ocean; these acoustic waves complicate the task of estimating the hydrostatic pressure changes related to the forming surface gravity wave. Furthermore, the forward model incurs a high computational complexity, since the pressure waves must be resolved in the 3D compressible ocean over a sufficiently long time span. Due to the infeasibility of rapidly solving the corresponding inverse problem for the fully discretized space-time operator, we explore options for using surrogate operators of the parameter-to-observable map.

Key Words:

Outer-loop problems arising in engineering applications (such as optimization, uncertainty quantification and inverse problems) require repeated evaluation of computationally intensive numerical models, such as those arising from discretization and solution of ordinary and partial differential equations, for many different choices of model parameters. The cost of these evaluations makes solution using the model prohibitive, and efficient accurate surrogates are a key to solving these high dimensional problems in practice. In this talk we will discuss various projected neural network strategies that bypass the high fidelity parametric mapping by learning informed modes of the mapping. These neural networks can be used in place of a high fidelity model to enable the solution of high dimensional outer-loop problems. These strategies include reduced basis projections, adaptive construction of residual neural networks and compression of derivative information that can be used both to construct and train neural networks. These reduced-basis architectural strategies outperform conventional data-driven approaches when limited training data are available due to computational costs of evaluating high dimensional nonlinear PDEs.

In recent years, Hamiltonian Monte Carlo (HMC) method has emerged as a state-of-the-art Markov chain Monte Carlo (MCMC) technique that exploits the geometry of the target distribution to generate samples in high dimensional space in an efficient manner. Despite its impressive empirical success and increasing popularity, its wide-scale adoption (in PDE-based models) is still limited due to the high computational cost associated with the gradient calculation at every step. Furthermore, application of this method is simply not possible in scenarios where the gradient of the posterior cannot be computed (for example, with black-box simulators and/or with non-differentiable priors). To overcome these challenges, we propose a novel multi-fidelity Hamiltonian Monte Carlo algorithm. In this two-stage algorithm the acceptance probability is computed in the first stage via standard HMC proposal using an inexpensive surrogate model (with easy-to-compute-gradients), and, if the proposal is accepted, the full posterior is evaluated using the high fidelity (HF) numerical solver in the second stage. Splitting the standard HMC algorithm into these two stages allows for the efficient and computationally inexpensive evaluation of the gradient of the posterior (by leveraging automatic differentiation capabilities of DL-based forward model surrogate for example), thus retaining advantages of HMC, such as scalability to high dimensions and faster convergence while producing accurate posterior samples by using HF numerical solvers in the second stage in forward mode. We demonstrate the effectiveness of the proposed algorithm on a variety of linear and non-linear Bayesian inverse problems using traditional and modern deep generative priors [1] and showcase that in all scenarios it significantly outperforms the traditional HMC algorithm in computational efficiency while retaining similar accuracy.

Operator Learning for Forward and Inverse Problems

Nicholas H. Nelsen[1*]

[1] California Institute of Technology, 1200 E California Blvd MC 305-16, Pasadena, CA 91125 USA,
nnelsen@caltech.edu (www.nicholashnelsen.com)

Key Words: Operator Learning, UQ, Convergence Rate, Bayesian Inference, Parametric PDE, Surrogate

Operator learning has emerged as a key enabler for accelerating the computation of existing scientific models [1] and for discovering new models from data when no model exists [3]. In this talk, I will describe recent scientific machine learning methodologies that are designed to scalably and efficiently emulate (potentially noisy and nonlinear) operators that define forward and inverse problems arising in science and engineering. Crucially, these methods are conceptualized on infinite-dimensional input and output function spaces and thus can handle parameters of arbitrarily high dimension after discretization.

The first contribution is a hierarchical operator regression approach [2] that generalizes traditional random feature methods operating between Euclidean spaces. Viewed as a randomized kernel method with a data-adapted feature map, it enjoys several computational advantages over its nonparametric counterparts, and through its Gaussian process connection, is naturally interpretable and provides automatic uncertainty quantification. The algorithm is used to regress parametric solution maps defined by nonlinear partial differential equations (PDEs) and rapidly solve PDE-based Bayesian inverse problems.

Moving on to theoretical advances, in the setting of learning linear operators I will provide large data convergence rates of nonparametric statistical estimators that give sharp in-distribution and out-of-distribution generalization guarantees in infinite dimensions [4]. The theory is valid not only for bounded or compact operators, but also for unbounded ones; a key conclusion of relevance to data-driven model discovery is that unbounded linear operators such as those appearing in linear PDEs require more training data to achieve a fixed error tolerance than do compact operators. Finally, I will remark on methods that directly learn the observation-to-parameter solution operator of linear and nonlinear ill-posed inverse problems.

Abstract The multi-scale design optimization of fiber-reinforced composite laminates has shown great potential in structural lightweight and functionalization and has become a research hotspot in recent years, especially with the development of composite additive manufacturing technology. Compared with traditional isotropic material structural topology optimization, concurrent multi-scale variable stiffness design optimization of composite laminates poses a greater challenge for large-scale design variables, constraint calculations, and real-time topology optimization. Based on these, the present paper investigates the concurrent multi-scale variable stiffness design optimization of fiber-reinforced composite laminates based on deep learning. Based on the convolutional neural network (CNN) method, a new deep learning approximate model for real-time concurrent multi-scale variable stiffness design optimization of fiber-reinforced composite laminates is proposed. In the proposed model, the initial element artificial density, discrete fiber laying angels, optimized macroscopic topology configuration, and optimized microscopic fiber laying angels are inputted as samples under random loading conditions for the deep learning CNN training. The optimization of 2D composite panels demonstrates the capabilities of the proposed framework. Numerical studies show that the proposed deep learning-driven model can realize real-time concurrent multi-scale variable stiffness design optimization of fiber-reinforced composite laminates, which provides a real-time choice for the design of composite structures in engineering applications.

Key Words: *Deep Reinforcement learning, Turbine Optimization,*

Turbine design requires intensive human labour costs because expert designers have to modify shape parameters manually. It is desired to optimize turbine design parameters, but the flow around the turbine is complicated and difficult to optimize using conventional optimization methods. In addition, designers have to optimize intensive number of airfoils whose flow conditions are slightly different from each other. If conventional optimization methods are employed, we have to solve different optimization problem for each design condition, which is inefficient and is not acceptable from practical point of view. In the present study, the reinforcement learning based optimization method is proposed that can handle such flow characteristics. The proposed method needs to be trained using intensive training dataset, but once it is trained, the trained model is reusable for different flow conditions; the proposed method can optimize turbine airfoils in a small time period.

Reinforcement learning is one of a unsupervised learning methods, which was successfully applied to optimal control and arcade games. Recently, reinforcement learning was also applied to mechanical and structural design optimization [1,2]. In the present study, RL model is trained to inputs information including flow field information and outputs optimal way to modify airfoil shape. The capability of dealing with unseen tasks, i.e. capability to optimize airfoil in different flow condition, is examined using numerical experiments.

Key Words: *MMC, Topology Optimization, Real-Time Optimization, Convolutional Neural Network, Deep Learning*

Based on the moving morphable component (MMC) method, a real-time Topology Optimization (TO) algorithm using a convolutional neural network (CNN) is presented. Comparing to the Solid Isotropic Material with Penalization (SIMP) TO method, MMC method describes the optimization structure together with level set function, which causes difficulty and complexity in using deep learning model with MMC method. In this study, a new data preprocessing method is proposed to ensure that the CNN model can be trained based on the accuracy structure boundary information. Meanwhile, such method can also help the CNN model capture data features with limited sample set. To avoid the component dislocation, the topology optimization boundary information of the optimized results is used as the sample set label. The new algorithm was implemented with several examples, the efficiency and effectiveness have been verified. The trained deep learning model can significantly improve the optimization efficiency of MMC method and offer accurate results with clear boundary. This study provides a new theoretical basis and numerical algorithm for real-time topology optimization of structures.

Key Words: *Real-time Topology Optimization, Convolutional Neural Network, Neural Network, Heat Dissipation Structure, MMC Topology Optimization Framework*

In the present study, a real-time topology optimization framework of heat dissipation structure is established by combining Convolutional Neural Network (CNN) model with the Moving Morphable Components (MMC) framework. The optimized topology is obtained in real-time while ensuring more efficient heat dissipation performance of the structure. This is because the clear geometric profile of the optimized topology structure can be directly obtained without any results post-processing work based on the MMC framework. The present study innovatively proposes a data pre-processing method for the MMC framework, so that it can be trained based on a small sample set to obtain sufficiently high-precision prediction results. At the same time, the optimized topology configuration is used as the training label of the model, which avoids the secondary processing of graph generation and reduces the data error. Numerical examples show the topological configuration of the structure under different heat sources and boundary conditions, which shows the effectiveness and superiority of the framework.

Key Words: *Topology optimization, Stiffened Structures, Deep learning*

Grid stiffened structures generally achieve various excellent properties through geometry and topology design of the stiffeners. However, it is difficult to obtain the optimal result only by empirical design, and it is impractical to explore the design space through repeated experiments. Topology optimization is one of promising methods applied to the design optimization of structures with multiscale characteristics. In the design optimization of grid stiffened structures, the optimum layout and types of the stiffeners should be solved. However, due to the high-dimensional topological design space, multiple local optima, and high computational cost, there still exist some challenges in realizing accurate inverse design. To address these obstacles, we will propose the design framework based on the gradient based optimization algorithm with the help of the deep learning, where a microstructure database will be established and discussed. The optimization formulation of reinforced ribs of thin-walled stiffened structures for minimizing the vibration response and maximizing buckling load is established. The optimum layout of stiffeners is realized in several numerical examples of stiffened plates to verify the effectiveness of the proposed method.

A data-driven, physics-compatible approach to model history-dependent materials

Pierre Ladeveze, David Neron and Paul-William Gerbaud

Université Paris-Saclay, CentraleSupélec, ENS Paris-Saclay, CNRS, LMPS,
91190, Gif-sur-Yvette, France, {ladeveze,neron,gerbaud}@ens-paris-saclay.fr

Key Words: Data-driven, Computational mechanics, History-dependent materials, Internal variables, Interpolation

In this work, a general view of data-driven computational solid mechanics, suitable for history-dependent materials, is developed within the Thermodynamics of Irreversible Processes framework. It is based on the Experimental Constitutive Manifold (ECM) concept. The mathematical structure of the ECM, which involves internal state variables, constitutes the material model associated with the available experimental data. The hidden variables are not known a priori but are calculated from the experimental data thanks to the so-called "ECM-Central Problem". A second and equally important step is defining the mathematical model as an interpolation of the experimental data obtained from the various tests carried out. That leads to a model very similar (mathematically speaking) to the standard models encountered in Materials Science. We use a kernel-based interpolation associated with a Reproducing Kernel Hilbert Space, which is very efficient here because the functions involved are very regular.

This paper presents recent advances in this data-driven computational approach, particularly the interpolation procedure used. Illustrations are given on the modeling of elasto-plasticity, for which we propose data-driven models for isotropic materials in which no a priori assumptions on the modeling are necessary.

A Mechanics-Informed Artificial Neural Network Approach in Data-Driven Constitutive Modeling of Elastic and Viscoelastic Materials

Faisal As'ad[1*], Philip Avery and Charbel Farhat[3]

[1] Stanford University, 94305, faisal3@stanford.edu
[2] Stanford University, 94305, pavery@stanford.edu
[3] Stanford University, 94305, cfarhat@stanford.edu

Key Words: *artificial neural networks, constitutive modeling, elasticity, regression, viscoelasticity*

A mechanics-informed, data-driven framework for learning the constitutive law of a complex material from stress-strain data is proposed. It features a robust and accurate method for training a regression-based, surrogate model capable of capturing highly nonlinear material behavior while preserving principles that are important to solid mechanics. In this sense, the proposed modelling framework is structure-preserving. The model it generates combines the form-agnostic advantage of purely phenomenological data-driven regressions and the physical soundness of mechanistic models. The underlying training procedure is equally compatible with both numerical and experimental stress-strain data.

While regression Artificial Neural Networks (ANNs) have excellent nonlinear function fitting capabilities, an ANN-based constitutive law that fits well to training data is not necessarily physically sound or exploitable in the context of a numerical simulation, due to imperfect training convergence, noise in the data, overfitting, and most importantly, the absence of mechanics (or physics)-based constraints. Therefore, the proposed framework supplements a typical ANN loss function with mechanics-informed contributions and enforces desirable mathematical properties on the network architecture, to guarantee the satisfaction of important physical properties regardless of training accuracy or training data quality. Furthermore, by embedding *a priori* a knowledge of mechanics into the model it constructs, the proposed framework favors the learning of the structure of a constitutive relation rather than overfitting to the training data. As such, it also regularizes the model it generates, reduces its sensitivity to training data noise, and promotes its robustness to inputs outside of the training domain.

First, the proposed framework is presented in the nonlinear elastic setting, as in [1], where the stress depends only on the instantaneous strain state. Various physics-based model constraints important for elasticity are discussed and formulated in the context of an ANN, including dynamic stability, material stability, objectivity, and preservation of rigid body modes. Next, the framework is extended to the viscoelastic setting, where the stress depends on both the strain and strain-rate, using two-different approaches that are informed by thermodynamic constraints such as the Clausius-Duhem inequality.

Finally, the performance of the proposed framework for data-driven modelling is illustrated with the nonlinear, dynamic, multiscale simulation of the supersonic inflation of an atmospheric aerodynamic decelerator system including a parachute canopy made of a woven fabric. It is shown to enable the computational tractability of the chosen homogenization approach and to reproduce flight test data.

A PDE-Based Transformation Method for Model Order Reduction of Nonlinear Geometrically Parameterized Microstructures

Theron Guo*, Ondřej Rokoš and Karen Veroy

Eindhoven University of Technology, 5612 AZ Eindhoven, The Netherlands, t.guo@tue.nl

Key Words: *Reduced Order Modelling, Geometrical Transformation, Computational Homogenization, POD, Gaussian Process Regression, Shape Optimization*

With the recent advances in additive manufacturing and in the field of metamaterials, designing microstructures has become a topic of high interest. To better understand structure-property relations for such microstructures, computational homogenization is typically used. The microstructure is explicitly modelled on a representative volume element, and thus replaces the macroscopic constitutive model with an effective one. Such procedure becomes computationally expensive and typically infeasible in the context of uncertainty quantification, material design and optimization, where numerous simulations must be run.

To make these analyses amenable, the parameterized microscopic problem is often approximated with an inexpensive-to-evaluate surrogate model, using for example data-driven methods from Machine Learning and Deep Learning. For optimization or inverse problems, the surrogate model must be able to handle different types of parameters (e.g., loading, material and geometry). In a recent work [1], we successfully constructed an accurate surrogate model for microstructures under varying loading and material parameters by approximating the microscopic stress field with proper orthogonal decomposition (POD) and finding the coefficients with Gaussian process regression (GPR).

In this work, we extend our previous methodology to also treat geometrical parameters. The main hurdle for geometrically parameterized problems lies in finding geometrical transformations that map each snapshot onto a common reference domain. After finding such a transformation, the same procedure as before (POD and GPR) can be adopted. Most existing works describe these transformations using free form deformations or radial basis functions (see, e.g., [2]). Instead, we obtain the transformation map by solving an auxiliary linear partial differential equation (see, e.g., [3]) and show how this, combined with the nonlinear microscopic problem, can be used to learn an accurate and fast-to-evaluate effective constitutive model. Moreover, we show that the predicted stress fields automatically fulfil the microscopic physics (balance laws and periodicity) for any parameter values.

The proposed method is tested on several composite microstructures, involving rotations and large variations in shape of considered inclusions. The examples involve two scales, showcasing a high accuracy and speedup, and its potential in two-scale shape optimization and material design.

A Physics-informed Complementary Energy Form in Solid Mechanics

Yizheng Wang[1*], **Yinghua Liu**[1]

[1] Tsinghua University, Beijing

Key Words: Physics-informed neural network, Deep energy method, Deep neural network

Many physical phenomena are modeled by partial differential equations (PDEs). In general, it is difficult to obtain the analytical solutions of PDEs. Hence, various numerical methods are developed to obtain the approximate solutions in a finite-dimensional space. Traditional ways to tackle the solution of PDEs are the finite element method, the finite difference method, the finite volume method, and mesh-free method. In the present day, deep learning is ubiquitous, empowering various fields. The success of deep learning is partially attributed to the powerful approximation capabilities of the neural network. It is natural to use the neural network as the approximation function of PDEs, i.e., physics-informed neural network (PINN). Another framework of PINN is the deep energy form (DEM), using the physical potential energy as the optimized loss function. Although DEM has the minimum potential energy formulation, the DEM lacks the principle of minimum complementary energy formulation. In this study, we propose the complementary energy form of DEM. We compare the PINN strong form and different energy forms including minimum potential and minimum complementary form. The accuracy and efficiency are carefully examined by applying different PINN methods to three loading cases of solid mechanics benchmark: only Dirichlet boundary condition, only Neumann boundary condition, and mixed boundary condition. Through the comparison with the analytical solution, it is found that: (1) DEM of minimum complementary energy form is suitable for handling the case of only Dirichlet boundary condition, (2) DEM of minimum potential energy form is suitable for handling the case of only Neumann boundary condition. Compared with PINN strong form, DEM shows certain advantages in terms of the simplicity of hyperparameter tuning and the computational efficiency due to the high tensor field in solid mechanics.

Adaptive Goal-oriented Phase Space Sampling in Data-Driven Computational Mechanics

Key Words: *Data-Driven Computing, Inelastic Material Behavior, Efficiency of Data-Driven Solvers*

The Data-Driven (DD) computing paradigm in mechanics problems [1] aims to obviate the need for empirical constitutive modeling, by directly using data from physical experiments and lower-scale computations to capture material behavior, while retaining all essential constraints and conservation laws. The goal of the data-driven solver is to determine, for every material point of a discretized system, the optimal local state, i.e. the material state (stress, strain) which results in the closest possible satisfaction of compatibility and equilibrium, by searching within the data set. The question of how to efficiently generate a data set suited for a particular application (i.e. goal-oriented) is still an open problem, particularly in the case of history-dependent material behavior.

The objective of this study is to develop an unsupervised goal-oriented data sampling algorithm furnishing an efficient DD scheme that converges in global distance. The idea is to iteratively expand an initial data set until this distance is acceptably small. We first analyze the spatial distribution of stress-strain paths in the material points and their corresponding distances from the data set. This analysis is used to propose new paths to be sampled using lower scale RVE calculations, and added to the preexisting data set. This process is repeated until the local state of each material point is well covered by the expanded data set.

To demonstrate the method, we carry out DD finite element simulations of a specimen of Hostun sand, a material with complex history-dependent behavior, subjected to triaxial compression [2, 3]. The sampling of the phase space of the local strain-stress pairs is performed with LS-DEM calculations of representative unit cells, subjected to loading paths determined by the proposed sampling algorithm, while material history is accounted for through a thermodynamically-motivated parameterization of the data sets [2]. It is shown that this adaptive expansion of the data set, tailored for the particular application, leads to superior convergence properties compared to preexisting sampling techniques, which can facilitate further applications of the DD computing paradigm.

Bayesian Neural Networks for Weak Solution of PDEs with Uncertainty Quantification

Xiaoxuan Zhang[1*] **and Krishna Garikipati**[1]

[1] University of Michigan, United States,
Email: xxzh@umich.edu, krishna@umich.edu

Key Words: Weak Form, Bayesian Neural Network, Uncertainty Quantification, Nonlinear Elasticity, PDE Solver, Partial Differential Equations

We will present our recent advance in Bayesian neural networks for weak solution of partial differential equations (PDEs) with uncertainty quantification [1]. Solving PDEs is the canonical approach for understanding the behavior of physical systems. However, large scale solutions of PDEs using state of the art discretization techniques remains an expensive proposition. In this work, a new physics-constrained neural network (NN) approach is proposed to solve PDEs without labels, with a view to enabling high-throughput solutions in support of design and decision-making. Distinct from existing physics-informed NN approaches, where the strong form or weak form of PDEs are used to construct the loss function, we write the loss function of NNs based on the discretized residual of PDEs through an efficient, convolutional operator-based, and vectorized implementation. We explore an encoder-decoder NN structure for both deterministic and probabilistic models, with Bayesian NNs (BNNs) for the latter, which allow us to quantify both epistemic uncertainty from model parameters and aleatoric uncertainty from noise in the data. For BNNs, the discretized residual is used to construct the likelihood function. In our approach, both deterministic and probabilistic convolutional layers are used to learn the applied boundary conditions (BCs) and to detect the problem domain. As both Dirichlet and Neumann BCs are specified as inputs to NNs, a single NN can solve for similar physics, but with different BCs and on a number of problem domains. The trained surrogate PDE solvers can also make interpolating and extrapolating (to a certain extent) predictions for BCs that they were not exposed to during training. Such surrogate models are of particular importance for problems, where similar types of PDEs need to be repeatedly solved for many times with slight variations. We demonstrate the capability and performance of the proposed framework by applying it to different steady-state and equilibrium boundary value problems with physics that spans diffusion, linear elasticity, and nonlinear elasticity.

The formulation and calibration of constitutive models is still a challenging task for materials which reveal complex nonlinear behavior. Due to this, numerous novel approaches – generally referred to as data-based methods – have recently arisen in the computational mechanics community [1]. In this contribution, an automated artificial neural network (ANN)-based strategy for the efficient description of isotropic and anisotropic hyperelastic solids is presented. Starting from a large data set comprising deformation and corresponding stresses, a physically based transformation of the problem into the space of invariants is performed. It enables to reduce the cardinality of the data set by several orders of magnitude. The thinned data set is then used to calibrate physically informed ANNs as a constitutive model within a customized training process. Thereby, the set of invariants serves as the input instead of the deformation tensor itself which automatically introduces material symmetry [2]. Furthermore, in order to fulfill the 2nd law of thermodynamics, the ANN is utilized on the energy level.

The proposed method is exemplarily shown for the description of highly nonlinear elastic materials in several demonstrative examples [2]. Thereby, the necessary data sets are generated synthetically, i. e., they are collected from virtual experiments of samples comprising a constitutive behavior defined by classical nonlinear models. It is shown that the trained ANN is able to achieve a high accuracy within fully three-dimensional simulations, although the training data are taken from pure two-dimensional plane stress states. Furthermore, the method is applied within a data-based multiscale approach, where the ANN serves as a surrogate or macroscopic model describing the effective behavior of periodic unit cells. To train the network, a data set is generated via offline computational homogenizations. The specific microstructural geometry of the considered unit cells is included within the macroscopic ANN-model via a related set of invariants. Consequently, the presented approach enables the solution of multiscale problems with comparatively low computational cost.

Data-driven Constitutive Laws for Hyperelasticity in Principal Space: Numerical Challenges and Remedies

Vu M. Chau[1*], Michal Habera[1], Hamidreza Dehghani[1], and Andreas Zilian [1]

[1] University of Luxembourg, 2 avenue de l'Université, 4365 Esch-sur-Alzette, Luxembourg.
E-mail: vu.chau@uni.lu

Key Words: Data-Driven Constitutive Relations, Artificial neural network, Hyperelasticity

Artificial neural networks (ANNs) have been employed to represent the constitutive relation of hyperelastic materials under large deformations. Various advancements have been made in order to obtain improved model performance, e.g. by incorporating certain physical constrains [1, 2]. However, most of these approaches still suffer from numerical instability during the numerical solution procedure. This contribution discusses a formalism for data-driven modelling of advanced materials with special interest in the large deformation response of three-dimensional specimens. The underlying hyperelastic deformation problem is formulated in the principal space using principal stretches and principal stresses. The associated constitutive relation is consequently using principal quantities and captured by the parameter-free representation using a deep neural network.

The presentation investigates certain physics-motivated requirements imposed on the architecture of the ANN such as the symmetry of its Jocobian matrix, growth conditions, and objectivity criteria [3]. The training phase of the constitutive ANN operator employs a loss function which ensures the identified consistency conditions. The prediction phase exploits a constitutive blending approach to stabilise the numerical solution procedure in the presence of typically local stretch/stress extrema. The non-convergence effect is overcome by using a modified Newton-Raphson procedure when solving global structural problems using Finite Element Method. The presented approach is implemented using FEniCS [4] and builds on symbolic representation of the ANN operator based on the Unified Form Language (UFL). The neural network is constructed, trained and tested using PyTorch.

Numerical benchmarks demonstrate the ability of the presented complete and general formalism to describe non-trivial load-deformation trajectories of 3D test specimens as well as real-world experiments.

Key Words: Elastic-plastic material, finite element method, mechanical testing; response surface, instrumented indentation test, material database

Nowadays, structure materials with high strength, ductility and good strength-to-weight ratio are required for industries. Instrumented indentation test provides an efficient, high through-put and non-destructive way to characterize the mechanical properties of alloys, although it is hard to get the stress-strain relationship corresponding to tensile test directly due to the complex stress state beneath the indenter. Various estimation approaches for the plastic properties have been purposed based on the results of instrumented indentation test [1–3]. In our previous study [4], the interaction effect between two neighboring indentation was utilized to determine the two material constants of a simple constitutive model of plasticity. The purposed approach was validated for application to aluminum alloys and stainless steel, the estimated stress-strain curve agree with the experimental results in aluminum alloys but the linear hardening behavior in stainless steel cannot be followed due to the power-law hardening constitutive model. In this study, a computer-aided approach to estimate the plastic properties of alloys using neighboring indentation test was purposed with a modified constitutive model to represent the various hardening behavior of alloys. The material database to determine a set of material constants for the modified plastic constitutive model was prepared by the finite element simulation of neighboring indentation. The material constants were estimated by load – depth curves and topography of indentation impression from neighboring indentation tests. This approach was validated for application to aluminum alloys and a stainless steel.

Data-Driven viscoelasticity in the frequency domain

Hossein Salahshoor and Michael Ortiz

Division of Engineering and Applied Science, California Institute of Technology, 1200 E. California Blvd., Pasadena, CA 91125, USA

Key Words: Viscoelasticity, dynamic mechanical analysis (DMA), Data-Driven mechanics, Fourier transform, Wasserstein metric

The classical computational paradigm has been to calibrate empirical material models using observational data and then use the calibrated material models in calculations. This process of modeling, if at all possible, necessarily corrupts the data and adds many uncertainties, especially in complex systems such as biological tissue. Data-Driven computational mechanics is a new paradigm, according to which calculations are carried out directly from empirical material data and pertinent physical constraints such as compatibility and equilibrium, thus bypassing the empirical material modeling step of conventional computing altogether [1, 2]. We develop a new Data-Driven framework capable of predicting wave propagation in viscoelastic solids directly from in-situ Dynamic Mechanical Analysis (DMA) data, without the need for regression or modeling of the data. Specifically, we formulate the problem in the frequency domain and seek to minimize a distance between physically admissible histories of stress and strain, in the sense of compatibility and equilibrium, and DMA data. Following [3], we find that the natural distance that metrizes the space of histories in the frequency domain is the Wasserstein distance from optimal transport theory [4]. The great advantage of the Wasserstein distance is that it naturally interpolates between frequencies and allows the response of the system at one frequency to be inferred from data at nearby frequencies. We demonstrate and verify the approach by means of selected test cases, with particular focus on convergence with respect to the data. As an illustrative application, we apply the approach to the simulation of neuromodulation of the human brain directly from patient-specific in situ Magnetic Resonance Elastography (MRE) data.

Abstract

The model-free distance-minimizing data-driven computational method has recently become a novel paradigm for solving various mechanics problems. With this paradigm, boundary-value problems can be solved with a discrete constitutive dataset. However, the paradigm may suffer from low efficiency since tremendous iterative searches of key data points in the discrete dataset are needed during the solution process and the mechanical behaviors of history dependent materials cannot be represented purely by a fixed dataset. To accurately and efficiently solve the elasto-plastic deformation problems with the paradigm in our work, on the one hand, the multi-level K-d tree and data supplement method are developed for effective data addition and fast data search, on the other hand, the fixed dataset considering path dependent behaviors of materials is constructed. With this kind of fixed dataset, a stress correspondence method is developed to compute the plastic strain of every integration point at each load step, and a data-driven classification model for yielding is constructed to rapidly determine the yield status of each integration point in the method. Moreover, a symmetric mapping method is developed to accurately determine the stress-strain state for the integration points under unloading or inverse loading with the fixed dataset. Results of some representative numerical examples of plastic deformation problems demonstrate that the method possesses high accuracy and efficiency. This work was supported by the NSFC (Nos. 12072062 and 12072061), the LiaoNing Revitalization Talents Program (XLYC1807193), Key Research and Development Project of Liaoning Province (2020JH2/10500003) and Fundamental Research Funds for the Central Universities (DUT20LAB203).

Key Words: *Unsupervised, Sparse Regression, Constitutive Models, Elasto-Plasticity*

We recently proposed a new approach for data-driven automated discovery of constitutive laws in continuum mechanics called EUCLID (Efficient Unsupervised Constitutive Law Identification and Discovery) [1]. The approach is unsupervised, i.e., it requires no stress data but only displacement and global force data, which are realistically available through mechanical testing and digital image correlation techniques; it delivers interpretable models, i.e., models that are embodied by parsimonious mathematical expressions discovered through sparse regression of a large catalogue of candidate functions; it is one-shot, i.e., discovery only needs one experiment - but can use more if available. The method was successfully demonstrated for discovering hyperelastic strain energy density functions [1,2] as well as perfectly plastic yield functions. As plastic yield functions in general depend on the loading history, i.e., the material behaviour cannot be assumed as perfectly plastic, the goal of the current work is to consider the effects of hardening in the discovery procedure. To this end a large catalogue of candidate yield functions and hardening laws is formulated. Then a sparsity promoting optimization problem, which enforces local equilibrium constraints in the bulk and global equilibrium constraints at the loaded boundary of a deformed specimen, is solved to select the yield surface and hardening law that both fit the given data and are described by concise interpretable mathematical expressions.

Key Words: Constitutive models; Experimental validation; Hyperelasticity; Interpretable models; Inverse problems; Sparse regression; Unsupervised learning;

We validate experimentally the data-driven approach for the automated discovery of isotropic hyperelastic material laws proposed in [1] and termed *EUCLID* (Efficient Unsupervised Constitutive Law Identification and Discovery). The approach only requires displacement and global force data and delivers interpretable models, i.e., models that are embodied by parsimonious mathematical expressions discovered through sparse regression from a large catalogue of candidate functions. The problem of unsupervised discovery is solved by enforcing equilibrium constraints in the bulk and at the loaded boundary of the domain. Sparsity of the solution is achieved by ℓ_p regularization combined with thresholding, which calls for a non-linear optimization scheme whose hyperparameters are partially determined by imposing physics-based constraints.

In the original paper, the approach was demonstrated on artificial results obtained by finite element computations. Here, we aim at its validation using experimental data. To this end, mechanical tests are performed on different rubber specimens with increasing geometrical complexity, so as to locally promote a multiaxial stress state. The displacement field is measured with digital image correlation (DIC), while the applied global force is monitored using a load cell. The effect of the geometrical complexity and of the DIC spatial and temporal resolution is investigated. Then, the obtained laws are used to predict an additional experimental test not involved in the discovery phase.

Key Words: *Elastoplastic Constitutive Law, Cyclic Loading, Bayesian optimization*

Accurately modeling cyclic elastoplastic behavior of structural steels is essential to establish reliable structural analysis results, especially for structural systems under earthquake excitations that commonly behave in a ductile manner. However, the identification of the underlying material parameters to simulate such behavior is very difficult because cyclic material tests are not usually available. Therefore, structural responses may be used for identification. Moreover, performing many nonlinear response history analyses or static cyclic elastoplastic analyses demands substantial computational cost. The dataset-specific bias has also not been fully addressed by the current identification methods.

To address this issue, this work proposes using Bayesian optimization (BO) [1] for solving an inverse problem by which certain parameters of the nonlinear combined isotropic/kinematic hardening model for structural steels are inferred from responses of a specimen or structure tested under cyclic loading. In this way, BO minimizes an error function that represents the difference between simulated responses and those measured experimentally, while providing a global-optimization framework for the identification and considerably reducing the number of simulation calls.

BO first creates a training dataset of different samples of material parameters and the corresponding error function values using a detailed finite element model of the experiment and the experimental measures. A Gaussian process model is constructed based upon this training dataset to produce a predictive model of the error function for a set of parameters. This model is then used for developing an acquisition function that intelligently guides BO during the search process by balancing exploration and exploitation of the parameter space.

Identification results from cyclic tests of a steel specimen show that the parameters identified by BO well reproduce the hysteresis behavior of the steel subjected to different cyclic loading conditions. Experimental results from different loading histories are also recommended to be utilized for the identification to mitigate the bias toward a specific load pattern that may lead the identified parameters to inaccurate predictions of the material behavior subjected to other load cases.

Abstract

Traditional simulations of complex mechanical deformation are technologically crucial and computationally expensive. Developing comparably accurate models directly from data with lower computational cost can enable more robust design, uncertainty quantification, and exhaustive structure-property exploration. We have been developing neural network models that are guided by traditional constitutive theory, such as tensor function representation theorems to embed symmetries, and also exploit deep learning to infer intrinsic microstructural features. Neural networks are flexible since sub-components of their graph-like structure can be arranged to suit particular tasks, such as image processing and time integration. This talk will describe the architecture and demonstrate the efficacy of neural networks designed to model the response of elastoplastic and viscoelastic materials with pores, inclusions or grains based solely on observable data.

Abstract: The traditional computational prediction of nonlinear history-dependent mechanical responses subjected to random excitation sequences suffers laborious manual modelling and unsatisfactory accuracy with low computational efficiency. In this paper, we propose a general deep learning model named *Mechformer* (**Mech**anical Trans**former**), which is able to efficiently reproduce the history-dependent mechanical responses with high fidelity under any loading protocols. First, we analyze and abstract the distinctive traits of the history-dependent mechanical response simulation: ultra-long sequence, significant memory effect, and causal autoregression. Upon these inductions, we introduce the Transformer architecture predicated on an advanced fast attention mechanism and further incorporate reversible network technique as well as GRU (gated recurrent unit), which manage to extract global historical information at any distance with linear algorithmic complexity. Moreover, to address arbitrary mechanical inputs, a new data normalization method named *NRVS* (**N**onlinear **R**eference-**V**alue **S**caling) is presented. Then we perform a numerical experiment based on a sophisticated constitutive model of low-yield-point steel featuring strong nonlinearity and strain range dependence effect. The results demonstrate the effectiveness, high efficiency, and excellent generalization capability of our developed model in reproducing the complicated mechanical responses, thus promising a new expressive alternative for the elaborated constitutive modelling. Finally, we discuss the mechanical interpretation of our model to facilitate a more intuitive comprehension.

Key Words: Neural Network, Constitutive Modelling, Plastic Deformation, Damage Mechanics

Constitutive models have been utilized to study the mechanical behaviors of solid material. The formulation of constitutive relations is difficult and could be associated with limiting hypothesis. In recent years, machine learning techniques have shown promising capabilities for capturing material behavior [1][2]. This work proposes novel neural network-based approaches to reproduce the complex nonlinear constitutive relations of solid materials including elastic behavior, plastic deformation and damage mechanism. A history-based strategy has been suggested using an artificial neural network for training path-dependent inelastic behavior. The network development is based on a general internal variable formalism. The number of selected internal variables is linked to the problem and degree of accuracy.

It is shown that the proposed methodology can represent exactly the von Mises elastoplastic material model in uni-axial stress state. The strategy was applied to sequences of training and validation data which were generated numerically for elastoplasticity with and without hardening as well as for elastoplastic damage. The results have been compared against established mathematical models and shown a potential of describing complex non-linear solid material behavior accurately in one-dimensional and multi-dimensional space.

Physics-informed neural-operator for multi-scale mechanics and materials

Burigede Liu

Department of Engineering, University of Cambridge, Trumpington Street, Cambridge, CB2 1PZ, UK

Abstract

The macroscopic behavior of materials that we observe and exploit in engineering applications results from complex interactions between physics at multiple lengths and time scales: electronic, atomistic, domains, defects, etc. Multiscale modeling seeks to understand these interactions by exploiting the inherent hierarchy where the behavior at a coarser scale regulates and averages the behavior at a finer scale. Such an approach can be challenging for two reasons. First, it is computationally expensive due to the need to repeatedly solve the finer scale model. Second, it requires a priori (empirical) knowledge of the aspects of the finer-scale behavior that affect the coarser scale (order parameters, state variables, descriptors, etc.). We address these challenges in a two-scale setting where we regard the solution of the fine-scale model as an operator (mapping between Banach spaces) and introduce a general framework for the data-driven approximation of such operators with the capacity of incorporating universal physics principles. This approach results in a physics-informed neural operator approximation that is computationally inexpensive, resolution (mesh) independent, and can be used directly in the coarser scale computations. Furthermore, we show that the physics-informed neural operator is capable of dramatically decreasing the amount of data required for learning the true material behavior compared to a pure data-driven setting.

Key Words: constitutive modeling, nonlinear elasticity, anisotropic hyperelasticity, physics-informed machine learning, input convex neural networks

In the present work [1], two machine learning based constitutive models for finite deformations are proposed. Using input convex neural networks, the models are hyperelastic, anisotropic and fulfill the polyconvexity condition, which implies ellipticity and thus ensures material stability. The first constitutive model is based on a set of polyconvex, anisotropic and objective invariants. The second approach is formulated in terms of the deformation gradient, its cofactor and determinant, uses group symmetrization to fulfill the material symmetry condition, and data augmentation to fulfill objectivity approximately. The extension of the dataset for the data augmentation approach is based on mechanical considerations and does not require additional experimental or simulation data.

The models are calibrated with highly challenging simulation data of cubic lattice metamaterials, including finite deformations and lattice instabilities. A moderate amount of calibration data is used, based on deformations which are commonly applied in experimental investigations. While the invariant-based model shows drawbacks for several deformation modes, the model based on the deformation gradient alone is able to reproduce and predict the effective material behavior very well and exhibits excellent generalization capabilities. In addition, the models are calibrated with transversely isotropic data, generated with an analytical polyconvex potential. For this case, both models show excellent results, demonstrating the straightforward applicability of the polyconvex neural network constitutive models to other symmetry groups.

Finally, we also extend the physics-guided neural network constitutive models towards inelastic and multiphysical material behavior.

Key Words: Machine learning, Nonlinear elasticity, Constitutive modeling, Skin mechanics

Data driven methods are becoming increasingly prevalent in many scientific applications including constitutive modeling of materials. It has been shown that neural network based material models can learn complex material response without the limitations of expert-constructed analytical models. All material models must satisfy a set of physics-based constraints such as polyconvexity of strain energy [1]. However, satisfying this condition in a data-driven approach is difficult. The most common approach to tackle this problem so far has been to simplify the problem by replacing the polyconvexity of strain energy with a more tractable condition such as convexity of strain energy with respect to the Green deformation tensor. Then neural networks are trained with loss functions that penalize nonconvex outputs.

While this approach may succeed under certain conditions, it is an approximate method and has a limited scope. There is no guarantee that the strain energy will be convex anywhere, especially outside the training region. The loss functions that are used to train neural networks in this approach also result in highly nonlinear loss spaces which in turn makes the training very difficult.

In this study we develop a data-driven material model that satisfies polyconvexity of strain energy a priori [2]. For this we employ a new type of neural networks known as neural ODEs [3] to estimate derivatives of the strain energy function with respect to invariants of deformation. In the current approach the strain energy derivatives are defined as the solution of a neural ODE at some fictitious time $t = 1$. Since the solutions of an ODE at any given time are monotonic this results in an automatically convex function.

We train the neural ODE using experimental data from porcine skin and synthetic data generated from popular closed-form models. We show that the neural ODE is able to learn and replicate the outputs of all the closed-form models and outperforms the models when trained with experimental data. We implement the neural ODE based material model in a finite element method software to test and showcase its use in practical applications.

Key Words: Bayesian Inference, Deep Learning, Hyperelasticity, Finite Element Method, Real Time Simulation

Computer simulation has acquired a preeminent role in recent years, particularly, many engineering applications rely on the predictive capabilities of computational models. Some of these applications, like biomedical simulations used to support or train surgeons [1][2] require computationally efficient or even real-time solutions. Conventional methods for solving the underlying non-linear problems, such as the Finite Element Method, are computationally far too expensive. This work efficiently leverages state-of-the-art data-driven techniques to give accurate non-linear solutions in real-time.

In this work, we propose a highly efficient deep-learning surrogate framework that can predict deformation responses of hyper-elastic bodies under external loads. We implement a special type of convolutional neural network (CNN) [3], the so-called U-Net. This architecture has strong resemblances to Finite Element multigrid methods and proves to be capable of capturing non-linear responses characteristic to large deformation regimes. We train variants of U-Net with synthetic force-displacement data generated with the finite element method. In addition to the standard deterministic version of the framework, we propose its probabilistic versions, which can provide reliable uncertainty estimates of U-Net models in addition to predictions. We study the properties of frameworks for several benchmark problems. In particular, we check the capabilities of the Maximum Likelihood and the Variational Bayes Inference [4] formulations to assess the confidence intervals of solutions.

The use of the U-Net surrogate model allowed us to gain x350 speedup, enabling us to achieve real-time responses. The solution errors of the surrogate model have been shown to correlate with the uncertainties predicted by the proposed probabilistic framework. We also show that uncertainties of solution rapidly increase in the extrapolated region [3]. With our framework we could assess both: model and data uncertainties, which we believe is an important step towards making real-time hyper-elastic simulations more reliable.

Surrogate model of elastic large-deformation behaviors of compliant mechanism using co-rotational beam element

Kai Suto[1*], Yusuke Sakai[2], Kotaro Tanimichi[1] and Taisuke Ohshima[1]

[1] Nature Architects, Inc., Tokyo 107-0052, Japan, info@nature-architects.com
[2]Sony Computer Science Laboratories, Inc. Kyoto Laboratory, Kyoto 600-8086, Japan, Yusuke.C.Sakai@sony.com

Key Words: Compliant mechanism, Large-deformation analysis, Surrogate model, Co-rotational beam element

In this study, we propose a surrogate model for predicting nonlinear structural deformations of elastic flexural mechanisms. Psuedo-rigid-body model is often used for describing the behaviors of a structure, such as compliant mechanism, with deformation degrees-of-freedom (DOF) as a combination of rigid bars and torsion springs [1]. However, it is necessary to construct a computational model based on the geometrical shape of each structure by trial and error.

In accordance with Ref. [2], by using co-rotational beam element, we develop a generalized surrogate model, which can predict nonlinear responses of a compliant mechanism with the essential deformation DOF of beam element without any geometrical assumption. The total number of DOFs of nodes at both ends of a two-dimensional beam is six, while the number of deformation DOFs is three, i.e., axial extension, symmetric bending, and anti-symmetric bending. Therefore, it enables us to reduce the computational cost, from 6×6 to 3×3, associated with the models by using the essential deformation DOFs of the co-rotational beam element.

It is difficult to predict the nonlinear responses of forces derived from displacements of a compliant mechanism represented by a co-rotational beam element. The reason is that a single forced-displacement simulation can produce multi-stable states due to the geometrical nonlinearities and numerical instabilities. To overcome this problem, we generate the data sets by applying external forces and use its inverse response for training the surrogate model.

In the numerical examples, large-deformation behaviors of several types of compliant mechanisms are predicted by the proposed model. The accuracies of the prediction are investigated for verifying that it can be a beneficial tool for designing structures with nonlinear elastic deformation behaviors.

Key Words: *Convolutional Neural Networks (CNNs), Phase-field fracture, FFT method*

Fibre reinforced composites are important structural materials in various industrial sectors. The optimised design and certification of such materials rely on efficient multiscale analysis. Physics-based models, described by partial differential equations (PDE), have been subject to intensive research since several decades, and have enabled high-fidelity simulations providing accurate predictions of the mechanical behaviour of composites. However, these PDE solving simulations suffer from limitations in computation time, especially when it comes to composite design and certification where a large number of simulations are required to cover the parameter space. Machine learning techniques have step-changing potential, accelerating the prediction by several orders of magnitudes [1]. This is particularly interesting in the context of multiscale computations.

In the present work, an FFT (Fast Fourier Transform) based phase-field model [2] will be applied to predict the elastic behaviour and failure of fibre-reinforced composite RVEs (Representative Volume Elements). Harnessing the efficiency of the FFT method in parallel computing, a large dataset of high resolution (250,000 elements) can be obtained in a reasonably short time. FFT methods rely on image-type (uniform structured) discretisation, which makes it relatively straightforward to apply Convolutional Neural Networks (CNNs) to the obtained dataset.

The aim is to predict not only the full stress-strain curves up to final failure, but also the local stress distribution and crack patterns. The latter are important for multiphysics problems to predict the interactions between mechanical fields (including damage) and environmental factors, such as hydraulic pressure and oxidation. Both geometric variations (e.g. fibre arrangement, void distribution) and material variations (e.g. inhomogeneous matrix properties) will be included in the parameter space. Several CNN architectures will be examined and compared. Auto-encoders will be tested as a technique for dimension reduction. Networks, such as Generative Adversarial Networks, will be tested for predicting the local stress and damage fields.

Key Words: Unsupervised learning, Linear viscoelasticity, Sparse regression

We extend the new approach for data-driven automated discovery of material laws, called EUCLID (Efficient Unsupervised Constitutive Law Identification and Discovery) [1], to linear viscoelastic materials. The approach is unsupervised, i.e., it requires no stress data but only full-field displacement and global force data. However, should stress-related data be available, as in the case of DMA data, the method is able to incorporate them in the discovery process. For linear viscoelastic materials, EUCLID discovers parsimonious material parameters through sparse regression of a potentially large catalogue of parameters. The material model library is constructed by using a Prony series in the frequency domain. The selection of the parsimonious parameters within the catalogue is made by solving an optimization problem that enforces the equilibrium constraints and, if available, exploits the DMA data. Sparsity promoting regularization is used to generate a set of solutions out of which the solution with lowest cost and highest parsimony is automatically selected. Through virtual experiments, we demonstrate the ability of EUCLID to accurately discover several linear viscoelastic materials.

Key Words: Structural Reliability, Machine Learning, Separable Monte Carlo, High dimensional problems

In the context of reliability, adaptive surrogate model-based approaches are receiving growing interest. The classical sampling-based method - Monte Carlo (MC) - used to compute failure probabilities requires a large number of evaluations of often complex and numerically expensive models. In order to reduce the overall computational burden two paths are generally followed: (1) by introducing a surrogate model or (2) adopting a sampling strategy able to reduce the number of samples of the complete model to achieve a targeted precision. In this work, we couple both alternatives with the aim of solving reliability problems with high dimensional uncertain variables. Indeed, real world engineering problems generally involve a large number of variables, making the surrogate modeling more challenging. In this work, we adopt an adaptive Kriging- Partial Least Square (KPLS) model [1], specifically introduced to deal with high number of input variables. This is coupled with a variance-based stopping criterion [2] and Separable Monte Carlo (SMC) approach [3], designed for applications where the systems exhibit independent response and capacity.

A high dimensional numerical test case, related to structural reliability, is presented. To achieve the same accuracy level, the presented approach can reduce by 50% (if coupled with MC) to 75% (if coupled with SMC) the number of full model evaluations, compared to analogue existing methods in literature.

Multi-fidelity modeling of multi-scale porosity defects in cast alloys

Shiguang Deng[1], Carlos Mora Sardina[1], Ramin Bostanabad[1*]

[1] University of California, Irvine (UCI), Irvine, California, 92617, USA

Key Words: *Multiscale simulation, Gaussian processes, multi-fidelity modelling, cast alloys.*

Cast alloys often contain heterogeneous pores that significantly affect alloy behavior in high-performance applications. To understand the cross-scale impact of microscale porosity characteristics on the cast component's macro-mechanical properties, expensive multi-scale simulations are typically required. In this talk, we will introduce a multi-fidelity and multiscale framework to simulate the behavior of metallic components containing process-induced pores. Major components of our approach include: (1) a porosity-oriented 3D microstructure reconstruction algorithm which mimics the material's local heterogeneity, (2) a novel mechanistic reduced-order model which significantly reduces computational costs by projecting solution variables into a lower dimensional space where the material's elasto-plastic behaviors are approximated, and (3) a novel multi-fidelity method based on latent-map Gaussian processes that streamline assimilating any number of data sources with variable fidelity level.

Sensitivity-free Topology Optimization using Stochastic Gradient Estimators

Gaweł Kuś[1*], Sybrand van der Zwaag[1] and Miguel Bessa[1]

[1] TU Delft, Mekelweg 5 2628CD Delft, The Netherlands ,
* G.I.Kus-3@tudelft.nl

Key Words: *Topology Optimization, Reinforcement –learning, Sensitivity analysis, topology optimization for crash-worthiness*

Sensitivity analysis is an essential element of current topology optimization methods. It usually takes the form of the derivative of the objective function with respect to the design parameters, and as such, it allows to guide the optimizer updating the design. However, for the objective functions which cannot be differentiated, obtaining the sensitivities becomes difficult. So far, the common approach was to approximate the objective with another differentiable function, such that the sensitivities can be still obtained by differentiation. However, designing such an approximation is oftentimes problem-specific, and comes with shortcomings due to the intrinsic nature of approximations.

Here, we propose an alternative approach inspired by reinforcement learning, where the optimizer does not have access to the derivatives of the objective, but instead it estimates the sensitivities by interacting with the model. This results in a non-intrusive topology optimization method, which no longer requires the user to provide sensitivities, but instead, estimates the sensitivities implicitly by interacting with the model of the objective. In other words, the sensitivity analysis becomes completely separated from the problem and is fully taken care of by the optimizer. The optimizer can be therefore plugged in ‘as-is’ to any physical model and does not require manually engineered approximations and sensitivity schemes.

We present our approach on several examples with differentiable and non-differentiable objectives and compare our method with the community standards.

Key Words: Neural Networks, Wake, Simulation

Computational fluid dynamics plays an important role in understanding complex flow phenomena. However, it is widely known that grid generation and adaptation are bottlenecks that hamper computational efficiency and scalability. For example, configurations that feature dynamic vortex shedding and evolution require careful grid generation to resolve separation events and dynamic grid refinement to capture the evolution of shed vortices. Therefore, we always encounter the trade-off relationship between the computational cost and accuracy of the simulation. To ease the burdens of conventional numerical approaches, supervised machine learning-based surrogate modeling has been actively proposed in recent years. For instance, a machine-learned turbulent inflow generator can produce the turbulent channel flow with much lower computational cost than the corresponding driver simulation [1]. In addition, supervised machine learning is utilized to enhance the resolution of coarse resolution simulation [2]. Despite the growing adoption of supervised machine learning among the fluid dynamics community, preparation of sufficient and refined training data using numerical simulation is an eternal challenge for supervised machine learning.

To overcome the aforementioned data preparation issue, an *Evolutional Deep Neural Network* (EDNN) has been devised [3]. Given only the initial/boundary conditions and governing equations, EDNN can produce temporal evolution of the flow by evolving the parameters of the network. Therefore, there is no need to prepare training data at all. In the original study, prediction of various canonical flows is demonstrated and EDNN shows notable producibility of flows in long-time prediction.

In this study, as a next interest, we focus on representing an external flow embedding a bluff body by EDNN. More concretely, the flow around a circular cylinder is considered. The predicted flow field at Re=40 shows agreement with reference direct numerical simulation (DNS). In the talk, we will show statistical assessments and dependence on the Reynolds number.

This work was supported from the Japan Society for the Promotion of Science (18H03758, 21H05007).

Key Words: *Non-destructive Testing, Concrete, Crack, Artificial Intelligence, Hammering test*

Visual inspection and hammering inspection are widely used as conventional inspection methods for cracks in concrete structures due to its capability to investigate a huge number of inspection targets in a short time. On the other hand, these methods depend on the experience and skills of the inspectors, and it has been pointed out that these skills are not easily transmitted.

Under such a background, a hammering inspection using a sensor (hereinafter referred to as "digital hammering inspection"[1]) has been developed for the evaluation of cracks in concrete structures objectively. However, it is difficult to comprehensively understand the influence of cracks on the digital hammering inspection, because the shapes of cracks (depth, length, direction, etc.) are diverse in actual structures.

Therefore, in this study, we developed a technique to quantitatively evaluate the shape of cracks from the results of 2-dimensional planar ditigal hammering inspection in the following two steps.

(1) Construct a large-scale DB of various concrete crack shapes and the 2-dimensional digital hammering inspection results using FEM analysis and machine learning.
(2) Develop an inverse analysis model to estimate the crack shapes from the planar inspection results by machine learning the obtained DB.

The developed inverse analysis model showed that the crack shape can be estimated with an accuracy of about ±15% by learning the nonlinear relationship between the digital hammering inspection results and the database of crack shapes. However, since the developed inverse analysis model is limited to the evaluation of a single crack in the concrete structures, we are planning to extend its applicability to actual cases in the field by learning the data of multiple cracks.

Key Words: *Randomized neural networks, Scientific machine learning, Extreme learning machine, Nonlinear least squares method*

Existing deep neural network (DNN) based methods for solving boundary/initial-value problems suffer from several drawbacks (e.g. limited accuracy, general lack of convergence with a certain convergence rate, extremely high computational/training cost) that make them numerically less than satisfactory and computationally uncompetitive.

We present a neural network-based method for computational PDEs that largely overcomes the above drawbacks. This method, termed local extreme learning machines (locELM), combines three ideas: extreme learning machines, domain decomposition, and local neural networks. The field solution on each sub-domain is represented by a local feed-forward neural network, and C^k continuity conditions are imposed on the sub-domain boundaries. The hidden-layer coefficients of the local neural networks are pre-set to random values and fixed, and only the output-layer coefficients are trainable parameters. The overall neural network is trained by a linear or nonlinear least squares computation, not by the back propagation (or gradient descent) type algorithms.

The presented method exhibits a clear sense of convergence with respect to the degrees of freedom in the neural network. Its numerical errors decrease exponentially as the number of degrees of freedom (e.g. the number of trainable parameters, number of training data points) increases, which is reminiscent of the traditional high-order methods. The current method far outperforms the state-of-the-art DNN based PDE solvers (e.g. the deep Galerkin method, and the physics informed neural network method) in terms of the accuracy and computational cost (network training time). We compare systematically the computational performance of the current method with those of the classical 2^{nd}-order and high-order finite element methods (FEM) for solving linear and nonlinear PDEs. The current method far outperforms the classical FEM. Its computational performance is comparable to that of the high-order FEM for smaller problem sizes, and for larger problem sizes the current method markedly outperforms the high-order FEM.

Key Words: *Neural Networks, Design Space Exploration, Isogeometric Analysis*

The projected increase in computational resources in the coming decades will pave the path for a fast, direct, interactive, and real-time approach for design space exploration of industrial problems. The traditional design space exploration approaches suffer from a design-through-analysis bottleneck that involves a significant user time commitment and prohibits real-time design space exploration. The isogeometric design space exploration framework proposed in [1] overcomes this is issue by leveraging concepts from isogeometric analysis (IGA), which provides seamless integration between FEA and CAD, with modern parametric modeling techniques and efficient design space sampling. The heart of this approach involves traditional approximation methods, such as modal and nodal approaches, for constructing an efficient mapping between design parameters and the solution manifold consisting of IGA control points. However, these parametric modeling methods suffer from the curse of dimensionality that limits them to a lower order of accuracy in a high dimensional parametric space.

In this presentation, we propose to use neural networks as a surrogate model to represent the mapping between high dimensional input design space and the solution manifold. Neural networks allow for an efficient and accurate representation of a high dimensional parametric space that does not suffer from the curse of dimensionality as other previously considered parametric approaches. We plan to test the limits of nodal, modal, and neural-network-based surrogate models by evaluating them for scenarios inside and outside the training design space for several structural mechanics problems. The overarching goal is to assess the performance of these methods for representing solution manifolds with rough characteristics as these problems are often challenging for traditional approaches.

Key Words: Deep Learning, Surrogate Model, Computational Fluid Dynamics

The application of deep learning to physics simulation has been addressed, and it is expected to reduce calculation costs by surrogating simulations, resulting in faster optimization calculations and more efficient design processes. Usual deep learning algorithms, however, don't take into account governing equations of physical simulations in the training process. Therefore, the predicted physics fields don't always satisfy the governing equations, which is one of the reasons why many researchers think these methods is not suitable for practical use. In our research, we focused on physics-guided learning[1], which considers the residuals of the governing equations in the loss function. This method is verified its effectiveness by applying to cavity flow, which is 2D incompressible flow simulations.

Different data were used for the training and the inference test. Target physicsal quantities are pressure, x and y components of velocity. The evaluation metrics such as mean absolute percetage error and residual were compared between usual deep learning and physics-guided learning. Residual of Navier-Stokes equation, which is governing equation of cavity flow, are computed by substituting the derivatives of inferred pressure and velocity field. The result revealed that although usual deep learning model seem to predict pressure and velocity fields well, the residual are relatively large. This is due to the roughness of inferred pressure field. On the other hand, physics-guided learning can predict pressure field smoothly, resulting in the residual is improved significantly. From the above, it is found that the inferred physical fields are smoothed by physics-guided learning and the effectiveness of physics-guided learning is confirmed.

Key Words: *PINNs, Deep learning, Heterogeneous materials, Hyperparameter sensitivity*

High-fidelity physics-based numerical models have often been utilized for subsurface modeling in the oil and gas industry. These models provide an efficient virtual platform to investigate the various operational parameters and guide on-field engineering decisions. The thermo-hydro-chemo-mechanical interactions in the subsurface processes are incorporated by means of coupled-field balance laws in these models. The resulting equations are discretized and then solved on a computer using a fit-for-purpose numerical method. However, all numerical methods require that the subsurface system be appropriately meshed into non-overlapping elements. Unfortunately, generating such meshes for subsurface systems is a non-trivial task. This is because most subsurface systems are geometrically complex and exhibit a high degree of heterogeneity. In addition to naturally occurring faults, and natural variation in material properties because of geological stratification, these systems also include the effect of fractures engineered through hydraulic stimulation. Consequently, the pre-processing step of generating conforming meshes that honor the various subsurface features adds an enormous computational burden. An appropriate discretization scheme is then chosen to compute the derivatives and other terms in the equations. This introduces discretization errors and could potentially lead to stability issues.

On the other hand, data-driven modeling approaches use large artificial neural networks to predict the outcome of physical systems. The training data for these models is generated by means of physics-based simulators (or experiments) for simpler models. Once trained, the artificial neural network is expected to mitigate the high computational cost of physics-based simulators through fast predictions. However, in practice, the outcome of these data-driven simulations is only as good as the training data. Often, the cost of training data acquisition is prohibitive and severely limits the applicability of these methods.

To address the above limitations, a novel class of methods known as the Physics Informed Neural Networks (PINNs) is increasingly becoming popular. These methods take a hybrid approach between purely physics-based and purely data-driven modeling by constructing loss functionals based on underlying physical principles. In contrast to the more traditional numerical methods, PINNs are not mesh-based and therefore obviate the need for mesh generation and discretization, while allowing the derivatives to be computed exactly using automatic differentiation. At the same time, in contrast to traditional data-driven methods, PINNs are guided by underlying physical principles and are therefore more computationally efficient. With a few exceptions, PINNs have so far been applied only for homogeneous materials. Here, we explore the applicability of the PINNs framework to materials with a heterogeneous character. Through simple 1D and 2D benchmark examples, an exhaustive parametric sensitivity study is conducted to isolate the effect of hyperparameters and activation functions on the numerical performance of the method. Through these examples, it will be demonstrated that the choice of activation functions has a significant impact on the convergence of the method for problems with material interfaces.

Bayesian Optimization on Fifth-Order Targeted ENO Scheme for Compressible Flows

Yiqi Feng[1*], Felix Schranner[2], Josef Winter[3] and Nikolaus A. Adams[4]

[1,2,3,4] Technical University of Munich, 85748 Garching, Germany, yiqi.feng@tum.de

Key Words: Bayesian Optimization, Targeted ENO, Implicit Large Eddy Simulation

Targeted ENO (TENO) has originally been proposed by Fu et al. [1] in order to overcome the shortcomings of WENO schemes which are excessive dissipation, and limited robustness for lower order upwind-biased, and central-biased schemes, respectively [2]. TENO offers a set of free parameters to alter the inherent effective local dissipation and dispersion. In the original formulation of [1], these free parameters have been adjusting by means of the approximate dissipation-dispersion relation [3].

Data-driven methods enable optimizing these free parameters instead of adjusting these. In this work, we demonstrate the application of an iterative Bayesian optimization approach on designing fifth-order TENO (TENO5) schemes. Exploiting that Bayesian optimization efficiently and robustly finds an optimum of an expensive function with a low number of trials, we construct specific TENO5-schemes for compressible flows with gasdynamic discontinuities, and implicit large eddy simulation (ILES) of turbulent flows. For the former, we measure the error between under-resolved simulations of the Sod shock tube and its analytical solution for automatically generated TENO5 formulations. For the latter, under-resolved inviscid Taylor-Green vortex flows are evolved to their turbulent state, in which their kinetic energy spectrum in the inertial subrange is compared to the theoretical Kolmogorov-scaling solution.

We show that these two TENO5 formulations perform superior to the original formulation of [1] for the wave-number ranges in dissipation-dispersion relation relevant to the specific types of flows. Also, a variety of benchmark test flows show that both TENO5 formulations perform better than the original one in terms of phase speed, shock resolution and physical consistency of turbulent flows, i.e. in practical applications.

Key Words: *Scientific Machine Learning, Dynamical Systems, Uncertainty Quantification, Model Discovery*

We present a machine learning framework (GP-NODE) for Bayesian systems identification from partial, noisy and irregular observations of nonlinear dynamical systems. The proposed method takes advantage of recent developments in differentiable programming to propagate gradient information through ordinary differential equation solvers and perform Bayesian inference with respect to unknown model parameters using Hamiltonian Monte Carlo sampling and Gaussian Process priors over the observed system states. This allows us to exploit temporal correlations in the observed data, and efficiently infer posterior distributions over plausible models with quantified uncertainty. Moreover, the use of sparsity-promoting priors such as the Finnish Horseshoe for free model parameters enables the discovery of interpretable and parsimonious representations for the underlying latent dynamics. A series of numerical studies is presented to demonstrate the effectiveness of the proposed GP-NODE method including predator-prey systems, systems biology, and a 50-dimensional human motion dynamical system. Taken together, our findings put forth a novel, flexible and robust workflow for data-driven model discovery under uncertainty.

University of Michigan, 500 S State St, Ann Arbor, MI 48109,
{doruk,chenbri,shravan,alben,rddeegan,goroda}@umich.edu

Key Words: Soft Robotics, Stacked MLP, Tensor Decomposition, Inverse Design

We consider data-driven design of soft robots using a novel locomotion mechanism based on a reaction-driven motion of an oscillating sheet. While a forward model for the simulation of this sheet is available as a PDE solver by Alben et. al (2019), design applications require the inversion of sheet motion into geometric and reaction parameters of the sheet. While PDE constrained approaches for this inversion is possible, they may be time consuming and computationally expensive. Instead we develop a deep-learning based model mapping sheet motion to sheet parameters. This framework is based on a stacked MLP design, whose hyperparameters we carefully tune to reconstruct the geometric and reaction parameters with high accuracy. However, this approach to train an inverse design framework for self-oscillating gels requires a large amount of data, which both makes training demanding and slows down the training procedure. To tackle these types of challenges in more general inverse-design settings, we investigate compact representations of the simulation data through low-rank matrix and tensor decomposition methodologies on different network structures. We compare the compressed-data inverse design framework with our original framework in terms of estimation accuracy of the continuous and discrete gel-sheet parameters, training speed, and memory requirements.

Key Words: GANs, Inverse problem, FEM, Metamaterials

With the advancement of additive manufacturing technologies in the recent past, rational design of human-made materials comprising of several unit cells or subunits have allowed us to program their structural response in a desired way. Extraordinary functionalities in such metamaterials can be engendered by suitably selecting the structure and geometry of the unit cells, rather than their material composition. These mechanical structures can be used for applications like soft robotics and adaptive structures, where designers can use programmable metamaterials architectures to generate complex sequence of output motions from a simple load input on a monolithic system [1]. These unique structures encompass a vast design space that cannot be possibly explored by experimental methods. Finite Element Analysis (FEA have been widely used to predict the effective properties of different metamaterials based structures. Although these works have demonstrated the enhanced design space of such Metamaterials with myriad of potential applications, we still require to address the inverse design problem, i.e predicting a metamaterial design given a specific structural response. Topology optimization (TO) [2] has been used to solve this problem. Both gradient and non-gradient based TO algorithms have been used to address this problem. However, gradient based method requires calculating cumbersome sensitivities of the objective function, which often converges to local optimal solutions. Although gradient free techniques have yielded promising results to solve the inverse design 1roblema, they primarily suffer from high computational cost. Data Driven approaches on the other hand offer a non-iterative, general-purpose solution by modelling properties as inputs and the design as output. Deep learning methods such as Generative Adversarial Networks (GANs) are promising alternatives to predict the design given a property [3].

The objective of this work is to develop a framework that can solve this inverse design paradigm. In this study we aim to find the design of the metamaterials cantilever beam subjected to a point load at the free end, for a desired centerline displacement of the beam. We arrange the metamaterial unit cells provided by Chan et al. [4], to build a cantilever beam, whose centerline displacement is calculated using a static FEA. Naturally, the deformed beam configuration depends on the choice and the arrangement of the unit cells. To predict the design of the beam (type and arrangement of the unit cells) that could result in each centerline deformation, we adopt a GANs based approach which represents the 2D structures in the form of images. As a first step, the GAN based approach has been utilized to predict a very simple metamaterials design. To cover a more extensive design space, a novel data compression strategy is employed to allow GANs to effectively train on the data. This approach results in a in a general purpose, highly expressive, and robust strategy to design more complicated metamaterial structures. We present a thorough analysis of the design results from the approach on a large dataset (>5000 samples) collated via FEM simulations. The developed framework can be extended to predict design of beams considering structural nonlinearities.

Key Words: *Deep Learning, Digital Photoelasticity, Stress Evaluation, Stress Intensity Factor*

In mechanical testing, photoelastic and digital image correlation techniques are used to obtain stress and strain fields. The stress distribution can be visualized by an isoclinic or isochromatic fringe pattern of birefringent materials subjected to mechanical loads. So image analysis of the fringe pattern is required to get information about the direction and magnitude of principal stresses. Still, it can require very complex methods such as the phase-shifting technique or inverse analysis. Machine learning models like deep convolution neural networks (CNN) are widely used for extracting information from images by posing the problem as classification, regression, segmentation, and super-resolution problem. CNN models are easy to implement and do not require any feature extraction from images. In this work, we generate isochromatic images by considering three different mechanical loadings such as (1) disk under diametrical compression, (2) half-space under concentrated surface force, (3) Half space under uniform normal loading for various force levels, and three different modes (I, II and III) of Griffith-Inglis Cracks for various stress intensity factors. Using our own developed CNN models, we extract the force levels and stress intensity factors from the images and compare them with Alexnet. The developed program achieves 90% accuracy in classification, and 0.001 mean square error in regression of images

Key Words: *External RC frame retrofit, image measurement, crack development*

This work participated the measurement work on a series of experiments of external reinforced concrete (RC) frame retrofitting using image analysis technique. The retrofit method adds an external RC frame along the weak direction of an RC building in order to improve the seismic resistance. The connection between the external frame and the existing frame dominates the effectiveness of the retrofitting. However, it is relatively difficult to measure the relative displacements between the external and existing frames by using conventional contact devices such as the linear variable displacement transducers (LVDTs) not only because there are multiple measurement points but also they are difficult to install in limited space. Image analysis is a relatively feasible manner to measure the relative displacements between frames.

This paper briefly presents the design of the image measurement as well as the preliminary measurement results. In addition to the relative displacement aforementioned, the measurement results also include the deformations of beams and columns of both frames, the crack development over the experiments, and the observed failure mechanism based on the image analysis measurement. The feasibility of extending the measurement to future structural health monitoring is also discussed.

Optical Principle and Accuracy Evaluation of Equilateral Prism used for Stereo Image Measurement

Key Words: *Image measurement, 3-D measurement, Prism, Single camera, Calibration*

PPSIM is a technology that uses the refraction of a prism to shift the light to produce a perspective difference effect, so as to obtain a virtual stereo image pair in the case of a single camera shooting, and use the image to perform stereoscopic reconstruction of the object space. The proposed measurement technique is specially designed to precisely measure the shape and deformation of micro-objects, especially for studying elastic and plastic behaviors in micro region, such as the measurement of stress intensity factors at the crack tip, the measurement of the deformation field around the hole by the hole-drilling method.

The purpose of this paper is to deduce the PPSIM optics, and introduce two calibration procedures for identifying system parameters. Finally, the accuracy of parameter calibration and spatial coordinate measurement of PPSIM is verified by experiments.
According to Snell's law of refraction and vector geometry, this paper deduces the equations to convert from object space coordinates to virtual stereoscopic image pair coordinates, and vice versa. Since it does not require an iterative direct calculation process to convert the coordinates of the virtual stereo image to the object space coordinates of the measurement point, it is not only used for forward intersection analysis, but also used in the calibration process of system parameters.

There are a total of 26 system parameters including lens distortion correction parameters, camera sensor density and image distance, camera external square parameters, and internal and external orientation parameters. The system parameters can be identified with the Levenberg-Marquardt algorithm, provided that at least 9 control points are arranged whose spatial coordinated are known or their displacements in three independent directions are given.

The experimental results show that reasonable system parameters can be identified whether using control points with known spatial coordinates or four images with known rigid body displacements in three independent directions. The Levenberg-Marquardt algorithm has good stability, and all experimental examples can converge smoothly. We recommend the second calibration method because it does not require a high-precision process to prepare the test body, nor does the calibration procedure require tedious operational procedures.

The experimental results of accuracy verification show that under the condition of FOV of 30mm, the root mean square of measurement error can be controlled below 0.011mm, that is to say, the relative error is about 1/3,000. This precision is close to that of the interferometer, which is enough to confirm that PPSIM has application value in experimental mechanics research and testing.

Constitutive model of expansive soils considering the influence of the cation exchange on osmotic pressure

Hiroyuki Kyokawa[1*], Yasuhiro Muto[1], Junichi Koseki[1] and Shintaro Ohno[2]

[1] University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113-8656, Japan,
kyokawa@civil.t.u-tokyo.ac.jp
[2] Kajima corporation, 1-3-8 Motoakasaka, Minato-ku, Tokyo 107-8477, Japan

Key Words: *Constitutive model, Expansive soil, Cation exchange, Osmotic pressure*

The double diffusion layer of cation surrounded clay crystals yields repulsive osmotic force, and it causes mechanical deformation and/or characteristic change of soils. According to the type and concentration of solution, furthermore, those cations adsorbed on clay crystals are exchanged with other cations (the cation exchange), and it also causes mechanical deformation and characteristic change. In particular, expansive soils such as bentonite, which have large surface area and high cation exchange capacity, are strongly affected by such exchangeable cations. Bentonites are considered as artificial barrier in a waste disposal facility because of their characteristics. Buffer bentonites would be exposed to groundwater and/or seawater environments containing an inflow of sodium ions, calcium ions leached from the cement material, and iron ions from the framework of the disposal facility. This transition of the chemical environment is a significant source of concern, as it changes the expansive characteristics of the soil.

Authors proposed the constitutive model combining the behaviors of soil skeleton and clay mineral crystal based on the double structure framework[1], which can capture various complicated hydro-mechano-chemical behavior of expansive soils. In this study, introducing the fraction of adsorbed cations calculated by the Gains-Thomas convection and the Davies equation for activity coefficients of ions to the repulsive osmotic force derived from the diffusion double layer [2], the model considering the influence of cation exchange on mechanical behavior of expansive soil is established. The simulation result of the osmotic consolidation test by the proposed model, in which Na^+ ion (0.01mol/L) is initially added and subsequently Ca^{2+} ion (0.01mol/L) is added into expansive soil. The proposed model can describe the transition of osmotic consolidation phenomena with multiple ions: the osmotic force continuously changes according to the fraction of adsorbed ion; divalent ion causes larger osmotic consolidation (settlement).

Key Words: *spalling, heterogeneity, nuclear waste repository*

This study presents a three-dimensional numerical analysis of multiple fracture growth leading to spalling around underground nuclear waste deposition boreholes. A multiple-borehole numerical model in a heterogeneous rock mass is considered, wherein thermo-mechanical spalling is simulated using a finite element-based fracture growth simulator [1]. Fractures initiate in tension based on a damage criterion, and grow in a manner controlled by the stress intensity factors at the fracture tips. Fracture tip propagation is multi-modal, resulting in final fracture patterns that are representative of both tensile and shear failure.

Several geomechanical cases are investigated, in which spalling initiation and growth is numerically evaluated as a function of host rock heterogeneity. A first level of heterogeneity is introduced by perturbing the mechanical (strength, elastic modulus, toughness) and thermal (conductivity, heat capacity) properties, following their expected frequency distributions at the Swedish Forsmark [2,3] site. Subsequently, another level of heterogeneity is added through a large, steeply dipping fracture zone that intersects the proposed repository site [4].

The effect of spalling on the structural integrity of the deposition boreholes is illustrated for both heterogeneous cases, and quantified in terms of maximum spalling depth, spalling width, and total fractured surface area. Fracture patterns and their extent are also compared with a homogeneous benchmark case. Numerical results show that rock heterogeneity influences the propagation of spalling fractures, and their interaction with the borehole walls and the pre-existing fault, through the creation of local stress shadow zones.

Key Words: *Performance Assessment, Site Selection, Repository-induced Effects, Geological Barrier, HLW, LLW, ILW, DGR*

In the field of deep geological disposal of radioactive waste, performance assessment focuses on the integrity and performance of the engineered and geological barriers as the disposal system evolves over time. To evaluate the suitability of a site for a deep geological repository (DGR), geoscientific data is integrated into site-specific assessments for the repository project. The performance of the geological barrier needs to be evaluated based on the characteristics at the start of the assessment period (i.e., at the time of repository closure) taking into account a certain degree of uncertainty associated with the exploration and characterization of the geology as well as the long-term evolution of the site. Furthermore, performance assessment includes an evaluation of the safety-relevant repository-induced effects on the disposal system, such as thermal-, gas-, and chemical effects introduced by the interaction of the waste with the nearfield. The complexity of the involved thermo-hydro-mechanical and -chemical processes (THMC) calls for model-supported workflows to reach a quantitative assessment of the barrier performance and an adequate evaluation of the associated conceptual and parametric uncertainties.

The Swiss Radioactive Waste Management Program foresees two types of repositories: a high-level waste repository (HLW) for spent fuel, vitrified high-level waste and long-lived intermediate-level waste, and a repository for low- and intermediate-level waste (L/ILW). The procedure for selecting repository sites in Switzerland is specified in the Sectoral Plan for a DGR which consists of three stages. In the current and last Stage 3, three candidate siting regions *Jura Ost*, *Nördlich Lägern* and *Zürich Nordost* in northern Switzerland are examined in detail and, where necessary, supplementary geological investigations such as deep exploratory boreholes are being performed. The broadened site-specific database forms the basis to select, for each of the repositories, the site for which the general license application will be prepared. The model-supported workflow is developed with an indicator-based approach supporting the site selection, aimed at comparing favorable and less favorable aspects of the potential siting areas. The workflow comprises a portfolio of numerical models addressing different aspects such as the efficiency of the unperturbed geological barrier, its long-term evolution, the THMC effects from the DGR, the barrier integrity, and the spatial and temporal uncertainties in the evolution scenarios. The numerical modelling is performed with deterministic as well as probabilistic variants to bracket the conceptual, parametric, and scenario uncertainties. The assessment aspects are addressed in terms of quantitative dimensionless performance indicators for the consistent comparison of the candidate sites. The model-supported workflow allows a traceable, transparent, and verifiable implementation of the site selection process.

On The Simulation of THM Behaviour of Forge Mock-up Experiment

Key Words: *Bentonite, Thermo-hydro-mechanical behaviour, Coupled Analysis, Unsaturated*

In the recent decades, the possible damage or deterioration of the engineered and natural barriers due to the accumulation of hydrogen and radiolysis gas with the corrosion of metals has been studied as one of the main concerns at nuclear waste disposal facilities. The FORGE project[1)] was a joint project, in which key gas migration issues on repository performance assessment was studied. In this project, a reproduction analysis of the water injection process was carried out by conducting a mock-up experiment from July 2010 to March 2013. As an engineered barrier, sand/bentonite (SB) mixture was selected, hence it is necessary to consider the swelling behavior and the permeability due to the void ratio change. Therefore, in this study, we adopted a model that can simulate the saturated swelling and elasto-plastic behavior of clay and performed hydro-mechanical coupled analysis.

The materials used in this test were mortar, bentonite and SB mixture, with initial dry densities of 1.8 and 1.5 Mg/m^3 for SB and bentonite, respectively. The thermo-hydro-mechanical (THM) coupled analysis of mock-up experiment was performed by CODE_BRIGHT[2)] with an axisymmetric model. SB and bentonite are modeled with elasto-plastic constitutive law, Barcelona Basic Model and details of the constitutive laws and parameters were explained in the report by Sakaki et al.[3)]. A mechanical condition of no displacement perpendicular to the boundary was imposed in all boundaries. Initial degree of saturation for SB was set as 0.64. Initial gas pressure of 0.1MPa was assigned to all surfaces to achieve initial equilibrium. After the initial conditions were set, two types of THM coupled analysis were performed. In the first analysis, saturation stages as applied in the experiment were set[4)] and water injection amount, water pressure and total stresses during the test were examined. In the second analysis, a simplified saturation process was applied and at the end of the analysis boundary conditions were set as simulating the dismantling process[5)]. At the end of the analysis, deformation and change in porosity were compared with the observed values due to the dismantling of the experiment.

As a result of this study, a good reproducibility of the measured water injection amount, water pressure and total stress of the mock-up experiment was obtained. Additionally, reproduction analysis could reproduce the expansion of the specimen after dismantling, and that the change in density distribution was mainly due to the expansion with dismantling. Therefore, the modelling of the water injection and dismantling processes and the validity of analysis parameters could be verified.

Key Words: *Storm Surge, Channel Flow, CFL, Finite Element, ADCIRC*

In this presentation, we introduce a dimension reduction technique to obtain discretized equations equivalent to 1D shallow water equations within the 2D finite element method framework. The Advanced Circulation (ADCIRC) model has been used for multiple purposes including hindcasts, forecasts, and risk evaluation of hurricane storm surges [1,2]. Among other ongoing development efforts, coupling the ADCIRC storm surge model with hydrological models is one of the key focuses. Coupling of these models is especially important in the context of compound flooding, where rainwater, riverine flows, and storm surges interact to possibly cause devastative floods.
This work addresses two issues we often face when we model smaller channels/rivers within a 2D finite element framework: 1) an overly restrictive time step imposed by the CFL condition in the cross-channel direction as the cross-sectional width becomes small, and 2) poor model physics due to the use of simplified equations such as weir formula to model the exchange of water between the channel and the floodplains.

To eliminate the cross-channel CFL condition we derive discretized nodal equations in the body of the channel that are equivalent to 1D shallow water equations. The equations are obtained by manipulating the 2D finite element nodal equations at paired nodes located on either side of the channel. This technique can be implemented with significantly less effort than introducing 1D equations to the existing 2D finite element code. We address the second issue by using weir formula primarily when the water depth in the channel is below the bank elevation. We abandon these when the channel water elevation exceeds the bank elevation by a small amount and then switch instead to full integration of the shallow water equations. In this case, the channel bank represents a discontinuity in the bathymetry, and the water flow responds to the 2D physics both in the floodplain and the channel. Finally, we can combine the two solution strategies to yield a single solution that is influenced both by the floodplains as well as the along channel flow while not being restricted by a cross-channel CFL condition.

A mesh generator for multidimensional hydrodynamic models

Younghun Kang[1*] **and Ethan J. Kubatko**[2]

[1] The Ohio State University, Department of Civil, Environmental and Geodetic Engineering, Columbus, Ohio, USA, kang.1049@osu.edu

[2] The Ohio State University, Department of Civil, Environmental and Geodetic Engineering, Columbus, Ohio, USA, kubatko.3@osu.edu

Key Words: Mesh generation, Multidimensional hydrodynamic model

The computational efficiency of hydrodynamic models significantly depends on the resolution of the computational meshes employed. For regions with complex geometries, high-resolution meshes are required in order to obtain accurate results, which decreases computational efficiency. Several mesh generators have been developed to generate 2D finite element meshes with resolutions adapted for local geometric features. However, the use of two-dimensional elements alone to capture topography/bathymetry of river beds, especially when river widths are very small, can be prohibitively expense. Therefore, multidimensional (1D/2D) hydrodynamic models have been developed to address this problem in which two-dimensional elements are used for floodplains, watersheds, and lakes, while one-dimensional elements are used for small open-channels. The computational domain of the two-dimensional model is represented by triangular elements and the computational domain of the one-dimensional model is represented by edges of triangular elements. In this study, an automatic mesh generator is developed for multidimensional hydrodynamic models. One of the main features of the mesh generator is efficient mesh sizing along 1D domains, which means that resolution of elements is high around curved channels whereas it is low around straight channels. Another main feature is that it identifies small channels according to user-defined criterion and automatically extracts centerlines to be used as 1D domains. Numerical studies are performed on several watersheds and coastal floodplains with complex geometries.

Key Words: Hydrodynamics, Oceanography

The increased frequency and magnitude of tropical and extratropical storms conveys a looming need to accurately predict storm surge and flooding that result from these extreme weather events [1]. Coastal flooding can be predicted using regional models that solve the depth-averaged Navier-Stokes equations, and recent developments have allowed for such models to use global domains [4, 3]. Because these models are oftentimes purely barotropic, they fail to capture baroclinic currents such as the Gulf Stream and cannot readily resolve seasonal disparities in dissipation rates.

Recently, a study was performed that couples an regional, operational, coastal forecasting system powered by the Advanced Circulation Model (ADCIRC) for Puerto Rico and the Virgin Islands with the data-assimilated Global Ocean Forecasting System (GOFS 3.1) in order to resolve baroclinic effects within the storm surge model [2]. It was found that by using salinity and temperature information on a coarse scale from the ocean-circulation model, it is possible to capture these effects within the regional 2-dimensional model.

This study extends this coupling from a regional storm surge model to a global one. Using temperature and salinity forecasts from GOFS 3.1, estimates are found for depth-averaged baroclinic pressure gradients, Brunt-Väisälä frequencies for use in the calculation of baroclinic-barotropic energy conversion, and steric adjustments. These estimates are then used within ADCIRC to resolve baroclinic effects normally lost in depth-averaged models.

Multi-year analyses are used to examine the how the incorporation of these baroclinic effects alter the currents captured within the ADCIRC model. These results are compared with current and tidal stations to examine the differences in barotropic and baroclinic simulations.

Key Words: *Isogeometric Analysis, Fluid-Structure Interaction, NURBS*

There have been presented a number of numerical methods for fluid-structure interaction problems with free surface. The finite element method is widely used as a numerical method. Although the finite element method has excellent adaptability to arbitrary shapes, it is time-consuming to create an analysis mesh, and curves may be approximated. Therefore, IGA (Isogeometric Analysis) [1], [2] has been attracting attention in recent years.

IGA is a method using NURBS functions used in CAD (Computer Aided Design) as a shape function. IGA can create an analysis mesh directly from CAD data, enabling us to create an analysis mesh easily and represent curves perfectly.

The purpose of this study is to develop a fluid-structure interaction analysis method using IGA. For fluid analysis, the numerical method based on VOF method is employed. The stabilized finite element method with IGA is applied as the spatial discretization method and the Crank-Nicolson method as the temporal discretization method. For structure analysis, to solve the equilibrium equations, the Galerkin method with IGA is employed as the spatial discretization method and the Newmark-beta method is employed as the temporal discretization method. Several numerical examples are presented to demonstrate the promise and potential of the present method to solve the solid-fluid interaction problems with free surface.

Gas-liquid-solid Three-phase Implicit Finite Element Analysis based on Multi-phase-field Model using Unstructured Grid

Junichi Matsumoto[1*]

[1] National Institute of Advanced Industrial Science and Technology (AIST),
1-2-1 Namiki, Tsukuba, Ibaraki 305-8564, JAPAN, matsumoto-junichi@aist.go.jp

Key Words: *Unstructured Grid, Multi-phase-field Model, Cahn-Hilliard Equation, Fluid Analysis, Implicit Finite Element Method*

An implicit mixed finite element method based on a multi-phase-field model [1] for gas-liquid-solid three-phase flow is proposed for the finite element parallel analysis. A bubble function element stabilization method [2,3] using unstructured grid (tetrahedron) is employed for incompressible Navier-Stokes equations and linear elastic body equation. Allen-Cahn equation [4] and Cahn-Hilliard equation [5,6] are applied to estimate interface of gas, liquid and solid. MINI element, bubble function element / linear element, is used to solve Cahn-Hilliard equation. As for the temporal discretization, an implicit scheme is used. In the implicit scheme, N-R method is employed to solve non-linear equations. A three-dimensional gas-liquid-solid three-phase finite element analysis is computed in this research.

Implementation and assessment of a parametric rainfall model in a hurricane storm surge model

Mackenzie Hudson*, Ethan Kubatko[1], and Younghun Kang[1]

[1] Department of Civil, Environmental and Geodetic Engineering, The Ohio State University, 417D Hitchcock Hall, 2070 Neil Avenue, Columbus, OH 43206, hudson.476@osu.edu

Key Words: *Discontinuous Galerkin methods, hurricane storm surge, rainfall*

Current operational storm surge models incorporate several physical processes that contribute to coastal flooding; however, these models do not typically include rainfall in their storm surge simulations. This omission creates an incomplete assessment of weather conditions during extreme precipitation events and has inspired efforts to improve upon current storm surge models by incorporating rainfall into storm surge simulations. In this talk, I will explain the significance of rainfall and its contribution to storm-driven coastal flooding and discuss our efforts to integrate a parametric rainfall model into a discontinuous Galerkin shallow water equations model (DG-SWEM) to create a more complete assessment of real-life storm conditions. Numerical results demonstrating the approach will be presented, and we will discuss some of the challenges involved in moving forward.

Mechanism of delayed leaching of heavy metals from naturally contaminated soils

Risa Komuro[1*] and Mamoru Kikumoto[2]

[1] Yokohama National University, Tokiwadai 79–5, Hodogaya, Yokohama, Kanagawa 240–8501, Japan, komuro-risa-kr@ynu.jp
[2] Yokohama National University, Tokiwadai 79–5, Hodogaya, Yokohama, Kanagawa 240–8501, Japan, kikumoto-mamoru-fc@ynu.ac.jp

Key Words: *desorption, naturally contaminated soil, porous particle, finite difference method*

Existing models for sorption kinetics of contaminants such as heavy metals (e.g., pseudo-second-order model introduced in [1]) mainly focused on describing artificial adsorption/desorption for a relatively short duration, where contaminants absorb onto the surface of the adsorbent. However, ground formed by metamorphism or sedimentation usually contains heavy metals during their natural formation process, and heavy metals are distributed throughout the ground in such cases. In fact, several research (e.g. [2]) has implied the significance of the effect of intra-particle adsorption/desorption kinetics of heavy metal leaching. From this perspective, naturally contaminated soils that contain contaminants deep within the particles may show delayed leaching. Therefore, a novel approach for predicting the distribution of contaminants, both in the soil particle and surrounding liquid, is achieved using the finite difference method. The approach is named the "intraparticle pore-diffusion model" and is applied to simulate the batch leaching test of heavy metal contaminated soils. Intraparticle diffusion and sorption equilibrium are considered. The desorption phenomena of heavy metal from soil particles are considered as a one-dimensional, polar-symmetric problem in the spherical coordinate system by supposing soil particles to be porous, perfect spheres. The results indicate that soil constituted of larger particles leach more contaminants at a certain time and faster for a certain leaching amount.

Key Words: *Tsunami, Virtual Reality, Disaster Mitigation Education*

Tsunami kill many human beings and damages economic activities seriously, such as tsunami caused by the Great East Japan Earthquake in 2011. It is very important to develop useful modelling, simulation and visualization methods for tsunami waves in order to perform the planning and design for the community development and the prevention of disaster. The visualization is also important to understand the power of tsunami and to improve the consciousness of disaster prevention. Recently, the visualization using the virtual reality (VR) technology is becoming more popular for numerical simulations.

In this presentation, the modelling, simulation and visualization methods are presented for tsunami waves. For the modelling method, several GIS, CAD and AUV data are employed. The stabilized finite element method is employed for tsunami based on the shallow water equation. We also propose a visualization system linked to the evacuation simulation using virtual reality technology to understand the power of tsunami and the importance of the evacuation. The present modelling, simulation and visualization methods are shown to be useful tools for disaster mitigation education.

Multiple Time Scales and DG Methods for Multi-Layer Ocean Modeling

Robert L. Higdon

Department of Mathematics, Oregon State University, Corvallis, Oregon 97331-4605, USA,
robert.higdon@oregonstate.edu

Key Words: Ocean modeling, multiple time scales, discontinuous Galerkin

The large-scale dynamics of the ocean contain motions that vary on a wide range of time scales. For the sake of computational efficiency, numerical models of ocean circulation generally split the fast and slow motions into separate subsystems that are solved by different techniques. The fast motions are represented by a vertically-integrated system that is similar to the shallow water equations. The other subsystem employs governing equations in each of the fluid layers. In this situation, it is essential to maintain various kinds of communication and consistency between the two subsystems. This talk will discuss such measures in the case where the spatial discretization is accomplished by discontinuous Galerkin (DG) methods. These measures include some ones that were recently encountered in the context of thin layers that can arise when layer interfaces outcrop to the upper surface of the fluid or when layer interfaces intersect variable topography at the bottom of the fluid.

Multivariate Flood Fragility Analysis for USACE Inland Levees

kubatko.3@osu.edu

Key Words: *fragility analysis, flood prevention, overflow, inland levees*

Floods cause more casualties than any other natural hazard in the United States so flood protection barriers like levees are highly important to preventing devastating damages to life and infrastructure. Levees can be classified according to their risk assessment as with the United States Army Corps of Engineers (USACE) Inland Levee Classification system [1], and according to their composition and structure. Understanding how different classes of levees perform during one of the most common failure events, overflow failure, can help improve flood prevention measures by predicting when, where and how levees will fail. This study serves to analyze the performance of several classes of levees during overflow failure and create flood fragility models to assess their capabilities. The parameters used as random variables for the fragility models are discussed in detail and the results of the study will be reported using graphical and analytical data. Numerical results detailing the conclusions gathered and further research necessary to make this study more robust will be presented.

On the shallow water, diffusive, and kinematic flow approximations for modeling rainfall runoff

Ethan J. Kubatko[1*], Younghun Kang[1] and Mackenzie Hudson[1]

[1] The Ohio State University, Department of Civil, Environmental and Geodetic Engineering, 2070 Neil Avenue, Columbus, OH 43210, kubatko.3@osu.edu

Key Words: Shallow water flow, diffusive wave equation, kinematic wave equation, rainfall runoff, finite element

Rainfall runoff can be a significant contributing factor to inland flooding during hurricanes due to the accompanying torrential rainfall that often occurs. When the rainfall rate exceeds the local infiltration rate of the inland area, overland flow occurs in the form of rainfall runoff. While this overland flow can be modeled using the full shallow water equations (with the addition of a source term for rainfall), simpler approximations to the shallow water equations — namely, the diffusive and kinematic wave approximations — have been shown to accurately represent overland flow under conditions often encountered in natural watersheds. In this work, we compare numerical solutions to the full shallow water, diffusive, and kinematic wave flow equations for a variety of rainfall runoff flow scenarios and discuss the merits of each approximation in terms of accuracy and computational cost.

Representation of Coastal Protections in the Shallow Water Equations Without CFL Restrictions

Kyle T. Mandli* and Chanyang Ryoo
Applied Physics and Applied Mathematics Department
Columbia University in the City of New York

The shallow water equations provide the basic modeling equations for a number of coastal flooding hazards, such as tsunamis and storm surge. In realistic scenarios there are often structures important to these flows that have a large extent but small width, including sea-walls, berms and harbor barriers. Explicit time stepping schemes, most often used for the shallow water equations, can therefore suffer from time step restrictions due to the CFL condition. In this talk, we introduce a set of approaches that sidestep these issues by allowing a barrier to have zero-width and to cut a cell arbitrarily without suffering from CFL restrictions. This is done by supplementing existing Riemann solvers and leveraging cut-cell methods that preserve the properties of the Riemann solver and add negligible cost to the original solvers.

Time Domain Sound Field Analysis Using the Finite Element Method and the Fast Multipole Boundary Element Method

Key Words: *Finite Element Method, Boundary Element Method, Noise Barrier, Auralization*

Noise is one of the seven major types of pollution in Japan, and it leads to the highest number of complaints according to a survey published by the Ministry of Internal Affairs and Communications in December 2021. Especially in urban areas, the evaluation of noise has been an urgent issue for planning and designing various constructions, such as roads, railways, and airports. Several evaluation methods for traffic noise simulation have been utilized. Based on the frame of reference used, those methods can be classified into two categories: 1) Methods based on the geometrical acoustic theory and 2) Methods based on acoustic wave theory. Both methods have advantages and disadvantages. For geometrical acoustic theory methods, the CPU time is very short but the numerical accuracy is comparatively low. Acoustic wave theory methods, on the other hand, provide accurate solutions but large-scale simulations.

This paper presents a noise evaluation system based on acoustic wave theory. This paper utilizes two methods – the finite element method [1] and the boundary element method using a fast multipole method [2], which are employed for the discretization of unsteady wave equation – and compares the numerical results of the benchmark problem. In addition, we show the results using the analytical model of the complex shape based on standard specifications of noise barriers and discuss the difference of the numerical results and auralization results between the two methods.

Towards Improved Storm Surge Modelling Using Spaceborne GNSS-R Systems

Mohammad Al-Khaldi[1]*, Joel T. Johnson[2], Stephen J. Katzberg[3,4], Younghun Kang[2], Ethan Kubatko[2] and Scott Gleason[1]
[1]University Cooperation for Atmospheric Research, Boulder, CO, USA
[2]The Ohio State University, Columbus, OH, USA
[3]NASA Langley Research Center, Hampton, VA, USA
[4]South Carolina State University, Orangeburg, SC, USA

Key Words: *Global Navigation Satellite Systems Reflectometry (GNSS-R), tropical cyclones, storm surge, CYGNSS*

The ability to provide accurate meteorological input wind fields is key for accurate storm surge modelling and prediction. Because tropical cyclones spend most of their life cycle in the open ocean and exist over large spatial scales, direct *in-situ* wind observations are challenging. Cyclone winds also can evolve rapidly, particularly as they make landfall. These challenges motivate exploring the use of remote sensing measurements of ocean winds for storm surge prediction. NASA's Cyclone Global Navigation Satellite System (CYGNSS) Earth Venture Mission (EVM) [1]-[2] is particularly well suited for this purpose and for providing insights into storm surge inducing tropical cyclone wind fields and their evolution in time. CYGNSS uses GNSS-Reflectometry in which CYGNSS's eight satellite-based receivers together with GPS satellites form a bistatic radar geometry (the GPS satellites act as transmitters and CYGNSS satellites act as receivers) such that over any given measurement reporting period (typically 0.5-1 seconds), the constellation is capable of providing 32 measurements of ocean winds. These measurement properties allow CYGNSS to provide extensive spatial coverage and frequent temporal revisits when compared to other ocean wind speed remote sensing approaches.

This presentation will present updates on a previously reported 'matched filter' framework in which CYGNSS's 'special-mode' full-DDM measurements are used to estimate maximum tropical cyclone winds that are further used to produce cyclone wind fields using a parametric approach [3]. Particular emphasis is placed on the potential for using CYGNSS's measurements for the accurate retrieval of maximum hurricane winds relative to independent reference datasets. The use of these CYGNSS-derived wind fields in ADvanced CIRCulation (ADCIRC) model storm surge simulations will also be presented, along with a discussion of the utility of spaceborne GNSS-R system measurements in storm surge prediction. Results from the approach are compared with storm surge predictions using 'Best Track' derived wind fields and with available *in situ* storm surge data for storms of interest over the period 2017-2021.

Key Words: *Bacteria, Cementitious Composite, Microstructure*

In order to achieve self-healing ability and to prolong the lifespan of cementitious composites, incorporation of bacteria has been investigated in recent decades [1]. The incorporation of bacteria into cementitious composites has advantages on repairing cracks which cracks can be autonomously and perpetually sealed via calcite precipitation of the bacteria [2]. Moreover, microbial-induced calcite precipitation is reported to densify the microstructure of the cementitious materials, thus can improve mechanical performances including the compressive strength and permeability of the cementitious materials [3]. Carbonate ions released by the ureolytic activity of the bacteria can combine adjacent cations to precipitate carbonate minerals which are able to reduce porosity in the microstructure [2]. Consequently, dense microstructure and enhanced mechanical performances can be achieved by the microbial-induced calcite precipitation. This paper revisits earlier works on the microstructural properties of the bacteria-based cementitious composites. An initial work on the early stage hydration of the bacterial-based cementitious materials will also be briefly presented [4].

Applicability of Large-Scale Finite Element Analysis to Nonlinear Problems of Concrete Structures

Eiji Tanaka[1*], Manabu Uchiyama[1]

[1] Institute of Technology, Shimizu Corporation, 3-4-17 Etchujima, Koto-ku,Tokyo, Japan, tanaka_e@shimz.co.jp

Key Words: *Large-Scale Analysis, Concrete, Smeared Crack, Boundary Nonlinearity*

This paper presents a study for large-scale nonlinear analysis of civil engineering structures. Conventional structural calculations of civil structures are performed using frame analysis based on beam and spring elements to reduce computation time. However, these simplified numerical modeling approaches are not necessarily required owing to the recent development of computers that enable computing of complex problems. In addition, the numerical modeling must be elaborated for complicated large-scale problems, such as the seismic safety assessment of critical infrastructure (e.g., nuclear power plants) and performance-based design to evaluate the certain performance directly without traditional specifications. In this study, large-scale parallel analysis is employed to improve efficiency when solving the abovementioned problems. The analysis procedure is based on the open-source code FrontISTR[1], deployed using the parallel finite element method (FEM). Furthermore, nonlinearity characterizing the behavior of concrete structures is introduced into the large-scale analysis.

Concrete structures exhibit the combinations of several sources of nonlinearity. In this study, we considered the effects of material nonlinearity and boundary nonlinearity. First, a non-orthogonal multi-directional smeared crack model[2] is implemented to accurately simulate the material nonlinearity of concrete material. This model accepts multiple cracks in an element so that it is appropriate to simulate complicated crack failure under cyclic loading, such as the seismic response. Next, we employed a contact analysis procedure based on penalty method to address the boundary nonlinearity. Therefore, the large-scale nonlinear analysis method of concrete structures is achieved.

Finally, we examined the applicability of the proposed method to large-scale problems through the nonlinear seismic response analysis of a concrete gravity dam and its foundation. The dam is separated into a certain number of cantilever monoliths by contraction joints, so that strong earthquake can induce opening-closing of the joints and crack failure of concrete material. The numerical results revealed that the proposed method can evaluate preceding nonlinear behavior of the dam and the practicality and scalability of the proposed method are sufficient for practical purposes. Therefore, it is concluded that the proposed method can overcome the large-scale nonlinear problem of concrete structures in the future.

Key Words: *Reinforced Concrete Slab, Air Blast, TNT, Finite Element Analysis, Concrete Damage*

Explosive loading can be a serious threat to urban buildings and infrastructures [1]. An explosion can be defined as a large-scale and high-speed release of energy, and it generates a huge amount of shock waves. The shock wave can be classified as high explosive when it is faster than the speed of sound and as deflagration when it is slower than the speed of sound [2]. Civil engineering mainly deals with high explosive phenomena that can cause damage to civil infrastructures.

Explosive substances can exist in solid, liquid, or gaseous state, and most of the high explosive phenomena are caused by solid explosive substances such as trinitrotoluene (TNT). In the case of TNT, a typical solid state explosive substance, 3000-4000°C gas is expanded to a pressure of 250-350 tonf/cm^2 when exploding in the air [3]. As a result, the expansion of air generates shock waves, thereby releasing energy to destroy the reinforced-concrete (RC) structures. However, the level of damage of RC structures may vary depending on the arrangement of rebars, concrete properties, and design of the structure.

In the present study, preliminary computational analysis of the structural response and damage of reinforced concrete (RC) slabs subjected to open air blast by using LS-DYNA explicit code. For computational analysis, various TNT mass levels were considered and implemented to ConWep code in LS-DYNA to simulate shock pressures on RC structures. First, incident and reflected pressures were numerically predicted and compared with measured pressure data [4]. Then, rear displacement and damage of RC slabs were computationally predicted and compared with the air blast experimental data [4]. Finally, an applicability of the computational approach using ConWep code in LS-DYNA to the optimal blast protective design will be discussed.

Key Words: *Conductive polymeric composites, Carbon nanotube, Piezoresistive sensor*

In recent years, studies have focused on the utilization of conductive polymeric composites for sensing applications [1,2]. Conductive polymeric composites have been practically applied in many sensing fields such as strain sensors, thermostats, and stretchable transistors [1,2]. Carbon nanotube (CNT) is one of the typical electrically conductive fillers consisting of conductive polymeric composites. Owing to their high aspect ratio and outstanding electrical conductivity, electrical pathways can be readily formed in a polymer matrix with only small amounts of CNTs [1]. Researchers have developed various piezoresistive CNT-incorporated polymeric composite sensors, reporting that the electrical resistance of the composites has been found to increase with increasing strain but remains almost constant as strain is released [2,3]. This paper overviews recent progress in piezoresistive CNT-incorporated polymeric composite sensors, including initial work on micromechanical prediction of the sensors done by the authors [4].

Key Words: *Micromechanics, Fiber-reinforced Laminates, Failure Analysis, Damage evolution*

In the past few decades, fiber-reinforced laminates (FRLs) have been widely used in various infrastructures owing to their high strength, durability, and rigidity [1]. Based upon inherent characteristics of FRLs, the presence of some inevitable defects such as micro-crack, void, fiber debonding, and an imperfect interface between fiber and matrix lead to difficulty in the failure analysis [2]. Correspondingly, the inevitable damage parameters of FRLs should be well addressed to precisely predict the failure [2]. Many of the relevant studies have been reported that void growth, fiber debonding, and imperfect interface potentially provoke the inter-fiber fracture (IFF), leading to inevitable damage factors in FRLs [2,3]. For the failure analysis of the IFF, the micromechanical framework considering the micro-void growth and fiber debonding has been proposed [3,4]. Puck failure theory can also be adopted as a phenomenological and physical analytical method to predict the failure analysis in FRLs [4,5]. This paper reviews micromechanics-based failure analysis for FRLs specifically via Puck failure criteria [5]. In addition, a preliminary study conducted by the authors to predict the behavior of the FRLs is briefly introduced [5].

Key Words: *Bottom ash; Geopolymer; alkali activation; strength; expansion;*

This research investigates a new method for application of bottom ash in geopolymer composite. Bottom ash is a by-product of thermal power plants, and many studies have been conducted to utilize bottom ash for geopolymer. However, it is difficult to use a large amount of bottom ash due to reasons such as decrease in strength, gas generation, and expansion. Therefore, in this study, a method of using bottom ash as an activator was developed. The degree of activation of bottom ash was analysed through ICP and pH test. Also geopolymer composites were conducted compressive strength and expansion test. It was observed that a large amount of gas was generated and escaped in the process of dissolving the bottom ash in the activator, and the compressive strength was also increased compared to typical method of replacement. Based on the result, it is expected that the suggested method of utilizing bottom ash can be an effective solution to consume large quantities of bottom ash in the concrete industry.

Key Words: Circular Tubes, Lattice Core. Axial Compression, FEM, Energy Absorption

Thin-walled circular and square tubes have been widely used in automobiles, ships and aerospace engineering as main structural parts owing to their effective energy absorption capacity per unit mass. There are many studies concerning the static and dynamic response of thin-walled tubes under axial compression[1, 2]. One of our co-authors has also published a paper regarding the estimation technique of the initial peak load for circular tubes subjected to axial impact loading[2].

Recently, more and more attention have been paid to improve the energy absorption capacity of tubes by adding porous materials such as foams and honeycomb cores in the tubes[3]. On the other hand. due to the novel development of additive manufacturing technology, a precise and complex lattice cores with the length of micrometres can be fabricated easily, and their stiffness and strength have been investigated by many researchers.

In this paper, the axial compressive response of lattice-cored sandwich tubes has been studied by using a nonlinear finite element method. The effects of micro-architecture of the lattice core and the overall geometries of the sandwich tube have been investigated. In addition, the lattice-cored tubes were manufactured by using our in-house metal 3D printer, and their axial compression tests have been conducted. The numerical and experimental results agree well with each other, and their great abilities of the energy absorption by the existence of lattice core have been confirmed.

Key Words: *Creasing, Energy barrier, Energy bottom, Finite element analysis*

In this study, we investigate the creasing instability using a perturbation force-based analysis and clarify the energy barrier necessary for the occurrence of the crease and the stable state of the crease, named energy bottom. Two-dimensional finite element analysis is conducted on the elastomer assigned with the incompressible Neo-Hookean material, along with considering compressive strain and wavelength of the crease as parameters. A perturbation force is applied to a point on the top surface of the elastomer. To simulate the creasing, we introduce the artificial viscosity, and later its effect is removed.

When a perturbation force works enough to get over the energy barrier, the crease is induced on the top surface of the elastomer. The energy barrier becomes smaller with increasing strain. In addition, the high resolution of finite elements makes the energy barrier small. These tendencies have already been reported in the previous study [1]. On the other hand, the energy barrier is independent of the wavelength of the crease. Thus, the onset of creasing is not affected by the scale of deformation.

Once the stored energy gets over the energy barrier, the crease quickly grows toward the energy bottom. The energy bottom is independent of the mesh resolution, unlike the energy barrier, which means that the evolution of the crease can be reasonably simulated. The wavelength of the crease at the energy bottom increases with a rise in applied compressive strain [2]. On the other hand, as applied compressive strain approaches the threshold of creasing, the wavelength converges to a specific length.

Key Words: *Pressure effect, Lode dependence, Finite element analysis, Digital image correlation*

Over the decades, the ductile fracture behaviours of metals have been studied by many researchers [1]-[4]. In the classical metal plasticity, it is assumed that the hydrostatic pressure has negligible effect on the materials strain hardening, and that the flow stress including the initiation of fracture is independent of the third deviatoric stress invariant. However, recent experiments on metals have shown that the both the pressure effect and the effect of the third deviatoric stress invariant should be included in the constitutive description of the materials [1]-[4].
In this study, the relationship between stress triaxiality and fracture strain of high-strength steel sheets that are widely used for many parts in automobiles was investigated through the nonlinear finite element analysis (FEA) and the strain measurement using stereo digital image correlation (Stereo-DIC). In the experiment, tensile load was applied to a notched thin sheet specimen, and the displacement and strain distributions on the both surfaces of a specimen were measured using a dual Stereo-DIC system. Then, not only the time-variation of the in-plane strains but the through-thickness strain and the stress triaxiality during the test were evaluated. In this numerical study, damage growth was considered in our FE model with a customized subroutine program. The results show that the relationship between the stress state of the high-strength steel sheet and fracture strain can be predicted with high accuracy by comparing with the experimental results. It was found that the larger the stress triaxiality, the greater the effect of damage.

Key Words: *FEM, Damage model, Fracture mechanics, Grain size, GP model, Extreme value statistics*

Structural ceramics have excellent properties such as heat resistance. However, the problem is that there is a large variation in strength compared to other materials. This is due to the distribution of microscopic defects inside the ceramics [1]. In order to reproduce these characteristics, the author's group has proposed a finite element analysis method to predict the variation in fracture strength of ceramics based on internal microstructure data (relative density, pore size distribution, grain size distribution, etc.) [2][3]. However, there is still room for improvement in this approach. One of them is that the analysis results depend on the mesh size.

In this study, we aimed to improve this problem by applying the Generalized Pareto (GP) model, one of the extreme value statistics, to the pore size distribution. The pore size distribution is the most important factor in the fracture strength of ceramics among the internal microstructure data. AS999, a high-purity alumina (Al_2O_3), is used as the target material, and data on the size and number of pores are measured by X-ray CT. Then, the parameters of the GP model were determined using the PWM method. Furthermore, the threshold of minimum pore size was determined to 0.009 mm based on the mean excess plot.

In the finite element analysis, pores is generated randomly in each element while according to GP model, and the maximum value among them is adopted as the maximum pore size in respective elements. It should be noted that the number of generated pore is adjusted to the change in mesh size.

As a result, our method was able to reproduce the results of the three-point and four-point bending tests, including the scatter of strength. The same three-point bending test was also performed with different mesh sizes of the specimens, and the test results were also reproduced.

In summary, this study was able to solve the mesh size dependency, which was an issue of the previous method [2][3]. In addition, in the process of applying the GP model, we developed the general scheme to determine the internal structure data from the measurement results by X-ray CT. In the future, we will study how to apply the measurement results by SEM and other methods.

dai.okumura@mae.nagoya-u.ac.jp

Key Words: *Nearly incompressible, Thermo-mechanics, Incremental variational formulation*

In this study, we propose an incremental mean-dilatation method to conduct thermo-mechanically coupled analysis on nearly incompressible materials. To this end, we define the thermo-mechanically coupled energy rate potential in line with an incremental variational framework (IVF)[1]. The energy rate potential contains three kinds of energy potential, internal energy, dissipation potential, and Fourier potential, and also considered the incompressible condition with Lagrange multiplier[2]. Then, the equilibrium temperature stemming from the volume change is originally introduced in connection with the introductions of volume change and pressure, which are constant in a whole domain of continuum body.

As a result, the established thermo-mechanically coupled problem, including control of volume change, is variationally consistent, so that we can enjoy several benefits associated with numerical accuracy and efficiency. For example, taking advantage of the benefit, which the consistent tangent modulus necessarily becomes symmetry, the fully implicit update algorithm based on the standard type of Newton-Raphson method can be constructed. Further, the proposed method can avoid the volume locking occurring in the use of the lower-order element, which is expected to improve the computational stability and efficiency.

To validate the applicability of the proposed method in practical use, the several numerical problems for hyperelastic and standard dissipative solids are solved by means of three kinds of numerical methods: standard IVF with 1st order element, standard IVF with 2nd order element, the proposed method with 1st order element.

Numerical study on effect of boundary condition for collapse behavior of plate subjected to axial compression and bending

Kenichi Masuda[1*]

[1] University of Toyama, Gofuku 3190 Toyama 930-8555 Japan, masuda@eng.u-toyama.ac.jp

Key Words: *FEM, Plate, Compression, Bending, Buckling*

In this research, the collapse behavior of a thin plate subjected to axial compression and bending is studied by using the finite element method. For various boundary conditions, the stress distributions at ultimate are compared with international specifications. The collapse of the plate which has various hardening characteristics is investigated. It means that local buckling, post-local buckling redistribution of stress and critical strain are investigated. Based on the above investigation, an approximate prediction of the collapse stress was proposed. Further, its validity was verified comparing with the numerical results by the FEM under various material and geometric properties.

Key Words: *Pallet Rack System, Progressive Collapse, Impact, ASI-Gauss Code, FEM*

Pallet rack systems used in warehouse are generally constructed with light weight uprights and beams, and are frequently subjected to accidental impact by forklift trucks [1]. When heavily loaded, those impact may cause partial or progressive collapse of rack systems which will mostly lead to catastrophic loss of goods and sometimes of human lives [2].

In this study, numerical investigation was conducted on progressive collapse behavior of rack systems using the Adaptively Shifted Integration (ASI) - Gauss code [3], which can supply highly accurate elasto-plastic solutions with minimum subdivision of finite elements and can stably simulate nonlinear phenomena such as member fracture and contact. Push-down and push-over analyses with and without upright removal were carried out on a two-bay rack system to observe the standard strength and effects of plan bracings installed at different levels. Furthermore, dynamic analyses with impact load in cross-aisle and down-aisle directions under fully- and over-loaded conditions were conducted and the effects of plan bracings were investigated.

According to the numerical results, plan bracings installed at first level affect greatly against lateral impact at lower levels, and those installed at top level affect greatly in preventing downward collapse making the most of its catenary action. Progressive collapse analysis of a large-scale pallet rack system was also conducted and the effect of optimal installation of plan bracings was confirmed.

Key Words: *Steel Deck, Steel Pipe, Reinforced Concrete Slab, Impact Test, Finite element analysis*

When constructing a building above public traffic lines such as roads and railway tracks, it is necessary to ensure sufficient safety to the space under the slabs. If a hanged object fall and perforate the reinforced concrete slab, and debris caused by the impact are scattered under the slab, those could cause serious consequences such as human casualties. This study focuses on those debris scattering under the slab. To prevent this, this study proposes an anchoring mechanism into concrete at the edge of steel deck plate used as permanent formwork.

In a typical steel-framed building, slab is constructed by pouring concrete on the deck used as a permanent formwork. Since the deck is usually not anchored into the concrete, it can easily fall off by the impact, and the generated debris scatter under the slab. In this study, the deck is anchored into the concrete by folding up the deck plate ends. The anchoring mechanism would be effective in preventing the deck plate from falling off by the impact, and damaged concrete from scattering.

In this study, half scale impact tests were conducted on specimens assumed to be RC slabs used in buildings, and it was confirmed that the proposed anchoring mechanism was effective in preventing the deck plate from falling off and scattering debris. In the cases without the anchor mechanism, the deck plate fell off at a falling height of 7.5 m, but in the case with the anchor mechanism, the deck did not fall off at 14 m, and fell off at 15m.

Moreover, it was confirmed that the effects of this experiment behaviour could be evaluated by finite element analysis. This analysis was performed with LS-DYNA. The anchoring mechanism between the concrete and the deck plate was reproduced using tie-break contact in LS-DYNA. In the case with the mechanism, the deck falling off and debris scattering were suppressed at a falling height of 13m in the analysis as well as the test. In addition, the falling object velocity, penetration depth of impact area of the slab, and reaction force were also in close agreement with the experiment.

It is now possible to suppress the scattering of debris caused by the impact under the slab in the event of a collision with a falling object during construction work above the public traffic line, thereby improving the safety of the lower part of the slab. As a result, such construction work can be made smoother, which will contribute to the advanced use of space on public traffic lines and the development of the city.

Key Words: Green-Ampt Infiltration, Surface Flow, Hovland Method, 3D Slope Stability Analysis

Because landslides caused by heavy rainfall have occurred every year all over the world, landslide mitigation and prevention are recognized as a global issue. Although a lot of slope stability analyses[1] have been reported, it is still difficult to predict landslide occurrence in a wide area with time-series data of rainfall. To overcome this problem, this study presents a novel framework for rainfall-induced landslide prediction by combining hydrodynamics and three-dimensional slope stability analysis.

In the proposed framework, infiltration analysis using the Green-Ampt model and two-dimensional surface flow analysis are employed to represent water transportation induced by rainfall. Regarding to the three-dimensional slope stability analysis, the Hovland method is employed on the assumption of ellipsoid-shaped slip surfaces. The infiltration depth at each calculation point is evaluated by the infiltration analysis and surface flow analysis, and the obtained spatial distribution of infiltration depth is used as an input datum for the slope stability analysis. A part of the area in Kamaishi City, Iwate Prefecture, located in the northeast of Japan, is selected as a target area for analysis. A lot of landslides occurred in the target area due to a typhoon attacked on October 12 and 13, 2019. Detailed terrain data measured using UAV were obtained before and after the typhoon. In addition, the actual slope failure locations were identified through a field survey. These data are used to verify the accuracy of the numerical analysis. The obtained results indicate that the proposed framework has a high potential for the predicting rainfall-induced landslides. It should be also noted that the results manifest that small forestry roads affected landslide occurrence.

Key Words: Lattice Boltzmann method, Cumulants, Free-surface flow, Volume-of-fluid, Bulk viscosity

Free-surface flow problems occur in numerous disaster simulations such as tsunami in an urban area. The characteristics of these flow fields are three-dimensional, highly non-linear and non-hydrostatic. A fully three-dimensional free-surface fluid model is required to simulate such a flow field. In recent years, the cumulant lattice Boltzmann method (CLBM) [1] has attracted much attention as a novel simulation method and has been successfully applied to various engineering fields.

In CLBM, the bulk viscosity is set independently of the kinematic viscosity. It is one of the critical parameters determining the accuracy and stability of impact pressure estimation in the weakly compressible flow model. When the bulk viscosity is set appropriately, the acoustic error caused by excessive numerical oscillations due to sound waves can be suppressed. However, if the bulk viscosity is too large, the calculation accuracy may be degraded. To ensure accurate calculations while suppressing the numerical oscillation of the pressure, the bulk viscosity must be validated.

In this study, we proposed a single-phase free-surface flow model based on CLBM using the volume-of-fluid (VOF) model to capture the interface. We performed the dam-breaking flow problem [2] to validate CLBM for estimating impact pressure in the violent flow field. The relationship between the bulk viscosity and impact pressure was examined. We demonstrated that values of the bulk viscosity between 0.6 and 1.0 are reasonable in terms of the reproducibility of peak pressure and suppression of pressure oscillations for violent flow fields. The results of the proposed model are in good agreement with the experimental results. It is concluded that the free-surface flow model using CLBM is an advantageous method for calculating the impact pressure acting on a structure, which suppresses the numerical oscillation.

Key Words: *Long-Period Bridge System, 3D FE Model, 2016 Kumamoto Earthquake*

The purpose of this study is to clarify the damage mechanism of a long-period bridge structure-underground interconnected system, such as the Ohkirihata Bridge damaged in the 2016 Kumamoto earthquake, subjected to the combined loads of long-period pulsive ground motions, surface fault displacements, and ground deformation by slope failures.
Firstly, the site-specific waveforms were estimated by the finite difference method as input ground accelerations to a bridge system model. Secondly, the target bridge system was modeled by three dimensional (3D) finite element (FE) method with 441,196 nodes and 2,437,126 solid elements. The target bridge system is the affected Ohkirihata Bridge which is a 5-span continuous steel girder bridge with the length of 265.4 m long and the width of 12.5 m wide. For the 3D FE model, the reinforced concrete (RC) slabs and steel girders were idealised by equivalent tetrahedral first-order elements with Young's modulus and density of mass of parallel serises of slabs and girders. The five laminated rubber bearings with total rubber thickness of 85 mm -150 mm are placed upon the top of each pier: A1Bs, P1Bs-P4Bs, A2Bs. The layers of natural rubbers and steel plates consisting of a bearing were modeled by hexahedral first-order elements with same plain size and different heights. The RC piers P1-P4 and RC abutments A1, A2 were modeled by tetrahedral first-order elements. The RC foundations of caisson piles supporting P1, P4 and A2 and cast-in-place piles supporting A1, P2 and P3 were modeled by tetrahedral first-order elements. The underground layers consist of nine different soil materials which mechanical properties were identified by soil tests. These shallowed layers were modeled by tetrahedral first-order elements. The minimum sizes of all tetrahedral first-order elements were set as about 1m in average. The stress-strain relationships set for all elements were assumed to behave isotropically in the elastic ranges.
We used a open-source program for large-scale parallel computation of FE analysis: FrontISTR. Linear dynamic analysis was performed by applying the site-specific waveforms of the main ground motions for 10 seconds as equivalent inertial forces to all nodes of the 3D FE model. The Newmark-β method (β=0.25, γ=0.5) was used in the time integration scheme. The time interval was set to be 0.005 sec, and the number of computational steps was 2000. Damping effect on equations of motion was formulated by stiffness-proportional damping matrix. The CG method was applied for the numerical linearization, and the SSOR preprocessing was used. The threshold for determining the convergence about relative error of computed displacement was set at 1.0×10^{-6}.
P3B, P2B, P4B, A2B, and P1B, in that transient order, exceed allowable shear strain of 250% in the 3.9 seconds before the maximum amplitudes of the site-specific EW and NS waveforms, and A1B follows to exceed 250% after the peak. The time-series horizontal motions of the superstructure supported by these bearings until the 3.9 seconds are demonstrated as first, the superstructure moves to the northwest direction between 1.86 s and 2.49 s, next to the southeast direction between 2.49 s and 2.82 s with a slight clockwise rotation around the A1, and further to the north direction between 2.82 s and 3.24 s with a counterclockwise rotation around the A1. The reasons are why the excitation of long-period pulsive ground motions to the primary eigenmode of the target bridge system in the 1.2 s to 1.5 s natural period causes these processes.

Key Words: ISPH-DEM, Resolved and Unresolved coupling, Karman vortex

As global warming progresses and seismic activity increases, landslides caused by torrential rains and tsunamis by huge earthquakes are becoming more frequent. There is no end to the damage to structures and human lives continue to occur all over the world. To estimate the damage level of these natural disasters in advance, numerical simulations using the particle method, which can predict the post-collapse behaviors, have been considered promising.

We develop a fluid-soil coupling analysis solver using ISPH [1] and DEM, which are both Lagrangian particle simulators, to analyze the seepage failure of a breakwater mound caused by a tsunami [2]. Since the simulator is suitable for reproducing discrete phenomena such as slope failure with sediment separation and merge, it can also estimate the protection effects of the breakwater with permeable gabions. Resolved coupling technique without permeability is applied to the caisson blocks and un-resolved coupling technique, which treats as a macroscopic seepage flow analysis, is applied to the soil mound and the gabions modeled by DEM. The coupling simulator reproduces the seepage failure process including the overturning and sliding of caissons and the backward erosion of mounds.

On the other hand, quantitative evaluation of the seepage failure of the rubble mound, in which the un-resolved coupling technique is applied, is a difficult issue because it relies on an empirical macroscopic drag force model. Through numerical tests, we recognize a hybrid technique between the resolved and un-resolved model may become more effective for the two-phase mixture flow of soil and water. Before the development of hybrid techniques, we have been working on the improvement of ISPH fluid analysis (negative pressure calculation, gradient, and Laplacian model, etc.) to reproduce the pore flow in the pore space between soil particles in detail by micro-scale Resolved coupling analysis. Then, we simulate the Karman vortex street behind the cylinder and sphere in the flow channel using these methods.

Key Words: *Tsunami scenario detection, synthetic GNSS data, POD, Bayesian update*

Tsunamis are one of the most significant coastal risks in the international community. Especially in Japan, which is frequently threatened by earthquakes and its subsequent tsunami inundation, considerable attention has been paid to the expected Nankai-Trough earthquake and tsunami in the next few decades, which will be an event with extremely short evacuation time (<30 mins) for the residents. Although there have been many tsunami forecast systems proposed, there is still room to improve minimizing the uncertainties relevant to the deterministic numerical simulations or erroneous/noisy data acquired in real-time.

This study focuses on the improvements of the previous tsunami scenario detection method [1], which uses a form of unsupervised learning and sequential probability updates. We now also incorporate geodetic data measured at GNSS stations. The fakequakes software [5] is used to generate 600 synthetic kinematic slip distributions for Nankai-trough-going ruptures, based on techniques developed in [2,6], along with the corresponding seafloor deformations and synthetic GNSS waveforms. The subsequent tsunami propagation and inundation in Kochi city, which is located in southern Japan, are realized by GeoClaw [3]. Then the approach developed in [1], which utilizes both POD and a Bayesian update, is used to identify the most similar tsunami scenario from a pre-computed database, which is a priori tagged together with its geodetic information. The validity of the predicted tsunami scenario is evaluated by either the wave history data at some synthetic gauges offshore, or the maximum inundation values in coastal zones. The previous reports on the use of GNSS data to improve tsunami forecasts [4] are examined in the context of our approach, by testing the combined/solitary use of GNSS (and the synthetic wave history data at gauge points).

Key Words: *Tsunami evacuation building, Debris impact, Fluid-structure interaction, Partitioned FSI analysis, Particle method, ASI-Gauss method, Improved ERP model*

Robustness of a tsunami evacuation building is one of the most important problems in protecting lives and properties against tsunami. To ensure robustness, it is necessary to design with consideration of strict external forces, including dynamic fluid force and debris impact force, caused by tsunami.

In this research, we numerically simulate behaviour of a tsunami evacuation building under tidal wave and debris impact to investigate trend of the forces due to tsunami. Partitioned fluid-structure interaction analysis scheme coupled with stabilized ISPH (Incompressible Smoothed Particle Hydrodynamics) method [1] and ASI (Adaptive Shifted Integration)-Gauss method [2] is applied for the simulation. The ISPH method is a semi-implicit particle method and suitable for free surface flow problem such as tsunami. The ASI-Gauss method is a finite element method using linear Timoshenko beam elements and can express a plastic hinge at any position in an element by shifting a numerical integration point. Besides, improved ERP (Explicitly Represented Polygon) wall boundary model is used as interface modelling between fluid and structure domain. This model accurately satisfies boundary conditions on solid walls and can directly calculate fluid force exerted on the walls.

As validation of the proposed FSI coupling scheme, we solved free fall problem of a beam member and dam break problem with an elastic obstacle. Results of these analysis showed that the coupling scheme can obtain precise solution. Furthermore, we conducted a simulation of a tsunami evacuation building under tsunami and debris. Specification of the building was determined according to current tsunami evacuation building design standard in Japan [3]. Based on the results, damage of the building caused by tidal wave and debris impact was verified.

Key Words: *Early tsunami forecast, Genetic algorithm, Bayesian theory, Gauge placement optimization*

Large earthquakes and the subsequent tsunamis cause extensive damage to coastal areas as experienced in the 2011 Great East Japan Earthquake. In recent years, people are concerned with the Nankai megathrust earthquakes in Japan, and the coastal area of Shikoku, which is close to the plate boundary, is expected to be attacked by a tsunami immediately after the earthquake. Thus, an early tsunami forecast is extremely important for evacuation and damage mitigation. For early and reliable tsunami forecasts, a lot of cable networking systems (e.g., S-net, DONET) have been installed in the ocean surrounding Japan. However, such multiple ocean gauges should be reasonably placed realizing the early forecast under limited resources.

In this study, we propose an optimization framework to identify effective placement of gauges for the early tsunami forecast, based on the recently developed scheme[1]. Our optimization framework employs the Genetic Algorithm(GA) for detecting the placement of n gauges from $N(\gg n)$ candidate gauges, based on the data extracted from the Proper Orthogonal Decomposition(POD). Thanks to the POD technique, we can carry out GA-based optimization with the dimensionality reduced data, which allows us to handle it more efficiently. According to the previously developed scheme, we calculated the tsunami propagation by TUNAMI-N2[2] for the 1564 earthquake scenarios from Mw 7.6 to 8.8 occurring in the Nankai Trough. Then the wave height data at $N = 131$ candidate gauges are stored for each simulation result. With the characteristics of the spatial wave height distribution and the scenario-specific information, which are both extracted from POD, we could determine the n=10 sensitive gauges for the tsunami prediction by applying GA. As a validation, the scenario-specific information of a test scenario extracted from the $n = 10$ observation gauges is compared with all stored scenarios. The likelihood calculated from the sequential Bayesian updates is then used to forecast the incoming tsunami wave by weighted average. Our gauge placement optimization further sophisticates the recent early tsunami forecast system, which has advantages because they only require the likelihood calculation of the scenario using the wave height observations, without time and cost-consuming numerical simulations. Although the tsunami forecast demonstration focuses on the Nankai megaquake and the Shikoku coastal area, our framework can be applied to other earthquake scenarios and regions.

Key Words: *Tsunami mitigation, Early forecast, POD (Proper Orthogonal Decomposition), Bayesian Update*

The coast of North America located near the Cascadia subduction zone is known to be exposed to a huge earthquake/tsunami risk, although there was little awareness of this until the second part of the 20th century. The papers [1] and [2], for example, suggest that the subduction zone caused at least 18 major earthquakes in the last 10,000 years. Since the last significant earthquake occurred more than 300 years ago, the necessity of earthquakes and tsunami mitigation along the North-West coast of America seems imperative in the recent century. In this study, we evaluate the risk of tsunami triggered by earthquakes in the city of Westport (Washington) by applying the method proposed in the previous study [3] which combines Bayesian update and Proper Orthogonal Decomposition (POD). The results are compared to other data [4].
The plausible earthquakes at the targeting sites were generated by a fakequakes (fake earthquakes) software [5], and a tsunami database has been created with GeoClaw [6] considering 4 magnitude classes: M7.5, M8.0, M8.5 and M.9.0. In total, 1964 earthquake/tsunami scenarios have been created and wave history data at 30 gauge-stations were stored for the forecast process. The concept of our forecast scheme is to determine the closest scenario from the scenario database to the occurring tsunami by comparing their main characteristics, i.e. the characteristics of their time-histories. Such characteristics are extracted by POD which enables reducing the computation cost and time of the process. Then, by using the Bayesian update, uncertainties are minimised at each time step. During the whole process, particular attention is paid to the observation-time required to obtain the closest scenario to the occurring tsunami and to the evolution of the closest scenarios themselves. The forecast process is fast as the database has already been studied before the occurrence of the event and at a low cost as the main characteristics only are compared. We could also consider combining a few of the most similar scenarios. The measures of the new event are made in the shortest time period possible.

Key Words: Tsunami, Evacuation, Great East Japan Earthquake, Multi-agent simulation

In the Tohoku region, a large tsunami is expected to occur in the near future, due to the occurrence of earthquakes with epicenters along the Japan Trench[1]. In addition, there are declining birthrate and aging population, and it is necessary to keep the population age distribution in mind when considering future tsunami disaster prevention.
In this study, we focused on Yamada Town, Iwate Prefecture, which was severely damaged by the Great East Japan Earthquake, and analyzed its residents' evacuation. performed by a multi-agent system NetLogo, adopting evacuation behavior in the previous research[2], and using open data on future population[3]. The population numbers in 2020 and 2045 were set as the initial evacuee population, three cases of the evacuation start time (10, 15, and 20 minutes after the earthquake) were set. In addition, in consideration of the decrease in evacuation speed due to snow accumulation on the road in winter, and analysis was performed when evacuation was performed at low speed.
As a result, that compared to the case where evacuated 10 minutes after the earthquake, for those who evacuated 20 minutes later, the rate of non-arrival at the evacuation center would increase by about 20 points. Furthermore, it was found that when the evacuation speed in winter was applied, the rate of non-arrival at the evacuation center was higher than in summer. In the future, it is considered necessary to proceed with the evacuation verification analysis in consideration and respond to people requiring assistance during a disaster due to the declining birthrate and aging population.

Tsunami Forecasting from Sparse Observations by Semi-Supervised Outlier Detection with Generative Adversarial Network

Hirokazu Shimauchi[1*], Shinsuke Takase[2]

[1, 2] Hachinohe Institute of Technology, 88-1, Obiraki, Myo, Hachinohe, Aomori, Japan
[1] shimauchi@hi-tech.ac.jp, [2] takase@hi-tech.ac.jp

Key Words: *Tsunami Forecasting, Generative Adversarial Networks, Outlier detection*

A tsunami warning should be issued quickly using limited observational data. Liu et al. [1] construct regression models of tsunami amplitudes at locations in the Salish Sea based on hypothetical sea surface elevation observations near the entrance of the Strait of Juan de Fuca: a support vector machine was used to predict the maximum amplitude at the forecast points, two convolutional neural networks (a denoising autoencoder and a variational autoencoder) to predict the full-time series at the forecast points. Herein, we transform the regression problem of tsunami amplitude into a binary classification problem with high waves as positive examples and others as negative examples. The transformed problem can be considered as a supervised outlier detection problem since large Tsunamis are rare events. To extract the effective feature from a small number of high waves, we consider applying semi-supervised outlier detection methods. In Shimauchi [2], it was shown that the augmentation of the extracted representations by unsupervised learning methods using a generative adversarial network (GAN) enhances the performance of supervised outlier detection on several datasets.

Liu et al. [1] used a set of 1,300 synthetic data of megathrust earthquake on the Cascadia Subduction Zone, which was generated by Melgar et al. 2016. Gauge 702 (located near the entrance of the Strait) is considered as an observation point. Forecast points are assumed as Gauge 901 (located deep in Discovery Bay where fieldwork has uncovered tsunami deposits) and Gauge 911 (located in the middle of Admiralty Inlet). We set thresholds (3 meters and 5 meters) for the Gauge 901 and Gauge 911 in the data: the data points that exceed the thresholds are labelled as positive and other data as negative. The percentage of positive examples is 5% to 26%. The labelled data is split into training sets and testing sets. The baseline model of the experiment is a classification model by a support vector machine.

In the experiment, we used ROC-AUC (the area under the receiver operating characteristic curve) and precision@n (the true positive rate for the top n results in a dataset that contains n outliers) on the testing datasets as evaluation metrics. The average and standard deviation of each metrics in ten independent trials were used in the evaluation. The method in Shimauchi [2] achieved the best scores in all cases: precision@n, ROC-AUC are 81-85%, 0.97-0.99. In particular, precision@n and ROC-AUC are improved 6-18%, 3-5 compared to the baseline. The standard deviation is also improved except in one case. The experiment may suggest that accurate Tsunami forecasting is possible by semi-supervised outlier detection with unsupervised representation learning and GAN even when the observation data of Tsunami is small, under certain settings.

High-rate deformation processes of metals entail intense grain refinement and special attention needs to be paid to capture the evolution of microstructure. In this work, a new formulation for coupling Cosserat crystal plasticity and phase field is developed [1]. A common approach is to penalize kinematic incompatibility between lattice orientation and displacement-based elastic rotation [2]. However, this can lead to significant solution sensitivity to the penalty parameter, resulting in low accuracy and convergence rates. To address these issues, a duality-based formulation is developed which directly imposes the rotational kinematic compatibility. A weak inf-sup-based skew-symmetric stress projection is introduced to suppress instabilities present in the dual formulation. An additional least squares stabilization is introduced to suppress the spurious lattice rotation with a suitable parameter range derived analytically and validated numerically. The required high-order continuity is attained by the reproducing kernel approximation. It is observed that equal order displacement-rotation-phase field approximations are stable, which allows efficient employment of the same set of shape functions for all independent variables. The proposed formulation is shown to yield superior accuracy and convergence with marginal parameter sensitivity compared to the penalty-based approach and successfully captures the dominant rotational recrystallization mechanism including block dislocation structures and grain boundary migration.

A General Terrain-Fitted Coordinate System for Modelling Hazardous Shallow Flows in Mountain Area

Yih-Chin Tai*, Ching-Yuan Ma, Chi-Jyun Ko and Hock-Kiet Wong

[1] Department of Hydraulic and Ocean Engineering, National Cheng Kung University, Tainan, Taiwan
E-mail: yctai@ncku.edu.tw (corresponding author *)

Key Words: *Hazardous shallow flows; Terrain-fitted coordinate system; Cartesian Coordinate system; Digital elevation map (DEM); Mountain area*

It is non-trivial to model the hazardous shallow flows in Mountain area. It is fraught with complexities of two kinds: on the physical side, various constitutive relations are requested and have to be postulated due to the complex composition. On the modelling side, depth-integration is often employ for reducing the complexity of computation over a large domain. The Cartesian coordinate system, with *xy*-plane lies horizontally and *z*-axis pointing upwards vertically, is generally adopted for its ease of describing the constitutive relations and rugged topography. However, the depth-integration process may yield high deviation of velocity direction in case the topographic surface does not tangential to the horizon, because the flow follows on the basal surface. In the terrain-following coordinate system, the depth-averaged velocities are tangential to the basal surface, so that it can fix this drawback of velocity direction deviation. But the terrain-following coordinate system is generally limited by the constrain of shallow curvature for the topographic surface, especially when obstacles (e.g. sabo dam) are constructed in the flow paths.

In the present study we propose a general approach, which integrates the terrain-following coordinate and conventional Cartesian coordinate systems. For highly rugged topography, the terrain-fitted coordinate axes are assigned to coincide with the Gaussian-filter-smoothed basal surface, on which the highly rugged landform sits (called “sub-topography”). In comparison with the conventional Cartesian coordinate, this approach reduces the deviation of the flow velocity deviations, and the constraint of shallow curvature is fulfilled without losing the precision of the landform. It is interesting to find that the coordinate axes tend to be straight and are comparable to the Cartesian ones after Gaussian filtering for infinite times. In other words, it is a general approach of unifying the terrain-fitted coordinate system and the Cartesian coordinate one.

Numerical examples are employed with respect to a two-phase grain-fluid model (Tai, et al., 2019) for investigating the results computed based on the Cartesian approach and on the one with sub-topography in terrain-fitted coordinate system. All the computations are performed by a CUDA-GPU accelerated simulation tool, MoSES_2PDF (Ko et al., 2021). And a back-calculation of historical event (2009 Hsaiolin landslide event) will be shown for highlighting the potential of engineering application.

Deep Learning Enhanced Dynamic Meshfree Analysis

Dongdong Wang*, Jian Chen, Jun Chen and Zhiwei Lin

Department of Civil Engineering, Xiamen University, Xiamen, Fujian 361005, China
E-mail: ddwang@xmu.edu.cn

Key Words: *Meshfree Method, Dynamic Analysis, Recurrent Convolutional Neural Network, Surrogate Model, Computational Efficiency*

Dynamic meshfree analysis requires the computation of structural response recursively at each time step, which significantly increases the computation burden since in each time step, the complexity in meshfree approximation already introduces high computational cost. In this work, the intrinsic relationships are established between the meshfree discrete data and the machine learning training samples, and between the recursive computational procedure of dynamic meshfree analysis and the temporal sequence information transmission mode of recurrent convolution neural networks. Meanwhile, it is also shown that there is a strong similarity between the receptive fields of convolutional neural network and meshfree supports.

With the aid of these intrinsic links, a recurrent convolutional neural network structure design method for meshfree discretization is proposed, which is then used to develop a recurrent convolution neural network surrogate model for dynamic meshfree analysis. This surrogate model takes full advantage of the flexibility of meshfree discretization. Meanwhile, meshfree analysis can provide versatile and highly accurate numerical samples, which then enhance the generality and applicability of the proposed surrogate model for dynamic meshfree analysis. In addition, the unique historical memory characteristics of the recurrent module embedded in the recurrent convolution neural network surrogate model enable an effective processing of the sequence information, and then accelerate the dynamic meshfree computation. The efficiency and accuracy of the proposed method is demonstrated through several examples, including large deformation meshfree modelling of slope failure.

Key Words: *Inland water flooding, Local inertial Equations, DEM*

This study aims to develop a numerical simulation model for inland water flooding. Recently, extreme weather conditions have increased short-time heavy rains in Japan, so inland water flooding occurs frequently. Therefore, an accurate prediction of flooding in real-time is required. However, few studies have been conducted to shorten the calculating time while enhancing analysis accuracy. In this study, we develop a high-accurate simulation of inland water flooding based on local inertial equations. The local inertial equations are suitable for relatively slow currents. We performed the simulation of the steady flow and the overflow on a weir and obtained effective calculation results. Furthermore, the numerical model was applied to downtown Morioka city in Iwate Prefecture, and the characteristics of inland water flooding in the area were cleared.

Key Words: *Submarine Landslides, Shear Bands, Impact Force, Eulerian Formulation*

Submarine landslides are the underlying cause of some of the most devastating natural disasters. They may cause the disappearance of entire regions along the shoreline, generate tsunami waves, and destroy the offshore infrastructure. The already existing and future planned gas transportation infrastructure along the continental slopes requires a better understanding of the processes that result in subsea landslides in order to improve our ability to predict, assess, and mitigate their potential hazards.

Unfortunately, laboratory and field studies cannot reproduce realistic subaqueous landslides. Computer simulations, on the other hand, enable us to simulate full-scale events and specific set-ups that are impossible to build in the laboratory (e.g., limiting material properties, extreme velocities, or large dimensions). Moreover, computer simulations usually cost much less than laboratory experiments, and they can reproduce much more complex and versatile phenomena. While some essential field data may be missing or impossible to collect, by changing possible geometric conditions (e.g., bathymetry, potential weak zones) and soil mechanical properties, it is possible to assess the upper and the lower limits of potential consequences of the landslide and possible hazards to subsea infrastructure. Moreover, through parameter analysis, it is possible to define how important each missing parameter is.

The process of landslide evolution involves large deformations and movements of the soil. In such problems, the traditional Lagrangian finite element approach, typically implemented for problems in soil mechanics, suffers from excessive element distortions and, therefore, cannot be adopted to analyze the above phenomenon. In the present work, the computational framework adopts an Eulerian approach [1-2]. In the Eulerian approach, the material is free to move through the mesh, which is fixed in space. Consequently, the problem of excessive element distortions becomes irrelevant. Several advanced continuum approaches to treat large deformation problems in soil mechanics exist; however, the main advantage of the Eulerian framework is that it is widely available within commercial codes, such as Abaqus, Ansys, LS-Dyna, etc., accessible to engineers. Moreover, Abaqus software, for example, can easily adapt various enhancements and modifications employing user subroutines and Python codes.

We demonstrate the framework through several examples of landslide events, including the impact on offshore infrastructure. The importance of the landslide trigger mechanisms is underlined.

Key Words: *Satellite Image, Machine Learning, Land Cover Classification, Additive Color Mixture*

In recent years, heavy rain which frequently occurs in various parts of Japan causes severe damages. It is important to identify the damaged area for disaster recovery and reconstruction.

To identify the damaged areas, a number of research have been conducted using satellite images. However, most the research has used the synthetic aperture radar (SAR) which is complicated to process, and the research using the optical satellite images has been limited to the preliminary level.

Therefore, in this study, we focus on the optical satellite images that are easy to process and interpret, and extract the damaged area by combining existing methods such as a land cover classification method by machine learning and an additive color mixing method.

With regard to the extraction of the damaged areas, it is necessary to extract the land cover changes. Therefore, we prepared the images before and after the disaster. First, we performed the land cover classification on the pre-disaster images and post-one. The results of the land cover classification showed that the land objects in the satellite images were properly classified. However, it was found that it was difficult to properly classify land objects below the resolution of satellite images (e.g., two-lane roads). Next, we applied an additive mixture method to extract the changes in land use before and after the disaster. As a result, it was found that the number of pixels indicating buildings decreased, while the number of pixels indicating fields increased in the damaged areas. It can be said that the area indicates the damaged area.

Based on the above results, it is possible to visually express the land cover changes before and after the disaster in a specific categories and to extract the damaged area.

Key Words: *Phase transformation, Fracture, Mesoscale model, Crack propagation*

The physical mechanisms triggering intermediate-depth earthquakes remain a puzzle for the scientific community. However, many studies discussed phase transformation being the primary mechanism behind the generation of these hazardous earthquakes. The objective of this study is to develop a numerical model for the simulation of phase transformation-induced failure in geo-materials. The materials of interest include different groups of minerals found in the earth crust such as granulite, eclogite, and olivine. To model the phase transformation behavior, a thermo-mechanical model approach has been taken. A thermodynamically consistent multiscale model, based on Mahnken et al, 2015, has been developed to capture the evolution of phase transformation taking place in such materials under different pressure and temperature conditions. In the model, each material point of the macroscale consists of polycrystals at the mesoscale level. Further, each crystal on the mesoscale is composed of various phases or variants of phases on the microscopic level. Crystal structure of different phases or variants has been incorporated through the rotated transformation strain in the model where additive decomposition of total strain has been used. The model is also capable of including different material properties for different phases or variants of phases and captures the orientation effect by including different orientations of grains at the mesoscopic level. The model also considers visco-plasticity and heat conduction and uses a volume averaging scheme to link different length scales. In the numerical scheme, the solution of coupled non-linear equations for the evolution of visco-plasticity and phase transformation has been obtained by a staggered algorithm. Implementation of the abovementioned thermomechanical model has been done using a user subroutine in a commercial finite element software ABAQUS. Validation of the model has been done using data for phase transformation from austenite to bainite and for olivine to spinel. For the simulation of microstructural failure in the material, the extended finite element method has been used with the above-mentioned model. A Higher amount of crack propagation has been observed from preliminary results of the model with phase transformation as compared to the case without any phase transformation under the same loading and boundary conditions. The effect of temperature has also been studied on the phase transformation and crack propagation for the olivine to spinel transformation. The model will be further validated with the data obtained from the laboratory experiments done on the materials of interest to investigate the phase transformation-induced instability leading to the formation of macrocracks. For further study, the model will eventually be upscaled to simulate the fault generation at the macroscale (kilometer-scale) and investigate the role of phase transformation in the formation of large-scale cracks or faults.

Effect of particle distribution and clustering degree of cement particles on the hydration process using a numerical approach

Su-Sung Jo[1] and Sang-Yeop Chung[1*]

[1] Department of Civil and Environmental Engineering, Sejong University, Seoul 05006, South Korea, E-mail: susung1996@sju.ac.kr (S.-S. Jo), sychung@sejong.ac.kr (S.-Y. Chung)

Key Words: *Reconstruction, Microstructure, Cluster, Simulation, Cement Hydration*

Microstructural characteristics of cementitious materials are crucial in determining the mechanical properties of the materials. For a better understanding of the behavior of cementitious materials, microstructural characterization and reconstruction methods, coupled with modeling and simulation, have been issued in the field of computational modeling of cement paste. For instance, microstructural imaging techniques such as a scanning electron microscope (SEM) image and its probabilistic description have been widely used to generate multi-phase microstructure. However, because of the complexity and limitations of the current approaches, it is highly desirable to develop a new method to model cement particles effectively.

This study aims to propose a model for generating virtual pre-hydrated specimens of cement paste using only very limited information, such as chemical composition and particle size distribution. In particular, the influences of the particle distribution and clustering degree of cement particles on the hydration process were investigated using computational simulation. For this purpose, the cement particles with different sizes were modeled based on the experimental data, and phase clustering of the main components, such as C_3S, C_2S, C_3A, and C_4AF, was controlled according to the chemical composition and quantitative information of several types of cement. Using the probabilistic description methods, the degree of phase clustering can be adjusted, and the virtual pre-hydrated cement microstructures with different phase distributions can be generated. The results of hydration for 28 days of each microstructure were obtained from a numerical approach using CEMHYD3D and then compared with the experimental data of a target cement.

The obtained results confirmed that the virtual specimen with a large degree of clustering shows a similar hydration profile to the experimental results. In particular, a significant difference in heat of hydration occurred during the initial reaction within a few minutes, which can affect the mechanical properties of cement paste. This indicates that the investigation of microstructural characteristics during the hydration process according to the degree of clustering can provide insights for a better understanding of multi-phase cement-based materials.

Key Words: *Concrete microstructure reconstruction, aggregate segmentation, X-ray tomography, Neutron Tomography*

For the realistic microstructure representation of concrete, connected aggregate segmentation is performed using the 3D CT images obtained from the complementarity of X-ray and neutron tomography. For the aggregate segmentation, most available techniques either reduces the aggregate volume fraction by eroding its surface area or over segment the aggregates particles which leads to inaccuracy of their size distribution. In this study, a recursive surface erosion and reconstruction algorithm was used to segment connected aggregates particles without having the previous issues [2]. As a result, disconnected aggregates can be classified according to their size and reconstructed in 3D in order to validate the accuracy of the presented technique. Additionally, characterization of the segmented aggregates such as their diameter, area, volume and circularity/roundness distribution was performed. The characteristics are compared in 2D and 3D before and after segmentation. Image analysis results show the advantage of the 3D segmentation and the good agreement between the images analysis and concrete mixing design.

The uncertainties of microstructural features affect properties of materials. The distribution characteristics of pores in cementitious material have great influence on its mechanical properties, and numerous pores that are randomly distributed in the material make it difficult to predict the material's properties. Existing studies are limited to the analysis of the statistical relationship between pore distribution characteristics and material responses [1], and the correlation between them is not yet fully determined. In this study, the mechanical response of cementitious materials is predicted through an image-based data approach using convolutional neural network (CNN), and the correlation of pore distribution and material response is analyzed.

The dataset for machine learning consists of high-resolution micro-CT images and properties (stiffness and strength) of cementitious materials. The microstructures are characterized, and the mechanical properties are evaluated through 2D direct tension simulations using the phase field fracture model [2]. Algorithms are developed to predict the material response when micro-CT images are inserted into input-data of CNN. Since the material responses need to be calculated for machine learning, various algorithms are used to prevent overfitting even for small size datasets. In the model with high learning accuracy, attribution of input image is analyzed [3] to identify the spot in the sample with the greatest influence on the prediction of material response. This study analyzed the correlation between pore distribution characteristics and material response by comparing the active region during the CNN process and the pore distribution.

Key Words: *Non-destructive Evaluation, Nonlinear Ultrasound, Rayleigh Surface waves, Microcracks*

In this paper, the nonlinear elastic behavior of cement-based materials under various kinds of damage is monitored using nonlinear Rayleigh surface waves. During several decades, numerous researchers have paid much attention to nonlinear ultrasonic techniques including nonlinear resonant ultrasound (NRUS), nonlinear wave modulation (NWMS), nonlinear wave mixing, and second harmonic generation (SHG) to characterize early-stage damage state in solid materials [1]. Among them, SHG using nonlinear Rayleigh surface waves holds a great promise for in situ assessment of full-scale concrete structures because of the advantages in measuring damage parameter regardless of the boundary condition and geometry of target structures. This talk will demonstrate the sensitivity of acoustic nonlinearity parameter, β (i.e., damage parameter) from the SHG method to early-stage microcracking formation in concrete. In comparison with the conventional contact-based detection methods, the robustness of non-contact, air-couple detection technique in precise detection of β is also examined [2]. Then, a variety of physical/chemical phenomena in concrete structures such as the sequestration of carbon dioxide into concrete cover [3], load-induced damage [4], and drying shrinkage [5] is assessed by a measure of β particularly with an emphasis on monitoring microcracking development. Finally, some synergetic effect of the proposed method towards improving infrastructure maintenance is discussed.

Microstructural characteristics of cement mortar using cockle shell aggregates and waste fishing net fibers

Sang-Yeop Chung[1*], Su-Sung Jo[1], and Seo-Eun Oh[1]

[1] Department of Civil and Environmental Engineering, Sejong University, Seoul 05006, South Korea, E-mail: sychung@sejong.ac.kr (S.-Y. Chung)

Key Words: *Cement Mortar, Microstructure, Cockle Shell, Waste Fishing Net*

According to the development of ostreaculture, numerous marine products are consumed in South Korea, and related waste becomes a serious problem simultaneously. To overcome the problems caused by marine wastes, recycling or utilizing marine produces becomes an issue in many engineering fields. In the construction material industry, several researchers have used waste materials as supplementary materials and demonstrated that proper use of marine products can be an effective approach to recycle the waste. Moreover, the use of recycled supplementary materials needs to be considered for the development of eco-friendly construction materials.

This study aims to investigate the effect of cockle shells as an aggregate replacement on cement-based materials. For this purpose, a series of cement mortar specimens were produced, and the crushed cockle shells were used as a substitute for fine aggregates. In addition, ground waste fishing nets were utilized as a fiber replacement to enhance the flexural performance of cementitious materials. Both cockle shells and waste fishing nets were washed with an ultrasonic cleaner in order to remove the influence from foreign substances or salt damage and ground accordingly considering the sizes of fine aggregates and polypropylene fibers. The cockle shell and the waste fishing net were then used as substantial materials for fine aggregates and fibers, respectively. 10, 20, and 30 wt.-% of cockle shells were substituted for fine aggregates, and the waste fishing net of 0.5, 1.0, and 1.5 % of the total volume was also considered in the mixtures. The compressive and flexural strength of the specimens were measured to examine the effect of replacement on the mechanical properties. Scanning electron microscope (SEM), X-ray diffraction (XRD), and micro-computed tomography (micro-CT) were utilized to investigate the microstructural characteristics of the materials with different substitution ratios.

The obtained results confirm that a proper substitute of fine aggregates with cockle shell powder can be used as alternative materials for conventional cement mortar, and the waste fishing net can be also utilized as a reinforcement for the flexural performance of cementitious materials.

Key Words: PVA Fiber Reinforced Cementitious Compsites, Microstructure, Fiber-Matrix Interface

The cementitious material is widely used in construction, but it has low tensile strength and displays brittle failure. To overcome such disadvantages of cementitious materials, the polyvinyl alcohol (PVA) - fiber reinforced cementitious composites (PVA-FRCCs) is developed [1]. Owing to its high strength and large elastic modulus of PVA fibers, PVA-FRCCs exhibit multiple cracking and strain-hardening behaviors. However, the fiber-matrix interface affects mechanical responses significantly, and it is important to characterize the fiber-matrix interface, and to evaluate its mechanical properties.

To characterize the fiber-matrix interface, 3D microstructures obtained from micro-CT images are investigated. In addition, field emission scanning electron microscope (FE-SEM) images are acquired to observe 2D microstructures of fiber-matrix interface in high resolution. A new segmentation method is proposed to characterize the fiber-matrix interface from micro-CT images effectively, and the 3D microstructures of PVA-FRCCs are successfully segmented into 3 phases (i.e., pore, PVA fiber, solid). The mean solid linear attenuation coefficient ($\bar{X}_{solid}$), and porosity are used as characterization parameters [2]. Using the 3D microstructures characterized by the micro-CT, simulations are performed to evaluate the effects of fiber-matrix interfaces on the mechanical behaviors of PVA-FRCCs. The proposed framework is expected to provide insights on the microstructural behaviors of complex materials by synergistically combining the state-of-the-art approaches of the experiments and simulations.

Key Words: *Internal curing, cellulose microfibers, nonlinear resonance, linear resonance, and crack density*

While the use of cellulose microfibers in cementitious materials has increased as a means of facilitating internal curing at early-age, issues associated with their interaction with cement matrices, the formation of microstructure, strength, etc., have not been fully understood. Utilizing linear and nonlinear acoustic techniques can be a promising approach because of the ability to detect both early-stage damage originated at microscale or mesoscale cracks. This talk will present a procedure for linear impact resonance acoustic spectroscopy (LINAS) and nonlinear impact resonance acoustic spectroscopy (NIRAS). Specifically, a hysteretic and nonlinear elastic behavior of cellulose microfibers-reinforced cement composites is assessed via the nonlinearity parameter, α. Together with the measurements of longitudinal wave velocity, the resonance frequency is also measured to estimate the crack density. Then, petrographic analysis and porosimetry confirm the presence of water desorption by cellulose microfibers and provides the evidence of internal curing. The results show that the measured α from the NIRAS test is sensitive to the microstructural change in cement composites, revealing the effect of cellulose microfibers on the internal curing, while the resonance frequency is capable of detecting the mesoscale change, showing a strong correlation with the measured crack density. Finally, the results highlight the potentials for this approach with an emphasis on carbon neutralized cementitious materials.

Prediction of Mechanical Response for Heterogeneous Materials considering Spatial Phase Distribution

Ji-Su Kim[1*] and Tong-Seok Han[2]

[1] University of Seoul, Seoul, Republic of Korea, jisu.kim914@gmail.com
[2] Yonsei University, Seoul, Republic of Korea, tshan@yonsei.ac.kr

Key Words: *Heterogeneous material, Microstructure, Phase field fracture model, Micro-CT, Nanoindentation*

Cement paste is one of the typical heterogeneous materials in the construction field, which has a complex microstructure with several phases. The behaviours of the cement paste are significantly affected by the spatial distribution of its components. To predict its mechanical response, it is necessary to investigate the phase distribution characteristics and identify each phase properties. Therefore, a framework to evaluate the mechanical properties of the material with complex microstructure based on characteristics of each phase through combining experiment and simulation is introduced in this study.

A virtual specimen of a microstructure for cement paste is constructed from micro-CT images. It can be segmented into several phases, such as pore, hydration products, and anhydrous cement; the linear attenuation coefficient value [1] of the micro-CT images is used as the phase characteristics. The virtual specimen reflects actual distributions of the phases, so that the complex behaviour of crack propagation can be detected from a simulation using the phase field fracture model [2]. Modeling input parameters of each phase for the simulation are obtained from nanoindentation test. The effect of considering multiple phases on the material response is investigated through a comparison of the behaviour between homogenized single and multiple phase solid models. The proposed framework can provide the guideline to design the new cementitious materials according to the purpose, and this study can be used for material property prediction of various heterogeneous materials.

Key Words: Phase Field Fracture, Microstructure, Property, Cement Paste, micro-CT, Multiscale Analysis

Microstructures of cementitious materials are complex, and it is not trivial to effectively evaluate and predict their properties. To develop innovative cementitious materials for sustainable and safe infrastructures efficiently, accelerated tools combining experimental and computational approaches are required. In this study, a synergistic tool for identifying mechanical properties of cementitious materials is presented through a two-scale (micro-macro) analysis framework.

At the micro-scale, microstructures of a cement paste are obtained from a high-resolution synchrotron micro-CT. The microstructures are characterized, and the mechanical properties are evaluated through direct tension simulations using the phase field fracture model [1] with the input paramters determined from nano-indentation test results. The homogenized properties are then linked to the upper-scale (macro-scale) microstructures, which are also obtained from a synchrotron micro-CT. At the macro-scale, in-situ micro-CT tensile splitting tests measurements are conducted. The experimental results are compared with the computational results, where the homogenized input parameters were homogenized from the micro-scale analysis. The multi-scale framework is expected to provide insights into the accelerated development of the innovative cementitious materials.

Key Words: Deep Neural Network, Residual Network, Explicit Integration, Augmented State

Despite great progress in seeking accurate numerical approximator to nonlinear structural seismic response prediction using deep learning approaches, tedious training process and large volume of structural response data under earthquakes for training and validation are often prohibitively accessible. In our methodology, the main innovation can be seen in of integration of deep neural networks (DNN) with a classical numerical integration method by using a hybridized integration time-stepper. In particular, we set the nonlinear restoring force vector as augmented states, and hence change the original nonlinear differential equation into a linear one, so that common explicit integration algorithms in control theory for linear time-invariant dynamic system can be applied. We propose to use residual network (ResNet) to learn time-stepping schemes specifically for the nonlinear state variables of the system. The original explicit integrator is then supplemented with the the DNN time-stepper with dimensional expanding. Our DNN-Augmented (DNN-A) time-stepping scheme provides important advantages over current pure data-driven approaches, including (i) a flexible framework incorporating known time-invariant physics information, (ii) requirement of structural seismic response data being circumvented by simple short bursts of trajectories collected from underlying nonlinear components, and (iii) efficiency in training and validation process. It is also remarkable that the proposed approach is parallelizable and allows relatively large time-steps. Several numerical examples are presented to demonstrate the performance of the methods.

Key Words: *3D building structure model, parametric study, seismic response analysis,*

With the development of computers in recent years, 3D analysis of building components has begun to be used for seismic response analysis of buildings. The demand for seismic response analysis using 3D building structure models is increasing in order to understand the behavior and safety of large buildings by evaluating the nonlinear characteristics of members caused by long-period earthquakes. The FEM programs used in conventional building structural design perform the analysis using the static implicit method. Since the static implicit method requires the solution of multiple simultaneous linear equations, the calculation time for large-scale buildings is often large. Therefore, reducing the time for seismic response analysis in 3D building structures models is an important issue in implementing large-scale projects. On the other hand, general-purpose detailed FEM programs use the dynamic explicit method to perform the analysis. Since the dynamic explicit method does not require the solution of simultaneous equations, the computation time tends to be smaller than that of the static implicit method. It is important for designers who use these programs to conduct parametric studies to understand the differences in analysis time, memory usage, stress and deformation behavior between them. However, it is not easy to perform a parametric study on a large scale 3D building structure models by manual operation.

The purpose of this report is to conduct an automated parametric study of several thousand 3D building structure models and to collect the results of seismic response analysis by two programs, in order to prepare for analysis of the differences between the results of the two programs.

We investigated the analysis time of a large 3D building structure model using implicit and dynamic explicit seismic response analysis software. As a result of the analysis on a Windows desktop PC, it was confirmed that the analysis time was reduced by 92% when the dynamic explicit method was used rather than the implicit method. In order to understand the modeling methods and material properties of members in the two programs and to compensate for the differences between them, a material property test of a simple one-member model was conducted. As a result of the material property test, it was confirmed that it is necessary to input parameters to take into account the movement hardening because an arbitrary plastic rotation angle-bending moment relationship defined using a load curve shows isotropic hardening behavior as a skeleton curve. In order to investigate the results of the implicit and explicit methods on a large scale 3D building structure model, we developed a program to automatically generate parameters for parametric studies using thousands of 3D building structure models.

In the future, the results of parametric studies using thousands of 3D building structure models will be statistically processed to analyze the results of the implicit and the explicit analysis. Then, we aim to improve the speed in seismic response analysis of 3D building structure models.

Damage Recognition of Wooden House Using Deep Neural Network Trained with Simulated Responses Considering Epistemic Uncertainty

Key Words: *Wooden Building, Epistemic Uncertainty, Deep Neural Network, Structural Health Monitoring*

The Data Science Working Group of the Numerical Shaking Table Committee of the National Research Institute for Earth Science and Disaster Resilience is working on the development of structural health monitoring technology using artificial intelligence.

In the 2016 Kumamoto earthquakes, some residents returned to their wooden houses that had been severely damaged by the strong ground motion, and the houses collapsed due to the following main shock causing human casualties. This kind of disaster should be reduced if they could understand the remaining performance of the house using a structural health monitoring system.

Deep neural networks have been reported to achieve high accuracy in various fields in pattern recognition and evaluation of regression equations with a large amount of training data. The authors have also taken the same approach of preparing big data for training by conducting time history response analysis with many input earthquake motions and damage patterns in advance [1], [2].

However, the stiffness and strength of the members assumed at the design stage do not necessarily match the actual values of the completed building. Epistemic uncertainty exists, and it is desirable to recognize damage patterns and evaluate residual performance with features that are robust to such variations.

In this study, we propose a method of generating training data with variability based on the results of elemental experiments conducted in conjunction with full-scale wooden building experiments in the E-Defense experiment, and constructing training data by providing input seismic motions of appropriate intensity so that the number of training data with and without damage is balanced.

Key Words: *Data Assimilation, Quality Engineering, Seismic Response Analysis*

INTRODUCTION

Since the Great Hanshin-Awaji Earthquake in Japan, many full-scale shaking table experiments have been conducted for the purpose of understanding the seismic performance of wooden houses. Then, the knowledge obtained in the experiment needs to be fed back to the simulation such as structural analysis. Compared to the shaking table experiment, the simulation has the advantage of being less costly and time-consuming and being able to visualize and analyse the results when the structure is changed in various ways. However, as a premise that makes them possible, it is indispensable to be able to perform reproducible analysis, that is, "data assimilation: combination of test and simulation". Therefore, in this study, we will examine the method of "data assimilation" for seismic design of wooden houses. In addition, in order to verify its effectiveness, we performed data assimilation for actual table shaking table experiments targeting three-story wooden houses and verified whether it could be reproduced in experiments on different wooden buildings and seismic waves.

RESERCH METHOD

"Data assimilation" is a method that has been developed in the field of meteorological forecasting and forecasting and has been studied as a theory that statistically corrects uncertain factors (initial conditions, model parameters, etc.) of numerical models by observed values. It is useful for improving the accuracy of weather forecasts. On the other hand, "data assimilation" in the field of manufacturing such as wooden construction, spacecraft, and automobiles has been done manually by the intuition and experience of the designer, and it is not only laborious but also dangerous to fall into a special solution. Therefore, from 2020, Kyoto University will focus on the quality engineering, which has the feature that comprehensive search can be performed with a small number of experiments, in joint research with Osaka Institute of Technology and JAXA, and a new target for wooden construction. We are researching various data assimilation methods.

In this study, we defined parameter values such as spring rigidity and yield strength that modelled each seismic element such as joints and walls of a three-story wooden house, and changed them variously by design of experiments. We searched for a combination of input parameters that can be reproduced with high accuracy. It was confirmed that the obtained results can be reproduced with different test specimens and seismic waves. Details and analysis of the results will be described in this conference.

Key Words: *Dynamic characteristics identification, non-linear structure, exposed column base, solid element*

In this study, it is discussed how to identify the natural frequency of a steel building frame which has an exposed column base and is modeled by solid finite elements. Bending moment-rotational angle relationship of the exposed column base exhibits non-linearity[1], because the steel base plate just comes into contact with foundation concrete and can separate from it due to bending moment. Eigenvalue analyses of vibration are generally conducted to investigate dynamic characteristics of numerical models. In eigenvalue analysis, however, above mentioned non-linearity cannot be considered. In the field of building and civil engineering structures, some materials and structures, such as masonry structures, cables, membranes and so on, show this kind of non-linearity which depends on amplitude and direction of loading.

Here, an exposed column base and first story column are extracted from a three-story steel frame specimen for a full-scale shake table test[2], which was conducted at E-Defense, NIED, Japan. Other parts of the frame are simplified as a rotational spring and a nodal mass at the top of the column. The exposed column base, which consists of components such as a column, base plate, anchor bolts, nuts, anchor plates and foundation concrete, is discretized with solid finite elements and contact, friction, and tying conditions are taken into account in the interface between the components[3]. Then we conduct dynamic analyses of the structure subjected to random ground motions and impulse loadings. The loading level is parametrically varied. By analyzing response displacement at the top of the column, the natural frequency of the target structure is identified and the obtained frequency is compared with the value measured in the experiment.

Evaluation of the Elastoplastic Behavior of Structures for use as Hysteretic dampers

Flavia Bustos[1*], Jorge Hinojosa[2]

[1] Engineering Systems Doctoral Program, University of Talca, Curicó, Chile, flavia.bustos@utalca.cl
[2] Engineering Systems Doctoral Program, University of Talca, Curicó, Chile, jhinojosa@utalca.cl

Key Words: *Metallic yielding dampers, seismic protection, finite element analysis*

In this research, we proposed 11 hysteretic dampers subjected to shear stresses, with constant height and volume of material to compare their hysteretical behavior. The geometries are based on plate and lattice structures, which are used in energy absorption applications [1].

For the finite element analysis in the software ANSYS, the material failure is modeled using the "ekill" command, which removes the elements that have reached a certain limit value. For validating the material plasticity, boundary conditions, and failure mode, the HHSD damper [2] was replicated, showing a good correlation between our methodology and the experimental results exposed in [2].

The finite element analysis gives the failure modes and the hysteresis curves of the dampers. From this curve, we obtained the elastic stiffness, yield force, yield displacement, ductility, and the number of cycles that the damper supports before decreasing its dissipation capacity. In addition, the graphs effective stiffness vs displacement, effective damping vs displacement, and accumulated dissipated energy vs accumulated displacement were determined for the dampers with equal or better performance than the HHSD since these graphs represent the behavior of a hysteretic damper [3].

From this study it is concluded that the elastoplastic behavior of the hysteretic damper is related to the orientation of the material, therefore it is possible to obtain a better device while maintaining the amount of material if it is oriented correctly. By orienting the material out of the plane, the stresses are better distributed, and greater displacements can be applied to the damper, so lattices structures, in this first study, would be a good option.

Earthquakes that exceed the current design criteria of buildings have been occurring frequently in Japan. In order to prepare for the occurrence of unexpected earthquakes, it is important to understand the damage caused to buildings by seismic motion through detailed analysis.

In this study, dynamic seismic response analyses of a four-story RC building are conducted considering the elasto-plasticity of materials, and the numerical results are compared and validated with the results of an experiment conducted at a 3-D full-scale seismic testing facility (E-Defense)[1]. Based on the comparison results, the building model is modified and the effect of the modification is confirmed. In addition, we conduct a data analysis of the analysis results using a large number of measurement data[2]. E-FrontISTR is used for dynamic analyses. E-FrontISTR is a nonlinear structural analysis software developed by Six organizations including the author's research group (NIED, JAMSTEC, CRIEPI, TEPSCO, TAISEI CORPORATION, and ARK Information Systems, INC.), based on FrontISTR[3].

Global Sensitivity Analysis of Wooden Building Based on Polynomial Chaos Expansion Considering Uncertainty in Material Property

Rikuto Mizobuchi[1*] and Masayuki Kohiyama [2]

[1] Keio University, 3-14-1 Hiyoshi, Kohoku-ku, Yokohama 223-8522, Japan,
rikuto.mizobuchi@keio.jp
[2] Ditto, kohiyama@sd.keio.ac.jp

Key Words: *Structural Health Monitoring, Polynomial Chaos Expansion, Global Sensitivity Analysis, Uncertainty Quantification, Wooden Building*

Structural health monitoring (SHM) is useful for quick and efficient damage recognition of a building under seismic excitation. It has the potential to replace the emergency safety evaluation, which is conducted after major earthquakes in purpose to prevent a secondary disaster from aftershocks. SHM systems are popular for large-scale civil structures in the world, but their application to low-rise buildings such as wooden houses are still limited.

One of the challenges in predicting the response of a wooden structure is that the effect of variance in its material property is considerably significant. To solve this problem, we propose a method using global sensitivity analysis with Sobol' indices based on polynomial chaos expansion (PCE) to find dependent parameters. By considering only material parameters with a high impact on the variability of the quality of interest, we can reduce computational cost in time history response analyses. PCE is a popular technique in the field of uncertainty quantification, which enables us to model the response of a dynamical system with uncertainty. PCE is also known to be highly compatible with global sensitivity analysis, which allows to identify the dependent input variables that contribute most to the variability of the computational model response.

Based on the results of a full-scale three-story wooden building experiments and its member experiments conducted by E-Defense of National Research Institute for Earth Science and Disaster Resilience[1], [2], we performed three-dimensional structural response analyses of a model of the specimen using a numerical collapsing simulation program, wallstat[3]. As input ground motions, we used design ground motion specified by the Building Standard Law with an amplification factor of 120%. Multiple models were prepared with a varied value of material properties to consider the epistemic uncertainty. As a result, the sensitivity analysis clarified that the variance of Young's modulus in columns and beams had a major contribution to the variance of the maximum inter-story drift angle of the model.

Key Words: *Cyber-Physical System, Geographic Information System, Seismic Response Analysis*

We have been developing an urban cyber physical system (CPS) for enhancing resilience against large-scale earthquakes [1]. Concept of the urban CPS is outlined below. Firstly, in the physical space, citizens, enterprises and governments build consensus on desirable state of the city and its evaluation indicators such as gross domestic product, population and quality of life. Secondly, in the cyber space, digital twins predict the state change caused by earthquake disaster, and then find required capacity such as robustness and resilience to satisfy desirable state after the seismic event. Finally, earthquake disaster-prevention technologies are implemented in the physical space to realize the required capacity.

In the digital twin, change in the evaluation indicators caused by earthquake disaster are introduced by predicting and evaluating the state change based on numerical simulations and data analyses. From the gap between the current and desirable states, it suggests optimal countermeasures to realize the desirable state. As to seismic response analyses in the digital twin, flexible selection of different types of simulation technologies are required according to available building information in the city and computational resources.

In this study, we constructed prototype of digital twin composed of heterogeneous seismic response simulations in Masiki, Kumamoto. In this prototype, Integrated Earthquake Simulator (IES) is employed for simplified model of many buildings in the city, wallstat is employed for detailed models of wooden buildings and E-Simulator is employed for a detailed model of an RC building. Building information, damage record in 2016 Kumamoto earthquake and simulation results are visualized on GIS. This prototype system was published on the website [2].

Slope Disaster Risk Evaluation in the 2018 Hokkaido Eastern Iburi Earthquake using DIPM and GIS

Fazlul Habib Chowdhury[1*] and Takashi Matsushima[2]

[1] University of Tsukuba, Tsukuba 305-0005, Japan, fhchy@yahoo.com
[2] University of Tsukuba, Tsukuba 305-8573, Japan, tmatsu@kz.tsukuba.ac.jp

Key Words: *Depth Integrated Particle Method, Slope Failure, Shallow Landslide, Hokkaido Eastern Iburi Earthquake*

DIPM (depth-integrated particle method) is an efficient numerical method appropriate for sediment-related disaster simulation like slope failure and subsequent long-distance debris flow or mudflow or the entire geo-hazard evaluation of a very wide area with detailed topographic information. The model deals with the flowing mass as a combination of soil columns. Equations of motion of such soil columns are solved as two-dimensional discrete 'particles' moving along the surface terrain. The particles are subjected to bottom shear stress of the flow based on the empirical Manning's formula with yield stress and particle-wise interaction formulated on their hydraulic gradient. Accordingly, the material parameters governing the flow behaviour are only two: the Manning's coefficient, n, and the critical deposition angle, i_{cr} related to the yield stress. The 2018 Hokkaido Eastern Iburi Earthquake triggered thousands of slope failures over a wide area and caused significant losses. Enormous destruction due to multiple slope failures occurred in the towns of Atsuma the north of the epicentre. Two landslides in Yoshino village in Atsuma town were studied for flow simulation. The landslides were shallow and classified as transitional earth slide types. The topographic information was extracted using ArcGIS software from widely available national data such as administrative area, Digital Elevation Model (DEM). From the detailed landslide inventory map available at the Geospatial Information Authority of Japan and flow simulation was conducted by setting the initial slope failure zones and the most appropriate values for n and i_{cr} were identified as 0.10 to 0.15 and 2° to 5° respectively. To select the best-suited parameters, visual and statistical comparisons of the simulation results were conducted. The average accuracy of the simulations was 75%. Slope distribution of the study area was analysed using ArcGIS, and slope stability was calculated using the 1-D slope formula with other researchers' test results from existing field studies. Finally, prediction of slope failure and possible affected areas were generated by the flow simulation for the risk assessment of the selected study area.

Key Words: *High Damping Rubber Bearing, Base Isolated Building, Structure-Heat Coupling, Finite Element Method, Seismic Response Analysis*

The authors[1] developed a framework for coupled structural and heat conduction finite element analysis for laminated high damping rubber bearings (HDRBs). The coupled analyses were conducted for full-scale tests of an HDRB subjected to several kinds of cycling loading. In the present study, a seismic response analysis of a ten-story RC building supported by two HDRBs is conducted. The finite element mesh used in this study was made in the previous study by the authors[2] for seismic response analyses of the building supported by natural rubber bearings, and the analysis condition is modified to include a constitutive model of high damping rubber.

Damping behavior of an HDRB is due to dissipated inelastic strain energy. The temperature rise is also caused by the dissipation energy. The equivalent stiffness and the equivalent damping factor for an HDRB decreases due to the temperature rise. The influence of the temperature rise on the mechanical properties of an HDRB is smaller than that of a lead bearing. However, the temperature rise in an HDRB subjected to an excitation of an earthquake with long duration and long natural period such as the expected Nankai Trough earthquakes is estimated as 70 to 80ºC. In this case the influence of temperature rise is significant.

The high damping rubber is modeled by an overlaid viscohyperelastic and elastic-plastic constitutive model. In the present study, cyclic coupon tests are conducted for a high damping rubber and material parameters of the overlaid model are identified using the results of the coupon tests. Then, a preliminary seismic response analysis using the analysis model of the base-isolated building considering structure-heat coupling is performed, and the influence of temperature rise on the responses of the building and the HDRBs is investigated.

Key Words: Thermal cracking, Convective and radiative cooling, Higher order particle discretization scheme, fire safety

Fire incidents post 1995 Great Hanshin and 1994 Northridge earthquake have caused damages to buildings and life-line structures. Despiste adequate seismic performance, reinforced concrete (RC) structures are vulnerable to high-temperature heat as concrete tends to crack under heat and leads to failire of structures. Also, scrapping of megastructures using LASER is an enviorment friendly choice. Therefore, it is essential to have a good understanding of thermo-mechanical response of RC under extreme temperature.

This article presents the formulation and implementation of thermal-shrinkage-induced-cracking to in brittle materials. Convective and radiative cooling, coupled with deformation and cracking, are rigorously treated, and related modules are implemented into a high-order particle-discretization finite element method [1].

Developed modules are verified by comparing with analytical solutions of static and transient heat problems. Modules are further validated by comparing with observations from a quenching experiment of 99% Al_2O_3 plate. Quantitative and stastical analysis shows that dimensions of cracks (length and direction) and numbers of cracks are similar to those in experiment for different temperatures. We further compared the cutting of an RC block using a LASER beam with experimental data. The cracking pattern in simulation results are in good agreement with those observed in experiment, which suggests the developed numerical model can be used study cracking induced by thermal shocks [2].

Key Words: *Fault displacement, Surface rupture, High performance computing, Joint element, Finite element method*

As an aftermath of the great earthquakes that occurred in Taiwan and Turkey in 1999, there are concerns about structural damages that are caused by surface earthquake faults. Important facilities such as nuclear power plants are separated from the primary faults that extend directly from the epicenter. However, there are several sites where secondary faults are distributed under or near these important facilities. Estimating the occurence and displacement of the surface earthquake fault is an important issue for the safety assessment of such sites. Numerical simulation based on continuum mechanics has the potential to provide reliable estimates of fault occurence and displacement.

Numerical simulations of fault rupture processes pose the two significant difficulties. The first is that a huge amount of numerical computation is required to simulate the processes over a range of several hundred meters. The second is the loss of the stability of the initial and boundary value problem to which the numerical simulations are applied. The loss of stability here means that a small disturbance can cause a large change in the solution. In this study, we developed a parallel finite element method that implemented the following two functions: 1) symplectic time integration (explicit method) to properly conserve the energy of faults; and 2) rigorously formulated higher-order joint elements [1].

We applied the parallel finite element method to simulate two recent earthquakes which induced surface earthquake faults in Japan, 2014 Northern Nagano Earthquake (reverse faulting) and 2016 Kumamoto Earthquake (right lateral strike-slip faulting). The analysis model was constructed in a 5 km x 5 km x 1 km area including the primary and secondary faults. On the bottom of the analysis model, we applied the displacement bounday conditions which were calculated based on the elastic dislocation theory using the slip distribution on the main fault which was obtained from the inversion analysis. As a result, we succeeded to reproduce the occurence and displacements of surface faults observed in the two earthquakes. The rupture characteristics of the secondary faults in the simulations were different between the two earthquakes. The largest slip was computed at the ground surface or at the contact point with the main fault, respectively, for the simulation of 2014 Northen Nagano Earthquake simulation or 2016 Kumamoto Earthquake.

Fast and Scalable Seismic Soil Liquefaction Simulation with Finite Element Method on GPUs

Ryota Kusakabe[1*], Tsuyoshi Ichimura[1], Kohei Fujita[1], Muneo Hori[2] and Lalith Wijerathne[1]

[1] The University of Tokyo, 1-1-1, Yayoi, Bunkyo, Tokyo, Japan, {ryota-k, ichimura, fujita, lalith}@eri.u-tokyo.ac.jp

[2] Japan Agency for Marine-Earth Science and Technology, 2-15, Natsushimacho, Yokosuka, Kanagawa, Japan, horimune@jamstec.go.jp

Key Words: Large-scale Simulation, Finite Element Method, Soil Liquefaction

Three dimensional earthquake simulation has been expected to give us knowledge on the earthquake and the way to mitigate the damage from it. However, it entails huge computational cost, which makes it difficult to perform simulation for large domain with high resolution. To overcome the high computational cost, we have been developing fast and scalable earthquake simulation methods.

In this study, we developed a GPU-accelerated large-scale earthquake simulation method considering soil liquefaction [1] based on the CPU-based soil liquefaction simulation method [2]. We used the finite element method with second order tetrahedral elements solved with a conjugate gradient based solver that adopted the MPI-OpenACC hybrid parallelization. The developed method achieved a 10.7-fold speedup over the CPU-based method on a compute node of the GPU-based supercomputer, AI Bridging Cloud Infrastructure (ABCI). With the developed method, the computation time for the simulation with an 89,146,716-DOF soil-structure model over 30,000 time steps was 3 h 33 min using only 13 computing nodes on ABCI. When the CPU-based method was used, it took 14 h 37 min using 128 compute nodes on OFP to perform the same simulation. By using GPU, large-scale simulation can be performed with smaller computation environment with shorter computation time.

The reduction of computational cost of simulation by the developed method is expected to make it easier to carry out analyses that require multiple cases of simulation, such as Monte Carlo simulation for uncertainty quantification and data assimilation for parameter optimization. In addition, it is expected that more learning data for surrogate models can be generated and more accurate surrogate models will be constructed.

Key Words: agent-based economic modeling, post-disaster economy, high-performance computing

We developed an integrated system for estimating economic impacts of earthquake disasters by performing end-to-end simulations of disasters and economy at 1:1 scale. In order to realize 1:1 scale simulations, we developed a High-Performance Computing (HPC) extension for Agent Based Economic Models (ABEMs) [1] and seamlessly integrated it with physics-based earthquake disaster simulators [2]. It is demonstrated that the HPC extension has sufficient numerical efficiency and scalability to simulate a model with 330 million agents, which is equivalent to an 1:1 scale model of Euro-zone economy, within a few minutes using a few hundred CPU cores. The economic model is validated by reproducing major indices of Japanese economy for the period of 2015 to 2020. Due to the unavailability of the economic data of each individual entity, we generated data for 127 million economic agents by disaggregating the macroeconomic data available from several Japanese government agencies. Using Performance Assessment Calculation Tool (PACT), developed by the Federal Emergency Management Agency, USA, to estimate the direct losses and the repair time of each building, we seamlessly integrated the physics based disaster simulators with the developed ABEM. As a demonstrative application of the developed system, we estimate the economic impacts of a disaster in Hanshin industrial region caused by a potential Nankai-trough mega-thrust earthquake, and the disaster hit economy is compared with the normal state of the economy.

Key Words: *Adjoint-based Optimization Methods, Inverse Theory, Dynamics of Crustal and Mantle Deformation, Earthquake Source Processes*

Advances in seismology and geodesy suggest that rock deformation surrounding earthquakes is affected by a range of transient processes deviating from Reid's simple seismic cycle model. In particular, observations from megathrusts including the disastrous Tohoku-oki 2011 M9 event have renewed interest in better constraining fault loading, and studies exploring if precursory signatures such as those often seen in the lab can be usefully exploited in nature for potential hazard assessment applications. Here, we address some of the challenges that remain for the integration of these multi-scale data into comprehensive numerical models. We ask how to best extract information to reduce uncertainties on any modeling-based estimates of megathrust state. For this, a multi-institutional team was recently funded by the US NSF to establish a Megathrust Modeling Framework (MTMOD), and we will highlight some of the participants' efforts in this presentation. One particular example of our efforts to move toward adjoint-based approaches for the static and time-dependent problems involved is a new, open-source finite-element framework to solve visco-elastic earthquake deformation problems. Based on two libraries for the forward and inverse problems, respectively, our new framework is flexible, transparent, and easily extensible to implement complex multi-physics coupled problems. FEniCS [1] offers a collection of software components for automated and efficient solution of PDEs, and hIPPYlib [2] state-of-the-art, scalable adjoint-based algorithms for deterministic and Bayesian inverse problems. Using this framework, we present a fault problem test case, representing the slip discontinuity with a mixed finite-element formulation. This approach solves for stress with higher order accuracy than typical approaches, and exposes the prescribed slip explicitly in the variational form without using split nodes or domain decomposition. Our formulation allows the optimality conditions, gradient and Hessian, to be expressed in continuous form, which leads to consistent discretizations of all field variables, including the slip. We show some applications of this new framework by inverting geodetic surface displacements to infer the coseismic slip distribution for earthquakes as well as the crustal and mantle material parameters. Moving beyond traditional Green's function, homogeneous medium approaches is important to understand the presence of fluids and poroelastic effects, for example, as likely reflected in time-dependent seismic velocity observations. More generally, this framework promises to allow exploring more general inverse questions, such as to the fault and rock constitutive behavior that best fits a range of observations. These efforts will be helpful in future optimal experimental design studies to provide answers and reduce the uncertainties for fundamental questions in earthquake science of societal relevance.

Key Words: *finite-element method, high-performance computing, fault-to-city earthquake simulation*

Finite-element analysis with low-order unstructured elements is suitable for earthquake simulation from fault to city for considering the complex 3D geometry and nonlinear material heterogeneity. However, such simulation entails huge computational cost as the target domain is large and the required time-resolution for assessing structural damage is high. Thus, we have been developing fast and scalable finite-element solvers suitable for large-scale supercomputer systems. In this talk, we will introduce our recent developments in implicit low-order unstructured finite-element solvers suitable for supercomputer Fugaku, which is the fastest supercomputer as of June 2021 Top 500 ranking. Here we developed methods to efficiently utilize SIMD units and many-cores of Fugaku's Arm A64FX CPU [1], and developed methods to use data acquired in past time steps to accelerate solving of the next time steps [2]. This solver is scalable to nearly full system of Fugaku (147456 compute nodes) with performance of 9.97% of FP64 peak, which corresponds to 59.2-fold speedup from the previous state-of-the-art solver running on the full K computer system, which is the previous flagship supercomputer in Japan. As the hardware performance ratio between K computer and Fugaku is 46.9-fold, we can see that effective speedup was obtained by suitable algorithm and implementation development. Using the developed solver, we show a fully-coupled fault-to-city earthquake simulation where wave propagation from fault to city, wave amplification at ground near surface, and structural response is computed using a monolithic mesh with 324 billion degrees-of-freedom with resolution varying from 0.125 to 64 m. Such simulation is expected to be useful for explicit evaluation of nonlinear coupling effects between earthquake subprocesses, which are difficult when computing each subprocess separately.

Key Words: *Large-Scale Reinforced Concrete Structure; High-Fidelity Model, Seismic Response Analysis*

For seismic response analysis of important facilities such as nuclear power plant buildings, it is effective to use a high-fidelity model with solid elements due to its higher reliability compared with a lumped mass model. When analysing the seismic response of large-scale reinforce concrete (RC) structures using high-fidelity models, high-performance computing (HPC) is indispensable because of the number of degrees of freedom (DOFs) especially in considering soil-structure interaction. This study shows the development of finite element method (FEM) for seismic response analysis of large-scale reinforced concrete structures utilizing HPC and a trial seismic response analysis of a nuclear power building model.

A key issue of development of HPC-FEM satisfying mensioned purpose is restriction of algorithms by its solver. We implemented a tensorial constitutive relation of concrete [1] [2] to the HPC-FEM program FrontISTR [3]. This constitutive relation employs an elasto-plastic and damage model, which expresses the damage to the material in terms of the softening of the stress-strain curve, results in the loss of positive-definiteness of elasto-plastic moduli at large deformation and prevents convergence of the conjugate gradient (CG) method, a solver of HCP-FEM. There are several non-linear analysis techniques or Newton method techniques for dealing with this problem; we adopted a method of calculating the stiffness matrix using elastic tensor of the material, which is a kind of modified Newton method, by comparing its speed and stability of computation with those of other methods. To check the performance, the developed software was validated by a simulated loading test of an RC structure. In this performance check, we also checked the performance of the CG method solver which changed by the non-linear analysis methods. It was shown that the non-linear analysis method using elastic tensor made the performance of the CG method solver higher and more stable.

Finally, we applied the developed method to the seismic response analysis of a nuclear power plant building with surrounding ground using high-fidelity model, which was a model of approximately 1.5 million DOFs. The results of the numerical analysis were discussed, focusing the numerical performance of HPC-FEM.

Key Words: *COVID-19, mathematical epidemiology, modified SEIRD model, dynamic parameterization*

The COVID-19 pandemic has raised the interest and use of mathematical models to understand and predict infectious disease dynamics, which has contributed to the decision-making of public health authorities [1]. These models can be broadly classified into two groups. Statistical models may handle complex outbreak dynamics, but they heavily rely on data series and do not provide insight into the underlying mechanisms of COVID-19 contagion spread. Mechanistic models usually rely on a compartmental formulation that facilitates the representation of the mechanisms of disease transmission and contagion but they may require specific data on disease infection status and recovery that is not often available [2]. Also, they usually employ constant parameters for separate waves of the pandemic, limiting their ability to represent complex outbreak dynamics.

To exploit the advantages of both modeling paradigms, our work proposes a data-informed mechanistic approach that leverages universally available epidemiological data (i.e., cumulative infections and deaths) to provide a smooth time-resolved parameterization of the dynamics of COVID-19 spread. We employ a modified SEIRD model featuring symptomatic and asymptomatic contagion [3]. This model is initially fit to successive one-week intervals of cumulative infections and deaths over a given timeframe using constant parameters. Then, we apply a mean filter to obtain time courses of daily estimates of the model parameters, which we subsequently fit quadratic B-splines to render a smooth model parameterization for analysis and forecasting. We tested our methodology in five representative states of the US between March 2020 and August 2020 (NY, CA, IL, TX, and FL). At this endpoint, nationwide seroprevalence estimates were available, which we also use to estimate the proportion of recovered individuals during model calibration.

Our method results in a median [range] normalized root mean squared error (NRMSE) of 3.64% [1.68%, 7.96%] and 4.22% [1.38%, 6.20%] during calibration for cumulative infections and deaths, respectively. The corresponding 2-week forecasts result in an NRMSE of 3.48% [1.30%, 12.16%] and 4.70% [0.86%, 8.91%], while the 4-week forecasts render an NRMSE of 3.95% [0.91%, 43.90%] and 11.03% [0.96%, 35.26%], respectively. When the subsequent 2 weeks of time-series data are assimilated, the forecasting accuracy of our method increases, with the NRMSEs of the prior 4-week forecast decreasing to 1.67% [0.61%, 6.48%] and 1.52% [0.09%, 4.72%], respectively. The dynamic parameters obtained offer insights into key temporal mechanisms, such as the substantial reduction in contact rates following governmental lockdowns. Thus, we think that our methods can potentially be developed into a predictive technology enabling the forecast of time-resolved mechanisms of infectious disease spread to guide public health decision making, such as medical resource allocations and non-pharmaceutical interventions.

Key Words: Cardiac electromechanics, Cardiac fiber architecture, Multiphysics modeling, Finite Elements, 3D-0D coupling.

Two crucial factors for accurate numerical simulations of cardiac electromechanics (EM), which are also essential to reproduce the synchronous activity of the heart, are: i) reconstructing the muscular fiber architecture that drives the electrophysiology signal and the myocardium contraction; ii) accounting for the interaction between the heart and the circulatory system, that determines pressures and volumes loads in the heart chambers. In this work, we present a 3D whole heart EM model coupled with a 0D closed-loop model of the whole cardiovascular system, that addresses the two former crucial factors. Our whole heart 3D-0D model includes a detailed myocardial fibers architecture, simulates the electrophysiology, the mechanical activation and the mechanics of ventricles and atria, and is strongly coupled with a 0D-closed loop model of the whole cardiovascular system. The main contributions in this work move along two strands: i) on the one hand, we developed a unified mathematical framework, based on Laplace-Dirichlet-Rule-Based-Methods (LDRBMs), to prescribe myocardial fibers orientation in computational full heart geometries [1]; ii) on the other hand, we provide a biophysically detailed 3D EM model coupled with a 0D closed-loop lumped parameters model for the haemodynamics of the whole circulatory system [2]. Specifically, we describe the whole heart LDRBM, which is able to quantitatively reproduce almost all the features of the different four-chambers. We also discuss in detail the coupling approach that stand behind the 3D-EM and the 0D-fluid models. Finally, we present physiological EM simulations, on a realistic whole heart geometry, using the 3D-0D model and we show that our results match the experimental data available in literature.

A Parallel Algorithm for the Simulation a Patient-specific Heart with Four Chambers

Yi Jiang, Rongliang Chen, and Xiao-Chuan Cai

We consider the numerical modeling of the elastodynamic behavior of the whole human heart whose geometry is reconstructed from MRI images. We propose a parallel domain decomposition method for the numerical simulation of a patient-specific heart with four chamber and fibers. Because of the complex hyperelastic model, the complicated geometry, the fiber directions, and the active stress distribution, the solution of such a problem is very difficult to obtain. Our algorithm is constructed within the framework of the implicit Newton-Krylov-Schwarz method modified for this particular problem. Numerical experiments show that the algorithm is able to simulate the cardiac elastodynamic involving hundreds of millions of degrees of freedom on a supercomputer with more than 10,000 processor cores.

[4] Università della Svizzera Italiana, Switzerland, michael.multerer@usi.ch

Key Words: boundary element method, bidomain model, electrophysiology, time integration

In cardiac electrophysiology, electric potentials generated by muscle cells impact the correct heart operation. Muscle contraction, for instance, depends on the transmission of electric signals from cell to cell, which in turn are affected by structural muscle disease, ageing and cardiomyopathies. Therefore, heart modelling at the cellular level is crucial for the accurate simulation of abnormal hearts.

At microscopic scale, the cardiac tissue is composed by tightly coupled myocytes, embedded into an extracellular matrix and surrounded by other cells. The bidomain model is a system of partial differential equations describing the spatio-temporal evolution of the electric potential within each cell and in the extracellular space. In particular, the model accounts for the cellular membrane dynamics and cell-to-cell coupling at fine scale. From a numerical perspective, the bidomain model at microscropic scale, henceforth called "μ-bidomain model", poses a number of difficulties: the cellular subdomains are separated by a sharp interface, that is the cellular membrane; the temporal dynamics, dictated by the membrane ionic model, is confined on such interfaces; and the membrane dynamics is typically nonlinear, multiscale and severely stiff in time. Therefore, the electric potential is globally discontinuous and the PDE is degenerate in time, due to the elliptic constraints.

In this work, clear away the uninteresting intra- and extra-cellular Laplace equation recasting the μ-bidomain model into a boundary integral formulation and employ the boundary element method for the space discretization. This yields a time dependent system living on the cellular membranes only, where the interesting dynamics occur. We analyse the local well-posedness of the reaction-diffusion system. Furthermore, we compare the efficiency of various families of time discretization schemes: implicit-explicit schemes, Rush-Larsen schemes, explicit stabilized (Chebyshev) Runge–Kutta methods, multirate methods.

Finally, we present some numerical experiments to compare the boundary integral formulation to a more standard finite element approach. We also discuss the feasibility of the approach towards the application to large scale models.

Efficient and robust parallel solvers for cardiac reaction-diffusion models

Ngoc Mai Monica Huynh[1]

[1] Department of Mathematics, University of Pavia, ngocmaimonica.huynh01@universitadipavia.it

Key Words: Cardiac Bidomain model, scalable parallel preconditioners, high-performance computing, nonlinear solvers.

The Bidomain model provides a mathematical description of the electrical activity in the heart. Its numerical solution still represents a challenging task for the scientific community, due to the coupling of macroscopic and microscopic phenomena (the propagation of the electric signal in the cardiac tissue and the ionic currents dynamics at a cellular level, respectively). Indeed, balancing accuracy in the solution of the system arising from discretization of such models while being computationally competitive (in terms of scalability and efficiency) is an actual issue which can be overcome with the development of specific techniques.

In this work, we present a numerical comparison of several parallel solvers for the numerical simulation of the Bidomain equations. We focus on a finite element discretization in space and different schemes for the time discretization, leading to the solution of large algebraic systems. Iterative methods are considered for their solution, where fast convergence is ensured by preconditioning with suitable algorithms. Whenever nonlinear algebraic systems arise, nonlinear solvers are employed, such as inexact Newton, quasi-Newton and nonlinear Generalized Minimal Residual methods.

We investigate strong scalability and robustness of the resulting solvers through extensive parallel numerical tests. These preliminary results provide a basis for further studies of parallel solvers for cardiac electrophysiology models that combine parallel efficiency while yielding accuracy in the solution and exploiting modern computational architectures.

Efficient and Scalable Solvers for Cardiac Mechanics

Nicolás Barnafi[1]*

[1] Department of Mathematics, University of Pavia, nicolas.barnafi@unipv.it, https://nabw.site

Key Words: Cardiac mechanics, Scalable preconditioners, Domain Decomposition, Nonlinear solvers

The development of realistic cardiac models is an active area of research, with the numerical approximation of these models being a great computational challenge. The main bottleneck is the repeated solution of large-scale and ill conditioned linear systems of algebraic equations arising from Newton's method, which require scalable preconditioners to obtain efficient iterative solvers. The most well-established iterative method for this aim is the GMRES algorithm, preconditioned by the Algebraic Multigrid (AMG) method. The AMG preconditioner is widely popular as it provides a black-box solution for preconditioning that works most of the time, but there are certain aspects that do not perform optimally, such as higher order elements, and it requires setting a plethora of parameters. Balancing Domain Decomposition by Constraints (BDDC) methods provide an alternative to AMG methods, which in classic linear problems have been shown to provide quasi-optimal conditioning, verified up to hundreds of thousands of parallel processors.

In this talk we will explore Newton, inexact-Newton and quasi-Newton methods for cardiac mechanics in detail. We start this by providing a detailed study of the performance of the BDDC preconditioner, where the advantage of considering this preconditioner instead of AMG will be shown through numerous tests. After this, we study the performance of alternative nonlinear solvers for the root-finding problem of solving the Euler-Lagrange equations associated to the mechanics. We focus on superlinearly convergent solvers, namely quasi-Newton BFGS and inexact-Newton, and show that (i) between them there is no clear winner in terms of performance, so that the method of choice is problem dependent and that (ii) in all cases, little effort is required to obtain a method that is not only faster than Newton, but also robust and scalable.

This is a joint work with Simone Scacchi (University of Milan) and Luca Pavarino (University of Pavia).

Higher-order time integration with algebraic adaptivity in a cell by cell discretization of cardiac excitation

Fatemeh Chegini[1*], **Martin Weiser**[2]

[1] Zuse Institute Berlin, Takustraße 7, 14195 Berlin, Germany, chegini@zib.de
[2] Zuse Institute Berlin, Takustraße 7, 14195 Berlin, Germany, weiser@zib.de

Key Words: cell-by-celll discretization, high-order time integration, spectral deferred correction, algebraic adaptivity

Cardiac arrhythmia causes about 15% of all mortality, primarily due to disorganization of cardiac tissue at the cellular scale, impacting the propagation of myocardium excitation. In order to understand disease mechanisms, diagnose illness, and design effective drugs for treatments, numerical modeling at the cellular level is necessary.

The most exact electrophysiological models, such as bidomain and monodomain models, represent the action potential on the tissue level, which can not describe details of propagation at the cellular level. We reformulate the electrophysiological model on the cellular level, with separate extracellular intracellular domains separated by cell membranes including ion channels and gap junctions.

We discuss the cell-by-cell model of cardiac excitation from [1] and its discretization with arbitrary order finite elements in space and arbitrary order time stepping with spectral deferred correction methods (SDC) [2]. A shrinking effective support of SDC corrections allows for a reduction of the spatial domains on which Euler subproblems need to be solved. The adaptive subset selection on the algebraic level leads to a natural multirate integration scheme, which results in reduced computational effort. The effectivity of this approach and the resulting efficiency in terms of computing time and energy consumption is illustrated at some numerical examples.

Simple Tools for Cardiac Simulation GPU-Parallel Nonlinear Multiphysics

Toby Simpson[1], Simone Pezzuto[1] and Rolf Krause[1]

[1]Università della Svizzera italiana, 6900 Lugano, Switzerland, www.usi.ch

Key Words: Multiphysics Problems, Cardiac Simulation, Electrophysiology, Mechanics, Fluid Dynamics, Fluid-Structure Interaction, GPU, Parallel Computing

Given the social and economic cost of cardiovascular disease, the value of in-silico cardiac simulation is self-evident, with applications in both clinical and research fields. There are established models for the various aspects of cardiac function, each operating at different scales in space and time. The key challenge of whole heart simulation is to combine of these models in a way that is both physically accurate and computationally feasible, with respect to both time and processing resources.

The aim of this work is to provide a simple computational framework which unifies these mathematical models into a single discretisation and processing environment without software dependencies, such that multiple cardiac simulations can be configured and generated by a clinician or researcher within minutes or hours on a single desktop processor.

The PDEs that represent the physical processes that propagate the wave of depolarisation through the myocardium (Mitchell-Schaffer and Monodomain Equations), leading to muscle contraction (Hyperelastic Finite Strain) and pressure changes that generate blood flow (Incompressible Navier Stokes) are integrated in space and time via techniques from Finite Volume and Finite Difference methods. Fluid-structure interaction is modelled via the Arbitrary Lagrangian-Eulerian approach.

The simulation environment consists of a set of scalar, vector and tensor fields discretized over a three-dimensional regular structured grid. Differential operators are assembled in matrix-free form into a set of computational kernels, which are processed in parallel on a Graphics Processing Unit. The solver handles each part of the problem in turn within a single computational loop, passing three-dimensional buffers containing physical quantities through a stream of parallel computation. The resulting software tools are simple enough to re-used by students, researchers and clinicians for a wide variety of valuable investigation.

The presentation will demonstrate the convergence of the discrete operators at each step of the computation and reproduce benchmarks for electrophysiology, solid and fluid dynamics, as well as show examples of more complex cardiac function.

Stabilizing numerical oscillations in cardiac active mechanics: an oscillations-free and accurate fully partitioned scheme

Francesco Regazzoni[1*], **Alfio Quarteroni**[1,2]

[1] MOX - Dipartimento di Matematica, Politecnico di Milano, Milan, Italy
[2] Math. Institute, École Polytechnique Fédérale de Lausanne (*Professor Emeritus*)

Key Words: Coupled problems, Cardiac modeling, Multiscale modeling, Active stress, Numerical stability

In this work we address an unresolved problem in the numerical modeling of cardiac electromechanics, that is the onset of numerical oscillations due to the dependence of force generation models on the fibers shortening velocity. A way to avoid numerical oscillations is to use monolithic schemes for the solution of the coupled problem of active-passive mechanics. However, staggered strategies, which foresee the sequential solution of the models of force generation and of tissue mechanics, are preferable, due to their reduced computational cost and low implementation effort. In light of this motivation, in this work we propose a new numerical scheme, that is numerically stable and accurate, yet within a fully partitioned (i.e. segregated) framework [1]. To derive our stabilized scheme, we move from energetic considerations on the coupling, at the microscale, between active and passive mechanics models. We show that instabilities are linked to the mismatch between macroscopic and microscopic strains, inconsistently expressed in Lagrangian and Eulerian coordinates, respectively. Hence, we formulate a novel scheme, in which all the variables are framed in a coherent fully Lagrangian reference system. By considering a model problem of active mechanics we prove that the proposed scheme is unconditionally absolutely stable (i.e. it is stable for any time step size), yet within a fully staggered framework. We apply the proposed method to several force generation models available in the literature, namely the Niederer-Hunter-Smith model, the model of Land and coworkers and the mean-field model that we proposed in [2]. We show, by means of several numerical tests, that the proposed stabilization term successfully removes the nonphysical numerical oscillations characterizing the non-stabilized segregated scheme solution. This is verified in several test cases, including a three-dimensional multiscale electromechanical simulation of the left ventricle. We show that the new scheme preserves the first order convergence with respect to Δt of the non-stabilized staggered scheme. The numerical error is only slightly larger than the error obtained with the monolithic scheme and it tends to zero with the same rate.

Key Words: Many-body Coulomb friction, Constraint mechanics, Differential-algebraic system, Discrete element method, Numerical stabilization

We have formally solved the Coulomb friction problem for many-particle multiple-contact systems in two [1] and three [2] dimensions. The discrimination between static or dynamic friction is based on the relative accelerations, projected onto the contact. So the problem is effectively one-dimensional and the formalism by Hairer et al.[3] for differential-algebraic system with unilateral constraints can be applied: The relative accelerations at each contact can be computed independently from the convex hull with both friction directions and be converted into forces via the tangential reduced mass.

The issue we treat here is the additional noise due to discretization errors for simulations with finite timestep. They lead to numerical drift away from the constraint, becoming effectively a vibrating force which dislocates particles from their equilibrium positions. In numerical analysis, the standard approach to prevent drift in constraint systems is via "stabilization by projection" (of the coordinates or velocities) into the constraint manifold [4]. However, for many-body multiple-contacts systems like discrete element methods, this is not feasible, as there can be simultaneously more than one constraint manifold. We will explain alternative stabilization approaches as well as the effects of different stiff integrators.

Texture Shape Optimization for Minimization of Friction Coefficient (Comparison of Shape Optimization Results for Circular and Herringbone Textures)

Hiroaki Arata [1*] and Takahiko Kurahashi [2]

[1,2] Nagaoka University of Technology, 1603-1, Kamitomiokamachi, Nagaoka-shi, Niigata 940-2188, Japan, [1] s193009@stn.nagaokaut.ac.jp, [2] kurahashi@mech.nagaokaut.ac.jp

Key Words: *Shape Optimization, Adjoint Variable Method, Finite Element Method, Friction Coefficient, Circular Texture, Herringbone Texture.*

In this study, we present numerical results of the texture shape optimization analysis for minimization of frictional force (cf. [1], [2].). The Reynolds equation is introduced as the governing equation, and is discretized in space by the finite element method. The performance function is defined by the frictional force. Also, the purpose of this study is to find the distribution of oil film thickness in the textured area, i.e., the design variables, so as to minimize the performance function. Here, it is necessary to consider the governing equations as constraints on the performance function. Therefore, the adjoint variable method is introduced to derive the Lagrange function. In order to obtain the stationary condition for the Lagrange function, the first variation of the Lagrange function is calculated. Finally, the gradient of the Lagrange function with respect to the design variable is obtained, and the iterative computation is performed to obtain the optimal solution for the design variable. In this study, we perform shape optimization analysis for the circular texture and the herringbone texture models, and present some numerical results (See Fig.1.).

Key Words: *Reliability-based design optimization (RBDO); Imprecise probabilities; Probability-interval hybrid uncertainty; Single-loop method.*

The Reliability-Based Design Optimization (RBDO) provides an effective way to obtain the optimum design in the presence of random uncertainties which follow the precise probability distribution function in the structural optimization design. However, in many practical engineering problems, the probability distribution which describes the stochastic nature of the uncertainties cannot be precisely obtained due to limited information. To quantify this kind of imprecise uncertainties, a probability-interval hybrid model emerged, where all uncertain variables are treated as random variables while some distribution parameters can only be given variation intervals. For such kind of uncertainties, this paper establishes a hybrid RBDO model and proposes a single-loop solution algorithm. The outer loop of the hybrid RBDO is performed to find the optimum design and the inner loop of that is performed to assess the reliability. However, the interval parameters lead to an interval of reliability for each constraint function, thus giving rise to a double-loop problem for the inner loop. Therefore, solving the hybrid RBDO would encounter the unaffordable computational effort and the hinder of convergency due to the nested strategy. In this paper, the Karush-Kuhn-Tucker (KKT) optimality conditions of the inner loops are imposed as equivalent deterministic equality constraints. The original triple-loop optimization is thus converted into an equivalent single-loop problem, which alleviates the computational demand significantly. The efficiency and accuracy of the proposed single-loop method (SLM) is verified through several practical engineering problems.

Identification of Key Parameters of Nonlinear Friction of Robot Joints based on Neural Network

Accurate identification of nonlinear friction parameters in robot joints is the linchpin to the trajectory and positioning accuracy as well as the kinematic stability of the arm-tip of robot during operations. However, it is not straightforward to derive these parameters exactly due to the complexity of the robot system. To this end, this study develops an inverse method through a neural network for determining the key parameters of nonlinear frictional torque model for robots. Specifically, the friction parameters of the robot joint are measured by a constant speed tracking experiment. The robot dynamics model containing nonlinear friction was established to calculate joint torques. The excitation trajectory is designed and the sensitivity of friction parameters to joint torques is analyzed to determine the key friction parameters. Then the optimal Latin hypercube method is used to sample in the friction parameter space. A neural network is subsequently established with 6 inputs produced with the robot dynamics model and 3 outputs generated by sampling. The friction model is established by using the friction parameters identified by the neural network to compensate the friction torque of the robot in the simulation experiment. The predicated friction parameter using the currently proposed identification method are accurate with the maximum test errors less than 0.4%. It can effectively improve the influence of the abrupt change of the friction torque on the trajectory of the robot when the robot moves in low speed and the trajectory accuracy of the robot is greatly improved.

A transformable wheel is a critical mechanical component in a mobile robot climbing up or down step obstacles of various heights. In the case of a tri-segmented transformable wheel to be considered here, it changes the effective radius and tilting angle of the three wheel segments for stable locomotion possibly with high energy efficiency. This study presents a multi-objective kinematic profile optimization of a one-degree-of-freedom (1-DOF) transformable wheel mechanism for highly adaptive locomotion. Compared with available 2-DOF wheel mechanisms [1, 2], the 1-DOF wheel mechanism has critical advantages in cost, weight, and actuator control. If 1-DOF wheels are designed for a step obstacle of a specific geometry, however, they cannot be directly used for other step obstacles of different widths and heights because they do not have sufficient DOFs. To address this critical issue, we propose to employ the initial angle of contact between the wheel and a step as a new additional variable. We show that this idea enables us to establish a one-to-one mapping between configurations of the wheel shapes and the target obstacles of any geometry. Here, the initial contact angle is defined as the pre-rotated angle at the moment of the climbing. By using one variable to transform the wheel and an additional variable of the initial contact angle, the transformable wheel can overcome various obstacles. However, the 1-DOF mechanism cannot represent all deformation shape because the profile of radius and angle are co-related unless the wheel is so transformed to follow an elaborate locomotion planning. This planning problem can be set up as an optimization problem where the wheel acceleration is minimized, and its instability is maximized for adaptive step-climbing. We employ the nondominated sorting genetic algorithm-II (NSGA-II) [3] to identify a Pareto-optimal front and examine the trade-off relation between performance indices. In order to analyze and design the movement of the transformable wheel, we use a simplified forward kinematics model. Finally, we present the 1-DOF optimal profiles utilizing a successfully configured Pareto-optimal front. The experiment results using an actual robot platform will be demonstrated.

The boundary element method (BEM) is an effective numerical tool for the calculation of acoustic radiation problem in infinite domain. Due to the addition of convection terms, the convective wave equation for uniform mean flow and its Green's function form are more complex than the traditional form[1]. Two technical routes have taken the mainstream for the use of the boundary element method in uniform mean flow fields. One is to directly substitute the convective Green function into the boundary integration equation in the stationary coordinate system[2], and the other introduces the approximate Lorentz transformation, which converts the wave equation and the Green function into the traditional concise form for quiescent medium and then substitutes the boundary integral equation[3].

The fast multipole acceleration for the above two techniques for acoustic problems in uniform subsonic flow are presented. The first and second use the Green's function in the rest frame and the Green's function in acoustic analogue Lorentz space as the FMM kernel, respectively. The radiation of a pulsating sphere in uniform subsonic flow with analytical solution is considered as a benchmark to test the performance of the two methods. CPU time, accuracy and convergence are included as the primary performance measures in the study. Two methods are investigated for the benchmark problem with different frequencies (from 5Hz to 200Hz), Mach number (from 0.01 to 0.9) and model scale (from 500 elements to 600000 elements). The comparison of the results of both methods shows that almost the same accuracy is achieved on the small scale, low-frequency problems. However, higher computational efficiency is witnessed due to the concise form of the kernel in the method using the Green's function in acoustic analogy Lorentz space. A possible improvement of the algorithm is also discussed based on the characteristics of sound propagation in the uniform subsonic flow.

Laminated composite structures have been widely applied in the engineering field due to their excellent performance such as light-weight and designability compared to traditional metal ones. Embedding the viscoelastic damping layers into the laminated composite to construct co-cured composite damping structures provides an effective way to improve the sound insulation capability. However, co-cured composite damping structures are inevitably subject to various uncertainties, which may come from manufacturing errors, environmental variability and simplified damping model. In this study, the sources of damping uncertainty of composite laminated structures with embedded damping layers are briefly discussed, and experimental tests by employing a number of cantilever beams with embedded a damping layer are carried out to demonstrate the uncertain damping properties of the damped composite structures. Furthermore, a semi-analytical model is proposed to investigate the sound transmission loss (STL) of a composite laminated plate with embedded viscoelastic damping layer subject to uncertain parameters. The results show the important effects of uncertain damping loss factor of a composite laminated plate on its STL valleys and peaks.
